

Performance of reconstruction and identification of τ leptons decaying to hadrons and ν_τ in pp collisions at $\sqrt{s} = 13$ TeV

The CMS Collaboration*

Abstract

The algorithm developed by the CMS Collaboration to reconstruct and identify τ leptons produced in proton-proton collisions at $\sqrt{s} = 7$ and 8 TeV, via their decays to hadrons and a neutrino, has been significantly improved. The changes include a revised reconstruction of π^0 candidates, and improvements in multivariate discriminants to separate τ leptons from jets and electrons. The algorithm is extended to reconstruct τ leptons in highly Lorentz-boosted pair production, and in the high-level trigger. The performance of the algorithm is studied using proton-proton collisions recorded during 2016 at $\sqrt{s} = 13$ TeV, corresponding to an integrated luminosity of 35.9 fb^{-1} . The performance is evaluated in terms of the efficiency for a genuine τ lepton to pass the identification criteria and of the probabilities for jets, electrons, and muons to be misidentified as τ leptons. The results are found to be very close to those expected from Monte Carlo simulation.

1 Introduction

Searches for new phenomena that consider signatures with τ leptons have gained great interest in proton-proton (pp) collisions at the CERN LHC. The most prominent one among these is the decay of Higgs bosons (H) to pairs of τ leptons, which constitutes an especially sensitive channel for probing Higgs boson couplings to fermions. The observation of the standard model (SM) Higgs boson decaying to a pair of τ leptons has recently been reported [1, 2]. Moreover, searches with τ leptons in the final state have high sensitivity to the production of both neutral and charged Higgs bosons expected in the minimal supersymmetric standard model (MSSM) [3, 4], in which enhancements in the couplings to τ leptons can be substantial at large $\tan\beta$, where $\tan\beta$ is the ratio of vacuum expectation values of the two Higgs doublets in the MSSM. Examples of such searches can be found in Refs. [5–7]. In addition, searches for particles beyond the SM, such as new or heavy Higgs bosons [8–11], leptoquarks [12], supersymmetric particles [13–16], or gauge bosons [17–19] benefit significantly from any improvements made in τ lepton reconstruction and identification.

The τ lepton, with a mass of $m_\tau = 1776.86 \pm 0.12$ MeV [20], is the only lepton sufficiently massive to decay into hadrons and a neutrino. About one third of the time, τ leptons decay into an electron or a muon, and two neutrinos. The neutrinos escape undetected, but the e and μ are reconstructed and identified through the usual techniques available for such leptons [21, 22]. These decay final states are denoted as τ_e and τ_μ , respectively. Almost all the remaining decay final states of τ leptons contain hadrons, typically with a combination of charged and neutral mesons, and a ν_τ .

The decays of τ leptons into hadrons and neutrinos, denoted by τ_h , are reconstructed and identified using the hadrons-plus-strips (HPS) algorithm [23, 24], which was developed and used in CMS when the LHC operated at $\sqrt{s} = 7$ and 8 TeV. The HPS algorithm reconstructs the τ_h modes by combining information from charged hadrons, which are reconstructed using their associated tracks in the inner tracker, and π^0 candidates, obtained by clustering photon and electron candidates from photon conversions in rectangular regions of pseudorapidity and azimuth, $\eta \times \phi$ regions, called “strips”. The major challenge in the identification of τ_h is to distinguish these objects from quark and gluon jets, which are copiously produced in pp collisions. The primary method for reducing backgrounds from jets misidentified as τ_h candidates exploits the fact that there are fewer particles present in τ_h decays, and that their energies are deposited in narrow regions of (η, ϕ) compared to those from energetic quark or gluon jets. In certain analyses, the misidentification (MisID) of electrons or muons as τ_h candidates can also constitute a sizeable background.

The τ_h identification algorithm improved for analyzing data at $\sqrt{s} = 13$ TeV contains the following new features:

1. A modification of the strip reconstruction algorithm, to the so-called dynamic strip reconstruction, that changes the size of a strip in a dynamic way that collects the π^0 decay products more effectively;
2. improvements in the multivariate-analysis (MVA) based discriminant [24] that reduces the background from jets, by combining information on isolation, lifetime of the τ lepton, and energy distribution in the shower; and
3. improvements in the MVA-based discriminant that suppresses electrons misidentified as τ_h candidates.

This paper is organized as follows. After a brief introduction of the CMS detector in Section 2, we discuss the data and the event simulations used to evaluate the performance of the HPS algorithm in Section 3. The reconstruction and identification of physical objects (other than τ_h) is briefly described in Section 4. Section 5 describes the HPS algorithm used for 13 TeV data and its simulation. The extended version of the algorithm used to reconstruct τ_h pairs produced in topologies with high Lorentz-boosts is presented in Section 6, while the specialized version developed for trigger purposes is discussed in Section 7. The selection of events used to evaluate the performance of the τ_h reconstruction algorithm, as well as systematic uncertainties common to all measurements are discussed in Section 8. The performance evaluation of the improved algorithm using selected data samples is given thereafter: Section 9 describes the τ_h identification efficiency, while Sections 10 and 11 summarize the respective jet $\mapsto \tau_h$ and $e/\mu \mapsto \tau_h$ misidentification probabilities. The τ_h energy scale is discussed in Section 12. Finally, Section 13 presents the performance of τ_h identification in the high-level trigger, and a brief summary in Section 14 concludes this paper.

2 The CMS detector

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter, providing a magnetic field of 3.8 T. A silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL), and a brass and scintillator hadron calorimeter (HCAL), each composed of a barrel and two endcap sections, reside within the field of the solenoid. Extensive forward calorimetry complements the coverage provided by the barrel and endcaps. Muons are measured in gas-ionization detectors embedded in the steel flux-return yoke outside the solenoid.

The CMS tracker is a cylindrical detector, constructed from 1 440 silicon-pixel and 15 148 silicon-strip detector modules that cover the range of $|\eta| < 2.5$. Tracks of charged hadrons are reconstructed with typical efficiencies of 80–90%, depending on transverse momentum (p_T) and η [25, 26]. The silicon tracker presents a significant amount of material in front of the ECAL, mostly due to the mechanical structure, the associated services, and the cooling system. A minimum of 0.4 radiation lengths (X_0) of material is present at $|\eta| \approx 0$, which rises to $\approx 2.0 X_0$ at $|\eta| \approx 1.4$, and decreases to $\approx 1.3 X_0$ at $|\eta| \approx 2.5$. Photons originating from π^0 decays therefore have a high probability to convert into e^-e^+ pairs within the volume of the tracker.

The ECAL is a homogeneous and hermetic calorimeter made of PbWO_4 scintillating crystals. It is composed of a central barrel, covering the region $|\eta| < 1.48$, and two endcaps, covering $1.48 < |\eta| < 3.0$. The small radiation length ($X_0 = 0.89$ cm) and small Molière radius (2.3 cm) of the PbWO_4 crystals provide a compact calorimeter with excellent two-shower separation. The ECAL is $>25 X_0$ thick.

The HCAL is a sampling calorimeter made of brass and plastic scintillator, with a coverage up to $|\eta| = 3.0$. The scintillation light is converted by wavelength-shifting fibres and channelled to photodetectors via clear fibres. The thickness of the HCAL is in the range 7–11 interaction lengths, depending on η .

The muon detection system is made up of four planes of gas-ionization detectors, where each plane consists of several layers of aluminium drift tubes (DTs) in the barrel region and cathode strip chambers (CSCs) in the endcap region, complemented by resistive-plate chambers (RPCs) that are used only in the trigger.

A two-tiered trigger system [27] is employed to select interesting events from the LHC bunch

crossing rate of up to 40 MHz. The first level (L1), composed of custom-made hardware processors, uses information from the calorimeters and muon detectors to select events at a rate of ≈ 100 kHz, within a fixed time interval of less than $4 \mu\text{s}$. The second level, known as the high-level trigger (HLT), consists of a farm of processors running a version of the full event reconstruction software, optimized for fast processing, and reduces the event rate to ≈ 1 kHz before data storage.

A more detailed description of the CMS detector, together with a definition of the coordinate system and kinematic variables, can be found in Ref. [28].

3 Data and simulated events

The performance of τ_h reconstruction and identification algorithms are evaluated in pp collisions recorded by CMS during 2016 at $\sqrt{s} = 13$ TeV, corresponding to an integrated luminosity of 35.9 fb^{-1} . The Monte Carlo (MC) simulated signal samples contain $H \rightarrow \tau\tau$, $Z' \rightarrow \ell\ell$, $W' \rightarrow \ell\nu$, and $Z/\gamma^* \rightarrow \ell\ell$ events, where ℓ refers to e , μ , or τ leptons. Simulated signal contributions from $H \rightarrow \tau\tau$, $Z' \rightarrow \ell\ell$ (with masses up to 4 TeV), $W' \rightarrow \ell\nu$ (with masses up to 5.8 TeV), and MSSM $H \rightarrow \tau\tau$ (with masses up to 3.2 TeV) are used to optimize the identification of τ_h candidates over a wide range of their p_T values. The $H \rightarrow \tau\tau$ events are generated at next-to-leading order (NLO) in perturbative quantum chromodynamics (QCD) using POWHEG v2 [29–33], while Z' and W' boson events are generated using leading-order (LO) PYTHIA 8.212 [34]. In simulation, the reconstructed τ_h candidate is taken as matched to the generated τ_h when both objects lie within a cone of $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.3$, where $\Delta\phi$ and $\Delta\eta$ are the distances respectively in ϕ and η between the reconstructed and generated candidates.

The W +jets and $Z/\gamma^* \rightarrow \ell\ell$ events are generated at LO in perturbative QCD using MADGRAPH5_aMC@NLO v2.2.2 [35] with the MLM jet merging scheme [36], while the single top quark and $t\bar{t}$ events are generated at NLO in perturbative QCD using POWHEG [37–39]. The diboson WW , WZ , and ZZ events are generated at NLO using MADGRAPH5_aMC@NLO with the FFX jet merging scheme [40] or POWHEG [41], while events comprised uniquely of jets produced through the strong interaction, referred to as QCD multijet events, are generated at LO with PYTHIA. The PYTHIA generator, with the CUETP8M1 underlying-event tune [42], is used to model the parton shower and hadronization processes, as well as τ lepton decays in all events. The $Z/\gamma^* \rightarrow \ell\ell$ and W +jets samples are normalized according to cross sections computed at next-to-next-to-leading order (NNLO) in perturbative QCD accuracy [43–47], while the $t\bar{t}$ sample is normalised to the cross section computed at NNLO supplemented by soft-gluon resummation with next-to-next-to-leading logarithmic accuracy [48, 49]. The cross sections for single top quark and diboson production are computed at NLO in perturbative QCD accuracy [50]. The production of off-shell W bosons ($m_W > 200$ GeV), with subsequent $W \rightarrow \tau\nu$ or $W \rightarrow \mu\nu$ decays, is simulated at LO with the PYTHIA generator. The differential cross section is reweighted as a function of the invariant mass of the W boson decay products, incorporating NNLO QCD and NLO electroweak corrections [46, 51, 52]. The NNPDF3.0 parton distribution functions [53] are used in all the calculations.

Additional pp collisions that overlap temporally the interactions of interest, referred to as pileup (PU), are generated using PYTHIA, and overlaid on all MC events according to the luminosity profile of the analyzed data. The generated events are passed through a detailed simulation of the CMS detector based on GEANT4 [54], and are reconstructed using the same CMS reconstruction software as used for data.

4 Event reconstruction

The particles emerging from pp collisions, such as charged and neutral hadrons, photons, electrons, and muons, are reconstructed and identified by combining the information from the CMS subdetectors using a particle-flow (PF) algorithm [55]. These particles are further grouped to reconstruct higher-level objects, such as jets, missing transverse momentum, τ_h candidates, and to quantify lepton isolation.

The trajectories of charged particles are reconstructed from their hits in the silicon tracker [26], and are referred to as tracks.

Electrons are reconstructed from their trajectories in the tracker and from clusters of energy deposition in the ECAL [21]. Electron identification relies on the energy distribution in the electromagnetic shower and on other observables based on tracker and calorimeter information. The selection criteria depend on the p_T and $|\eta|$ of the electron, and on a categorization according to observables sensitive to the amount of bremsstrahlung emitted along the trajectory in the tracker.

Muons are reconstructed by combining tracks reconstructed in both the inner tracker and the outer muon spectrometer [22]. The identification of muons is based on the quality criteria of reconstructed muon tracks, and through requirements of minimal energy deposition along the muon track in the calorimeters.

The isolation of individual electrons or muons ($I_{\text{rel}}^{e/\mu}$) is measured relative to their transverse momenta $p_T^{e/\mu}$ by summing over the scalar p_T values of charged and neutral hadrons, as well as photons, in a cone of $\Delta R < 0.3$ for electrons or 0.4 for muons around the direction of the lepton at the interaction vertex:

$$I_{\text{rel}}^{e/\mu} = \left(\sum p_T^{\text{charged}} + \max \left[0, \sum p_T^{\text{neutral}} + \sum p_T^\gamma - p_T^{\text{PU}} \right] \right) / p_T^{e/\mu}. \quad (1)$$

The primary pp interaction vertex is defined as the reconstructed vertex with largest value of summed p_T^2 of jets, clustered using all tracks assigned to the vertex, and of the associated missing transverse momentum, taken as the negative vector sum of the \vec{p}_T of those jets. To suppress the contribution from PU, the charged hadrons are required to originate from the primary vertex. The neutral contribution to the isolation from PU (referred to as p_T^{PU}) is estimated through a jet area method [56] for electrons. For muons, the p_T^{PU} contribution is estimated using the sum of the scalar p_T of charged hadrons not originating from the primary vertex, scaled down by a factor of 0.5 (to accommodate the assumed ratio for the production of neutral and charged hadrons).

Jets are clustered from PF particles using the infrared and collinear-safe anti- k_T algorithm [57, 58] with a distance parameter of 0.4. The jet momentum is defined by the vectorial sum of all particle momenta in the jet. The simulation is found to provide results for jet p_T within 5 to 10% of their true values over the whole p_T spectrum and detector acceptance. To suppress contributions from PU, charged hadrons not originating from the primary vertex are discarded, and an offset correction is applied to correct the remaining PF contributions. Jet energy corrections are obtained from simulation to bring the measured response of jets to that of particle level jets on average, and are confirmed with in situ measurements through momentum balance in dijet, γ +jet, Z+jet, and multijet events [59]. The combined secondary vertex v2 (CSVv2) b tagging algorithm [60] with a medium working point (WP) is used to identify jets originating from b quarks. The working point corresponds to an identification efficiency of about 70% for b quark jets with $p_T > 30$ GeV, and a probability for light-quark or gluon jets to be misidentified as b quarks of $\approx 1\%$.

The missing transverse momentum vector, \vec{p}_T^{miss} , is defined as the projection of the negative vector sum of the momenta of all reconstructed particles in an event on the plane perpendicular to the beams. The \vec{p}_T^{miss} is corrected by propagating to it all the corrections made to the momenta of jets. Its magnitude is referred to as p_T^{miss} .

5 Reconstruction and identification of τ_h

The basic features of the HPS algorithm are identical to those used during the previous data taking at $\sqrt{s} = 7$ and 8 TeV [24], except for the improvements in π^0 reconstruction described below in Section 5.1.1. Sections 5.2, 5.3, and 5.4 discuss the discriminants used to distinguish reconstructed τ_h candidates from jets, electrons, and muons, respectively.

5.1 The hadrons-plus-strips algorithm

Starting from the constituents of reconstructed jets, the HPS algorithm reconstructs the different decays of the τ lepton into hadrons. The final states include charged hadrons, as well as neutral pions, as shown in Table 1. The π^0 mesons promptly decay into pairs of photons, which have a high probability of converting into e^+e^- pairs as they traverse the tracker material. The large magnetic field of the CMS solenoid leads to a spatial separation of the e^+e^- pairs in the (ϕ, η) plane. To reconstruct the full energy of the neutral pions, the electron and photon candidates falling within a certain region of $\Delta\eta \times \Delta\phi$ are clustered together, with the resulting object referred to as a “strip”. The strip momentum is defined by the vectorial sum of all its constituent momenta. The procedure is described in Section 5.1.1, together with the improvements introduced to the previous algorithm.

Table 1: Weak decays of τ leptons and their branching fractions (\mathcal{B}) in % [20] are given, rounded to one decimal place. Also, where appropriate, we indicate the known intermediate resonances of all the listed hadrons. Charged hadrons are denoted by the symbol h^\pm . Although for simplicity we show just τ^- decays in the table, the values are also valid for the charge-conjugate processes.

Decay mode	Resonance	\mathcal{B} (%)
Leptonic decays		35.2
$\tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau$		17.8
$\tau^- \rightarrow \mu^- \bar{\nu}_\mu \nu_\tau$		17.4
Hadronic decays		64.8
$\tau^- \rightarrow h^- \nu_\tau$		11.5
$\tau^- \rightarrow h^- \pi^0 \nu_\tau$	$\rho(770)$	25.9
$\tau^- \rightarrow h^- \pi^0 \pi^0 \nu_\tau$	$a_1(1260)$	9.5
$\tau^- \rightarrow h^- h^+ h^- \nu_\tau$	$a_1(1260)$	9.8
$\tau^- \rightarrow h^- h^+ h^- \pi^0 \nu_\tau$		4.8
Other		3.3

Charged particles used in the reconstruction of τ_h candidates are required to have $p_T > 0.5$ GeV, and must be compatible with originating from the primary vertex of the event, where the criterion on the transverse impact parameter is not highly restrictive ($d_{xy} < 0.1$ cm), to minimize the rejection of genuine τ leptons with long lifetimes. The requirement of $p_T > 0.5$ GeV on the charged particles ensures that the corresponding tracks have sufficient quality, and pass a minimal requirement on the number of layers with hits in the tracking detector.

Based on the set of charged particles and strips contained in a jet, the HPS algorithm generates all possible combinations of hadrons for the following decay modes: h^\pm , $h^\pm \pi^0$, $h^\pm \pi^0 \pi^0$, and

$h^\pm h^\mp h^\pm$. The reconstructed mass of the “visible” hadronic constituents of the τ_h candidate (i.e., the decay products, excluding neutrinos) is required to be compatible either with the $\rho(770)$, or the $a_1(1260)$ resonances in the $h^\pm \pi^0$ and in the $h^\pm \pi^0 \pi^0$ or $h^\pm h^\mp h^\pm$ decay modes, respectively, as discussed in Section 5.1.2. The $h^\pm \pi^0$ and $h^\pm \pi^0 \pi^0$ modes are consolidated into the $h^\pm \pi^0$ mode, and are analyzed together. The combinations of charged particles and strips considered by the HPS algorithm represent all the hadronic τ lepton decay modes in Table 1, except $\tau^- \rightarrow h^- h^+ h^- \pi^0 \nu_\tau$ with $\mathcal{B} = 4.8\%$. This decay is not considered in the current version of the algorithm, because of its greater contamination by jets. The τ_h candidates of charge other than ± 1 are rejected, as are those with charged particles or strips outside the signal cone, defined by $R_{\text{sig}} = (3.0\text{GeV})/p_T$, where the p_T is that of the hadronic system, with cone size limited to the range 0.05–0.10. Finally, only the τ_h candidate with largest p_T is kept for further analysis, resulting in a single τ_h candidate per jet.

5.1.1 Dynamic strip reconstruction

Photon and electron constituents of jets, which seed the τ_h reconstruction, are clustered into $\Delta\eta \times \Delta\phi$ strips, and used to collect all energy depositions in the ECAL that arise from neutral pions produced in τ_h decays. The size of the $\Delta\eta \times \Delta\phi$ window is set to a fixed value of 0.05×0.20 in the (η, ϕ) plane in the previous version of the HPS algorithm [24]. However, this fixed strip size is not always adequate to contain all electrons and photons originating from the τ_h decays, meaning that some of the particles from τ_h lepton decay can contribute to the isolation region and thereby reduce the isolation efficiency for genuine τ_h candidates.

Our studies of τ_h reconstruction have led to the following observations:

1. A charged pion from τ_h decays undergoing nuclear interactions in the tracker material can produce secondary particles with lower p_T . This can result in cascades of low- p_T electrons and photons that can appear outside of the strip window, and affect the isolation of a τ_h candidate, despite these particles originating from remnants of the τ_h decay.
2. Photons from π^0 decays have a large probability to convert into e^+e^- pairs and, after multiple scattering and bremsstrahlung, some of the remaining electrons and photons can end up outside a fixed size window, also affecting the isolation.

Naively, these decay products can be integrated into the strip by suitably increasing its size. Conversely, if the τ_h has large p_T , the decay products tend to be boosted in the direction of the τ_h candidate momentum. In this case, a smaller than previously considered strip size can reduce background contributions to that strip, while taking full account of all decay products.

Based on these considerations, the strip clustering of the HPS algorithm has been changed as follows:

1. The electron or photon (e/γ) with the highest p_T not yet included in any strip is used to seed a new strip, with initial position set to the η and ϕ values of the new e/γ seed.
2. The p_T of the second-highest e/γ deposition within

$$\begin{aligned} \Delta\eta &= f(p_T^{e/\gamma}) + f(p_T^{\text{strip}}) \quad \text{and} \\ \Delta\phi &= g(p_T^{e/\gamma}) + g(p_T^{\text{strip}}) \end{aligned} \quad (2)$$

of the strip position is merged into the strip. The dimensionless functions f and g are determined from single τ lepton events, generated in MC with uniform p_T in the range

from 20 to 400 GeV and $|\eta| < 2.3$, such that 95% of all electrons and photons that arise from τ_h decays are contained within one strip. The functional form is based on the $\Delta\eta$ and $\Delta\phi$ between the τ_h and the e/γ candidate, studied as a function of the p_T of the e/γ candidate. As shown in Fig. 1, the 95% envelope of points in each bin is fitted using the analytic form $a/(p_T)^b$, resulting in:

$$\begin{aligned} f(p_T) &= 0.20 p_T^{-0.66} \quad \text{and} \\ g(p_T) &= 0.35 p_T^{-0.71}, \end{aligned} \quad (3)$$

where the p_T is in GeV. The upper limits on the strip size are set to 0.3 in $\Delta\phi$ and 0.15 in $\Delta\eta$, and the lower limits are set to 0.05 for both $\Delta\phi$ and $\Delta\eta$. The size of the window depends on the p_T values of both the strip and the merged e/γ candidate. The size is defined by the maximum separation between the two objects, assuming they have opposite charges and are produced back-to-back in their rest frame. Although, strictly speaking, this reasoning applies only to the ϕ direction, it is also used for the η direction.

3. The strip position is recomputed using the p_T -weighted average of all e/γ constituents in the strip:

$$\begin{aligned} \eta_{\text{strip}} &= \frac{1}{p_{\text{strip}}} \sum p_T^{e/\gamma} \eta_{e/\gamma}, \\ \phi_{\text{strip}} &= \frac{1}{p_{\text{strip}}} \sum p_T^{e/\gamma} \phi_{e/\gamma}. \end{aligned} \quad (4)$$

4. The construction of the strip ends when there is no other e/γ candidate within the $\Delta\eta \times \Delta\phi$ window. In this case, the clustering proceeds by selecting a new strip, seeded by the e/γ candidate of highest p_T that is not as yet associated with any strip.

As defined above, the size of the strip does not depend on the cone-size of the τ_h signal. The p_T -weighted center (η, ϕ) of the strip is required to be within the signal cone, while part of the strip can lie outside of it.

5.1.2 Mass constraints on decay modes

Strips are combined with charged particles to form τ_h decay hypotheses. Then, to check the compatibility of each hypothesis with the signatures expected from different τ_h decay modes, the reconstructed mass of the visible hadronic constituents of the τ_h candidate (that we refer to as m_{τ_h}) is required to lie within a mass window corresponding either to the $\rho(770)$ or $a_1(1260)$ meson. The widths and positions of the mass windows are optimized for each decay mode to maximize the ratio of the τ_h reconstruction efficiency to the jet $\mapsto \tau_h$ misidentification probability, with results that can be summarized as follows:

1. $0.3 \text{ GeV} - \Delta m_{\tau_h} < m_{\tau_h} < 1.3 \text{ GeV} \sqrt{p_T^{\tau_h}/(100 \text{ GeV})} + \Delta m_{\tau_h}$ for $h^\pm \pi^0$, with the mass window enlarged for τ_h candidates of high p_T to account for resolution, and the upper limit on the mass window constrained to lie between 1.3 and 4.2 GeV,
2. $0.4 \text{ GeV} - \Delta m_{\tau_h} < m_{\tau_h} < 1.2 \text{ GeV} \sqrt{p_T^{\tau_h}/(100 \text{ GeV})} + \Delta m_{\tau_h}$ for $h^\pm \pi^0 \pi^0$, with the upper limit on the mass window restricted to lie between 1.2 and 4.0 GeV, and
3. $0.8 < m_{\tau_h} < 1.5 \text{ GeV}$ for the $h^\pm h^\mp h^\pm$ channels,

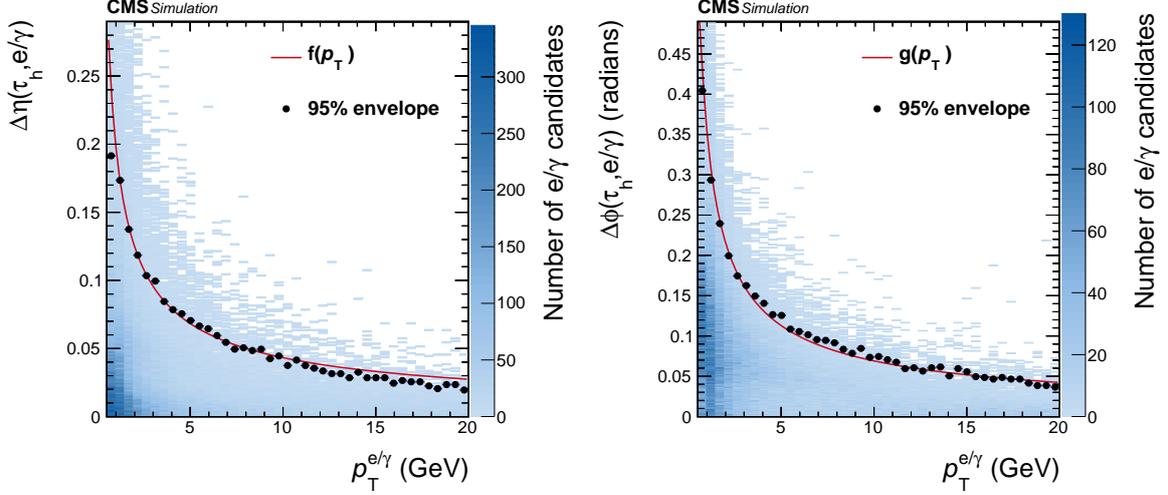

Figure 1: Distance in η (left) and in ϕ (right) between the τ_h and e/γ candidates for τ_h decay products, as a function of the p_T of the e/γ candidate, in simulated τ_h decays. The points show the 95% envelope for a given bin, and the solid red lines represent the fitted functions f and g given in Eq. (3).

where Δm_{τ_h} is the change in the mass of the τ_h candidate brought about by the addition of the e/γ candidates to its strip. It is calculated as follows:

$$\Delta m_{\tau_h} = \sqrt{\left(\frac{\partial m_{\tau_h}}{\partial \eta_{\text{strip}}} f(p_T^{\text{strip}})\right)^2 + \left(\frac{\partial m_{\tau_h}}{\partial \phi_{\text{strip}}} g(p_T^{\text{strip}})\right)^2}, \quad (5)$$

with

$$\frac{\partial m_{\tau_h}}{\partial \eta_{\text{strip}}} = \frac{p_z^{\text{strip}} E_{\tau_h} - E_{\text{strip}} p_z^{\tau_h}}{m_{\tau_h}} \quad \text{and}$$

$$\frac{\partial m_{\tau_h}}{\partial \phi_{\text{strip}}} = \frac{-(p_y^{\tau_h} - p_y^{\text{strip}}) p_x^{\text{strip}} + (p_x^{\tau_h} - p_x^{\text{strip}}) p_y^{\text{strip}}}{m_{\tau_h}},$$

where $p_{\tau_h} = (E_{\tau_h}, p_x^{\tau_h}, p_y^{\tau_h}, p_z^{\tau_h})$ and $p_{\text{strip}} = (E_{\text{strip}}, p_x^{\text{strip}}, p_y^{\text{strip}}, p_z^{\text{strip}})$ are the four-momenta of the τ_h and of the strip, respectively.

5.2 Discrimination of τ_h candidates against jets

Requiring τ_h candidates to pass certain specific isolation requirements provides a strong handle for reducing the jet \mapsto τ_h misidentification probability. The two τ_h isolation discriminants developed previously [24], namely the isolation sum and the MVA-based discriminants, have now been reoptimized. A cone with $\Delta R = 0.5$ was originally used in the definition of isolation for all event types. However, in processes with a high number of final-state objects, such as for Higgs boson production in association with top quarks ($t\bar{t}H$), the isolation is affected by the presence of nearby objects. Studies using such $t\bar{t}H$ events with $H \rightarrow \tau\tau$ decays led to the conclusion that a smaller isolation cone improves the τ_h efficiency in such events. A smaller isolation cone of radius $\Delta R = 0.3$ is therefore now used in these types of events.

5.2.1 Isolation sum discriminants

The isolation of τ_h candidates is computed by summing the scalar p_T of charged particles ($\sum p_T^{\text{charged}}$) and photons ($\sum p_T^\gamma$) reconstructed using the PF algorithm within the isolation cone

centered on the direction of the τ_h candidate. Charged-hadron and photon constituents of τ_h candidates are excluded from the p_T sum, defining thereby the isolation as:

$$I_{\tau_h} = \sum p_T^{\text{charged}}(d_z < 0.2 \text{ cm}) + \max\left(0, \sum p_T^\gamma - \Delta\beta \sum p_T^{\text{charged}}(d_z > 0.2 \text{ cm})\right). \quad (6)$$

The contribution from PU is suppressed by requiring the charged particles to originate from the production vertex of the τ_h candidate within a distance of $d_z < 0.2$ cm. The PU contribution to the p_T sum of photons in the isolation cone is estimated by summing the scalar p_T of charged particles not originating from the vertex of the τ_h candidate ($\sum p_T^{\text{charged}}$ with $d_z > 0.2$ cm), but appearing within a cone of $\Delta R = 0.8$ around the τ_h direction multiplied by a so-called $\Delta\beta$ factor, which accounts for the ratio of energies carried by charged hadrons and photons in inelastic pp collisions, as well as for the different cone sizes used to estimate the PU contributions.

Previously, an empirical factor of 0.46 was used as the $\Delta\beta$ [24]. However, this is found to overestimate the PU contribution to the isolation in data taken in 2015 and 2016. And a new $\Delta\beta$ factor of 0.2 is therefore chosen. This value corresponds approximately to the ratio of neutral to charged pion production rates (0.5), corrected for the difference in the size of the isolation cone ($\Delta R = 0.5$) and the cone used to compute the $\Delta\beta$ correction ($\Delta R = 0.8$): $0.5 \times (0.5^2/0.8^2) \approx 0.195$.

The loose, medium, and tight working points of the isolation sum discriminants are defined by requiring I_{τ_h} to be less than 2.5, 1.5, or 0.8 GeV, respectively. These thresholds are chosen such that the resulting efficiencies for the three working points cover the range required for the analyses.

In dynamic strip reconstruction, a photon candidate outside the signal cone can still contribute to the signal. This effectively increases the jet $\mapsto \tau_h$ misidentification probability because of the decrease in the value of I_{τ_h} for misidentified τ_h candidates. An additional handle is therefore exploited to reduce the jet $\mapsto \tau_h$ misidentification probability using the scalar p_T sum of e/γ candidates included in strips, but located outside of the signal cone, which is defined as

$$p_T^{\text{strip, outer}} = \sum p_T^{e/\gamma}(\Delta R > R_{\text{sig}}). \quad (7)$$

A reduction of about 20% in the jet $\mapsto \tau_h$ misidentification probability is achieved by requiring $p_T^{\text{strip, outer}}$ to be less than 10% of $p_T^{\tau_h}$, for similar values of efficiency.

A comparison of the expected performance of the isolation sum discriminant for the previous and current versions of the HPS algorithm is shown in Fig. 2. The efficiency is calculated for generated τ_h candidates with $p_T > 20$ GeV, $|\eta| < 2.3$, having a decay mode of h^\pm , $h^\pm\pi^0$, $h^\pm\pi^0\pi^0$, or $h^\pm h^\mp h^\pm$, and matching to a reconstructed τ_h candidate with $p_T > 18$ GeV. The misidentification probability is calculated for jets with $p_T > 20$ GeV, $|\eta| < 2.3$, and matching to a reconstructed τ_h candidate with $p_T > 18$ GeV. The different sources of improvement in performance of the algorithm with fixed strip size are shown separately for $\Delta\beta = 0.46$, $\Delta\beta = 0.46$ with $p_T^{\text{strip, outer}} < 0.1 p_T^{\tau_h}$, and for $\Delta\beta = 0.2$ with $p_T^{\text{strip, outer}} < 0.1 p_T^{\tau_h}$. The signal process is modelled using MC events for $H \rightarrow \tau\tau$ (for low- p_T τ_h) and $Z' \rightarrow \tau\tau$ decays, with $m_{Z'} = 2$ TeV (for high- p_T τ_h). The QCD multijet MC events are used as background, with jet p_T values up to 100 and 1000 GeV, respectively, such that the p_T coverage is similar to that in signal events. The improvement brought about by the dynamic strip reconstruction for high- p_T τ leptons can be observed by comparing the two plots in Fig. 2. At low- p_T (Fig. 2, left), the performance for τ_h candidates for medium and tight WPs improves slightly. However, in the high-efficiency region, the misidentification probability starts to increase faster than the efficiency in the current algorithm. This is caused by choosing the working points of the algorithm through changes in

the requirements on I_{τ_h} . To reach a higher efficiency, the requirement on I_{τ_h} is relaxed, which in turn leads to an increase in the misidentification probability. However, the $p_T^{\text{strip, outer}}$ requirement prevents the efficiency from rising at a similar rate, leading thereby to the observed behaviour of the response in the high-efficiency region.

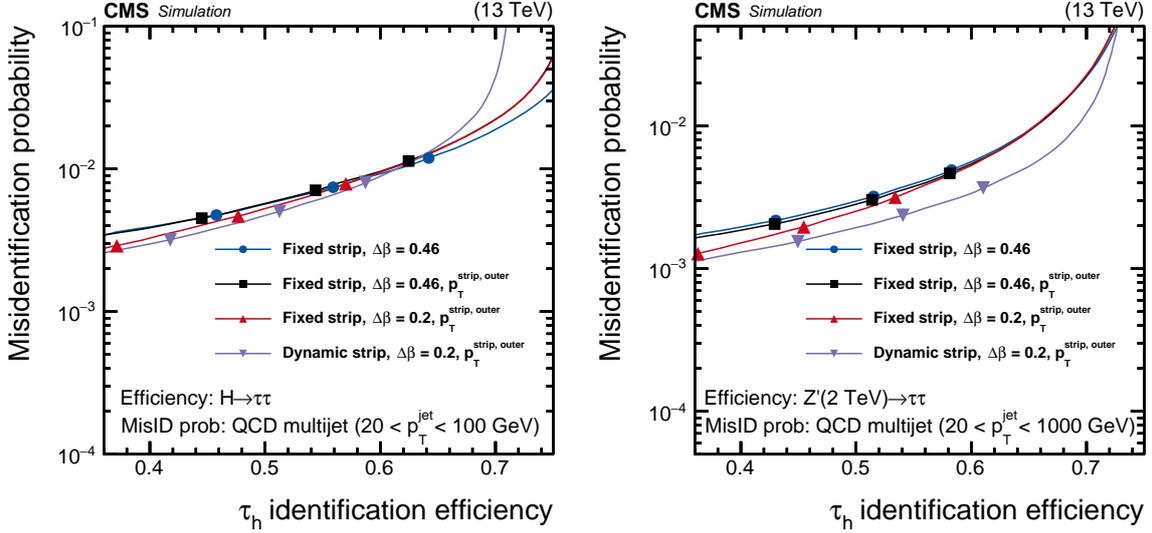

Figure 2: Misidentification probabilities as a function of the τ_h identification efficiencies, evaluated for $H \rightarrow \tau\tau$ (left) and $Z'(2 \text{ TeV}) \rightarrow \tau\tau$ (right), and for QCD multijet MC events. Four configurations of the reconstruction and isolation method are compared. The three points on each curve correspond, from left to right, to the tight, medium, and loose WPs. The solid curves are obtained by imposing cutoffs on I_{τ_h} that decrease linearly from small to large efficiency.

5.2.2 MVA-based discriminants

The MVA-based τ_h identification discriminants combine the isolation and other differential variables sensitive to the τ lifetime, to provide the best possible discrimination between τ_h decays and quark or gluon jets. A classifier based on boosted decision trees (BDT) is used to achieve a reduction in the jet $\mapsto \tau_h$ misidentification probability. The MVA identification method and the variables used as input to the BDT are discussed in Ref. [24].

In addition to those discussed in Ref. [24], the following variables are included in the classifier to improve its performance:

1. Differential variables such as $p_T^{\text{strip, outer}}$ in Eq. (7), and p_T -weighted ΔR , $\Delta\eta$, and $\Delta\phi$ (relative to the τ_h axis) of photons and electrons in strips within or outside of the signal cone;
2. τ lifetime information, based on the signed three-dimensional impact parameter of the leading track of the τ_h candidate and its significance (the impact parameter length divided by its uncertainty); and
3. multiplicity of photon and electron candidates with $p_T > 0.5 \text{ GeV}$ in the signal and isolation cones.

The charged and neutral-particle isolation sums and the $\Delta\beta$ correction, as defined in Eq. (6), are used as separate variables in the BDT classifier, and correspond to the most powerful discriminating variables. Other significant variables are the two- and three-dimensional impact parameters of the leading track and their significances, as well as the flight length and its significance

for the τ_h candidates decaying into three charged hadrons and a neutrino. The multiplicity of photon and electron candidates in the jet seeding the τ_h candidate is found to contribute to the decision of the BDT classifier at levels similar to those of the lifetime variables.

The BDT is trained using simulated τ_h candidates selected with $p_T > 20$ GeV and $|\eta| < 2.3$ in $Z/\gamma^* \rightarrow \tau\tau$, $H \rightarrow \tau\tau$, $Z' \rightarrow \tau\tau$, and $W' \rightarrow \tau\nu$ events (with the mass ranges of H , Z' , and W' detailed in Section 3). The QCD multijet, W +jets, and $t\bar{t}$ events are used to model quark and gluon jets. These events are reweighted to provide identical two-dimensional distributions in p_T and η for τ_h candidates in signal and in background sources, which makes the MVA training insensitive to differences in p_T and η distributions of τ leptons and jets in the training samples.

The working points of the MVA-isolation discriminant, corresponding to different τ_h identification efficiencies, are defined through requirements on the BDT discriminant. For a given working point, the threshold on the BDT discriminant is adjusted as a function of p_T of the τ_h candidate to ensure uniform efficiency over $p_T^{\tau_h}$. The working points for the reconstructed τ_h candidates are chosen to have isolation efficiencies between 40 and 90%, in steps of 10%, for the reconstructed τ_h candidates.

The expected jet $\mapsto \tau_h$ misidentification probability is shown in Fig. 3, as a function of expected τ_h identification efficiency. It demonstrates a reduction in the misidentification probability by a factor of 2 for MVA-based discriminants, at efficiencies similar to those obtained using isolation-sum discriminants. We compare two sets of MVA-based discriminants that were trained using MC samples that correspond to different conditions during data taking. The working points of the MVA-based discriminants are shifted relative to each other, but follow the same performance curve. This confirms the stability of the MVA-based discriminants. The expected τ_h selection efficiencies and jet $\mapsto \tau_h$ misidentification probabilities for low to medium p_T , for the most commonly used working point (tight) of the training in 2016 are 49% and 0.21%, respectively. For high p_T , the expected misidentification probability drops to 0.07%, while the τ_h selection efficiency remains constant, as desired.

Figure 4 shows the respective expected τ_h identification efficiency (left) and the misidentification probability (right), as a function of p_T of the generated τ_h and of the reconstructed jet. The efficiency is computed from $Z \rightarrow \tau\tau$ events, while the expected jet $\mapsto \tau_h$ misidentification probability is computed for QCD multijet events with jet $p_T < 300$ GeV.

5.3 Discrimination of τ leptons against electrons

Isolated electrons have a high probability to be misidentified as τ_h candidate that decay to either h^\pm or $h^\pm\pi^0$. In particular, electrons crossing the tracker material often emit bremsstrahlung photons mimicking neutral pions in their reconstruction. An improved version of the MVA electron discriminant used previously [24] is developed further to reduce the $e \mapsto \tau_h$ misidentification probability, while maintaining a high selection efficiency for genuine τ_h decays over a wide p_T range. The variables used as input for the BDT are identical to the ones described in Ref. [24], with the addition of the following photon-related variables:

1. the number of photons in any of the strips associated with the τ_h candidate;
2. the p_T -weighted root-mean-square of the distances in η and ϕ between all photons included in any strip and the leading track of the τ_h candidate; and
3. the fraction of τ_h energy carried away by photons.

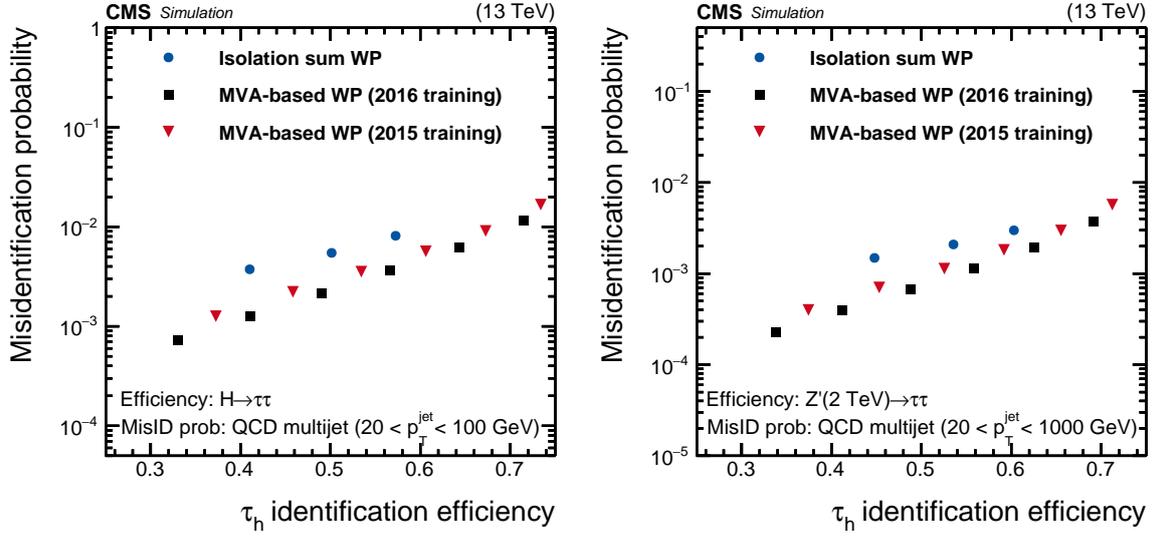

Figure 3: Misidentification probabilities for τ_h as a function of their identification efficiency, evaluated using $H \rightarrow \tau\tau$ (left), $Z'(2\text{ TeV}) \rightarrow \tau\tau$ (right), and QCD multijet MC events. The MVA-based discriminants trained on their corresponding MC events are compared to each other, as well as to the isolation-sum discriminants. The points correspond to different working points of the discriminants. The three points for the isolation-sum discriminants from left to right correspond to the tight, medium, and loose WPs. Similarly, the six points of the MVA-based discriminants define the WP as very-very tight, very tight, tight, medium, loose, and very loose, respectively.

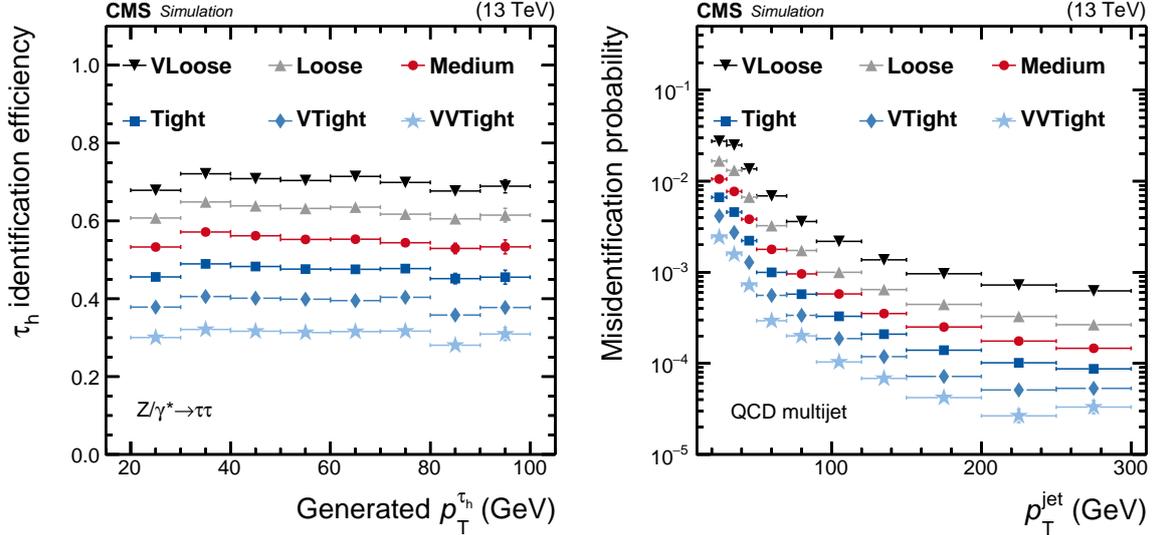

Figure 4: Efficiency of τ_h identification, estimated using simulated $Z/\gamma^* \rightarrow \tau\tau$ events (left), and the misidentification probability estimated using simulated QCD multijet events (right) are given, for the very loose, loose, medium, tight, very tight, and very-very tight WPs of the MVA-based τ_h isolation algorithm. The efficiency and misidentification probabilities are shown as a function of p_T of the generated τ_h and of the reconstructed jet, respectively. Vertical bars (often smaller than the symbol size) correspond to the statistical uncertainties (the 68% Clopper-Pearson intervals [61]), while horizontal bars indicate the bin widths.

These variables are computed separately for the photons inside and outside of the τ_h signal cone to improve separation. The most sensitive variables are the fraction of energy carried by the photon candidates, the ratio of the energy deposited in the ECAL to the sum of energies deposited in the ECAL and HCAL, the ratio of the deposited energy in the ECAL relative to the momentum of the leading charged hadron, the m_{τ_h} , and the p_T of the leading charged hadron.

The BDT is trained using the simulated events listed in Section 3, which contain genuine τ leptons and electrons. Reconstructed τ_h candidates can be considered as signal or background, depending on whether they are matched to a τ_h decay or to an electron at the generator level. Different working points are defined according to the requirements on their BDT output and the efficiency for a genuine τ_h candidate to pass the working points of the discriminants. The expected efficiency of τ_h reconstruction and the $e \mapsto \tau_h$ misidentification probability are presented in Fig. 5. Both are found to be approximately uniform over p_T , except for a dip at ≈ 45 GeV, whose depth increases with the tightening of the selection criteria. This is because the MC events used to model the $e \mapsto \tau_h$ misidentification in the training of the MVA discriminant have electron p_T distributions that peak at ≈ 45 GeV, since the sample is dominated by $Z/\gamma^* \rightarrow ee$ and $W \rightarrow e\nu$ events.

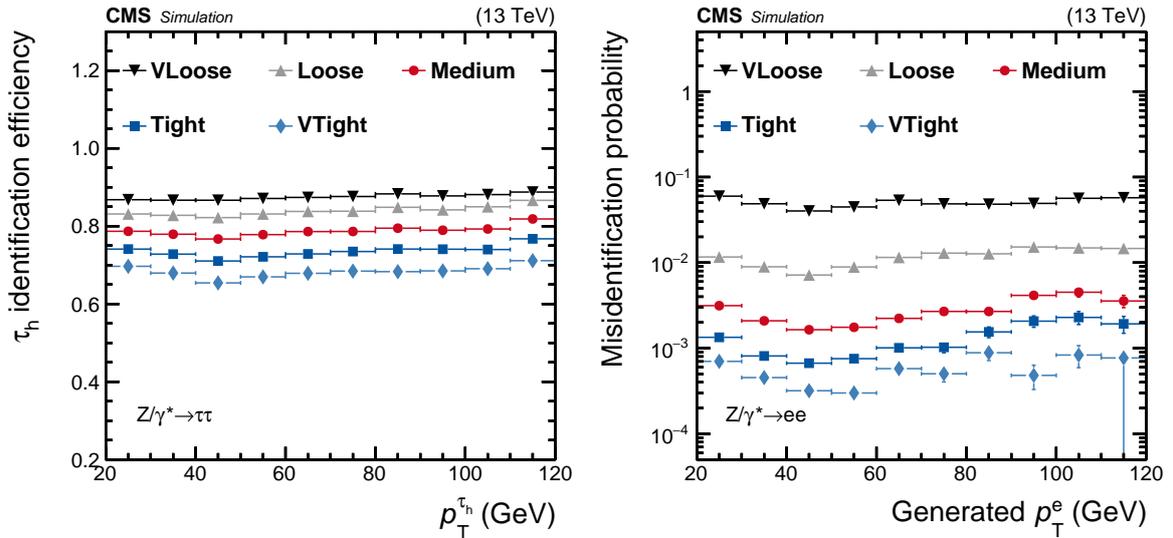

Figure 5: Efficiencies of τ_h identification estimated via simulated $Z/\gamma^* \rightarrow \tau\tau$ events (left), and the $e \mapsto \tau_h$ misidentification probability estimated using simulated $Z/\gamma^* \rightarrow ee$ events (right) for the very loose, loose, medium, tight, and very tight WPs of the MVA-based electron discrimination algorithm. The efficiency is shown as a function of p_T of the reconstructed τ_h candidate, while the misidentification probability is shown as a function of the generated electron p_T . The efficiency is calculated for τ_h candidates with a reconstructed decay mode that pass the loose WP of the isolation-sum discriminant, while the misidentification probability is calculated for generated electrons of $p_T > 20$ GeV and $|\eta| < 2.3$, excluding the less sensitive detector region of $1.46 < |\eta| < 1.56$ between the barrel and endcap ECAL regions. Vertical bars (often smaller than the symbol size) indicate the statistical uncertainties (the 68% Clopper-Pearson intervals), while horizontal bars indicate the bin widths.

5.4 Discrimination of τ leptons against muons

Muons have a high probability to be misreconstructed as τ_h objects in the h^\pm decay mode. The discriminant against muons, developed previously [24], is based on vetoing τ_h candidates when signals in the muon detector are found near the τ_h direction. The two working points

corresponding to different τ_h identification efficiencies and $\mu \mapsto \tau_h$ misidentification rates are:

1. “against- μ loose”: τ_h candidates fail this working point when track segments in at least two muon detector planes are found to lie within a cone of size $\Delta R = 0.3$ centered on the τ_h direction, or when the energy deposited in the calorimeters, associated through the PF algorithm to the “leading” charged hadron of the τ_h candidate, is $<20\%$ of its track momentum.
2. “against- μ tight”: τ_h candidates fail this working point when they fail condition (i), or when a hit is present in the CSC, DT, or RPC detectors located in the two outermost muon stations within a cone of size $\Delta R = 0.3$ around the τ_h direction.

The efficiency for τ_h candidates from $Z/\gamma^* \rightarrow \tau\tau$ events to pass the against- μ discriminant selection requirements exceeds 99%. The $\mu \mapsto \tau_h$ misidentification probability, for muons in $Z/\gamma^* \rightarrow \mu\mu$ events, is $\approx 3.5 \times 10^{-3}$ and $\approx 1.4 \times 10^{-3}$ for loose and tight WPs, respectively.

6 Reconstruction of highly boosted τ lepton pairs

In events containing a (hypothetical) massive boson with large p_T , e.g., a radion (R) decaying to a pair of Higgs bosons [62, 63], with at least one of these decaying to a pair of τ leptons, the jets from the two τ leptons would be emitted very close to each other, thereby forming a single jet. The performance of the HPS algorithm in such topologies is poor, as it was designed to reconstruct only one τ_h per jet. A dedicated version of the HPS algorithm was therefore recently developed to reconstruct two τ leptons with large momenta that typically originate from decays of large-momentum Z or Higgs bosons. This algorithm takes advantage of jet substructure techniques, as follows. A collection of “large-radius jets” is assembled from the PF candidates using the Cambridge–Aachen algorithm [64] with a distance parameter of 0.8 (CA8). Due to the large boosts, the emitted τ lepton decay products are expected to be contained within the same CA8 jet, when its p_T exceeds 100 GeV. The algorithm proceeds by reversing the final step of the clustering algorithm for each given CA8 jet, to find two subjets sj_1 and sj_2 that can be expected to coincide with the two τ leptons from the decay of the boosted massive boson. To reduce the misidentification of jets arising from QCD multijet events, sj_1 and sj_2 must satisfy the following additional restrictions:

1. the p_T of each subjet must be greater than 10 GeV, and
2. the mass of the heavier subjet must be less than $2/3$ of the large-radius jet mass, where mass refers to the invariant mass of all jet constituents.

These requirements are obtained from an optimization of the reconstruction efficiency, while maintaining a reasonable misidentification probability. When these requirements cannot be met, the pair of subjets is discarded, and the procedure is repeated, treating the subjet with largest mass as the initial jet that is then split into two new subjets. If the algorithm is unable to find two subjets satisfying the above criteria within a given CA8 jet, no τ_h reconstruction is performed from this CA8 jet, and the algorithm moves on to the next such jet. When two subjets satisfying the requirements are found, they are passed to the HPS algorithm as seeds. At this stage, the algorithm does not differentiate between subjets arising from hadronic or leptonic τ decays. After reconstruction, the decay-mode criteria (Section 5.1.2) and the MVA-based isolation discriminants (Section 5.2.2) are applied to the reconstructed τ_h candidate, taking into

account just the PF candidates belonging to the subjet that seeds the τ_h in the reconstruction and the isolation calculations. The decay-mode criteria are relaxed relative to those used in the standard HPS algorithm by accepting τ_h candidates with two charged hadrons, and therefore an absolute charge different from unity. This relaxation recovers τ leptons decaying into three charged hadrons when one of the tracks is not reconstructed in the dense environment of a high- p_T jet. If an electron or muon, reconstructed and identified through the usual techniques available for these leptons [21, 22], is found to be near ($\Delta R < 0.1$) to a τ_h candidate reconstructed from a subjet, the corresponding CA8 jet is considered to originate from a semileptonic τ lepton pair decay. Cases in which both τ leptons decay leptonically are not considered.

Figure 6 compares the efficiencies in standard reconstruction with that for highly boosted τ lepton pairs in simulated events of $R \rightarrow HH \rightarrow b\bar{b}\tau\tau$ decays in the $\tau_h\tau_h$ and $\tau_\mu\tau_h$ final states. In addition, the expected probability for large-radius jets to be misidentified as τ_h pairs is shown for simulated QCD multijet events. While the efficiency in $\tau_\mu\tau_h$ events is computed just for the τ_h candidate, it is computed once relative to one τ_h candidate and once relative to both τ_h candidates in $\tau_h\tau_h$ events. The misidentification probability is calculated in $\tau_h\tau_h$ final states for both τ_h candidates. The τ_h candidates are selected requiring $p_T > 20$ GeV and $|\eta| < 2.3$, using the very loose WP of the MVA-based isolation.

The algorithm used for highly boosted events provides a considerably higher efficiency than the standard HPS algorithm for τ lepton pairs with p_T greater than ≈ 0.5 TeV, with an expected increase in misidentification probability. Since at such high p_T , the contributions from background are highly suppressed, and the misidentification rate remains of the order of 10^{-4} , this algorithm can be used for searches in this kinematic regime.

7 Identification of τ_h candidates in the high-level trigger

Several analyses are based on experimental signatures that include τ_h signals, and therefore, along with the offline reconstruction discussed in Sections 5 and 6, we also employ dedicated τ_h identification algorithms in the trigger system, at both L1 and HLT.

The L1 system went through a series of upgrades [65] in 2015 and 2016, and it is now based on more powerful, fully-programmable FPGA processors and μ TCA logic boards. This allows more sophisticated τ_h reconstruction and isolation algorithms at L1, the performance of which can be found in Ref. [66].

The HLT system uses the full-granularity information of all CMS subdetectors, and runs a version of the CMS reconstruction that is slightly different than that used offline, as the HLT decision is made within 150 ms, on average, a factor of 100 faster than offline reconstruction. This is achieved using specialized, fast, or regional versions of reconstruction algorithms, and through implementation of multistep selection logic, designed to reduce the number of events processed by more complex, and therefore more time consuming subsequent steps. Both methods are exploited in the τ_h reconstruction at the HLT.

The τ_h HLT algorithm has three steps. The first step, referred to as Level 2 (L2), uses only the energy depositions in the calorimeter towers in regions around the L1 τ_h objects with $\Delta R < 0.8$. The depositions are clustered into narrow L2 τ_h jets using the anti- k_T algorithm with a distance parameter of 0.2. The only selection criterion required at L2 is a p_T threshold.

In the second step, known as Level 2.5 (L2.5), a simple form of charged-particle isolation is implemented, using just the information from the pixel detector. Tracks are reconstructed from hits in the pixel detector around the L2 τ_h jets (rectangular regions of $\Delta\eta \times \Delta\phi = 0.5 \times 0.5$), and

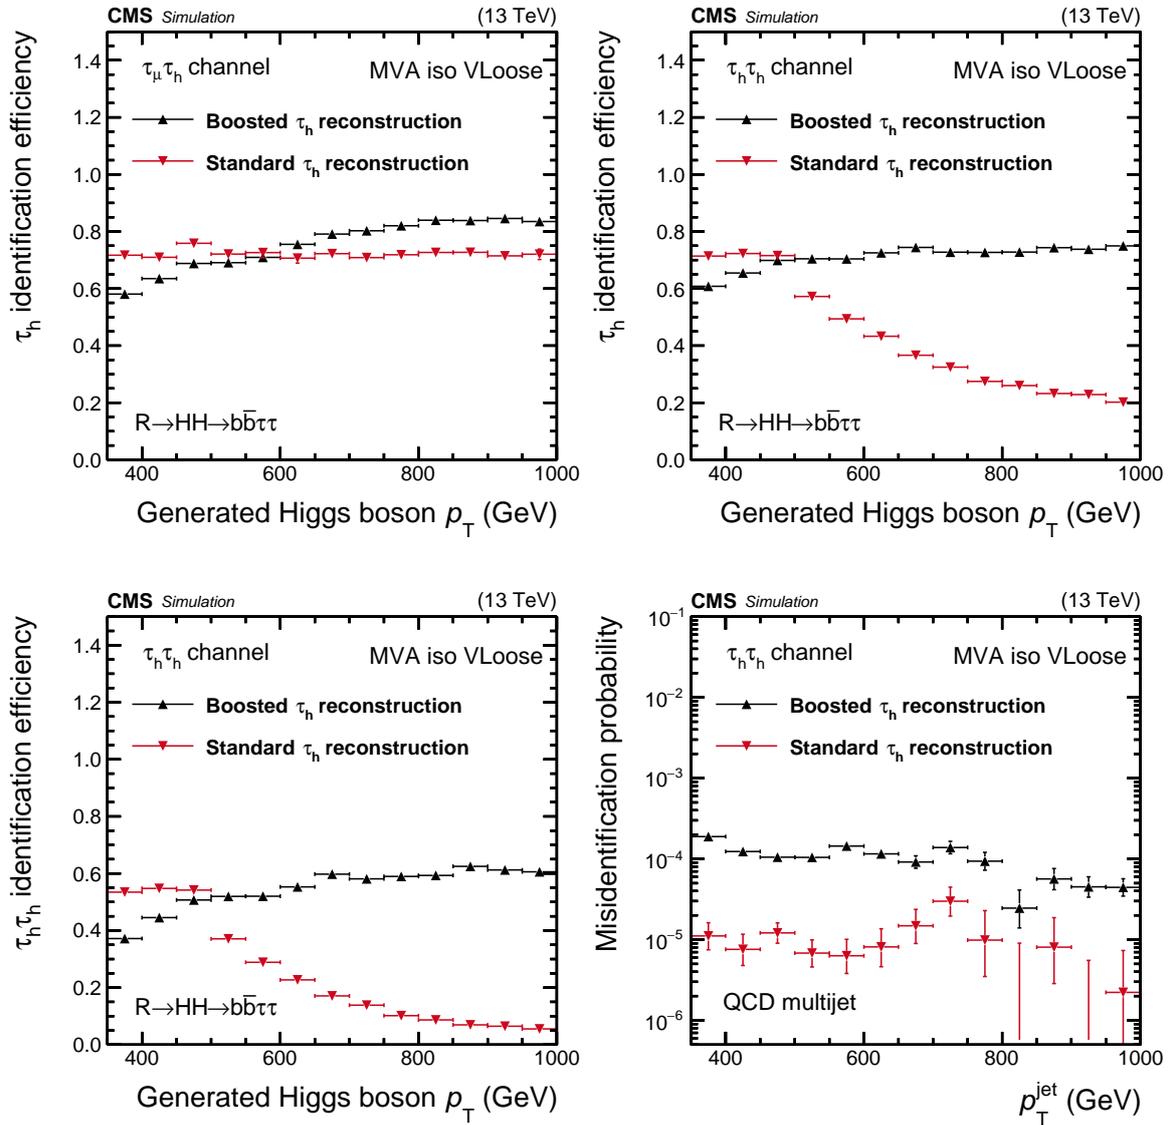

Figure 6: Reconstruction and identification efficiencies for the τ_h in the $\mu\tau_h$ (upper left) and $\tau_h\tau_h$ (upper right) final states, and for the $\tau_h\tau_h$ pair (lower left), as a function of the generated p_T of the Higgs boson, and the probability for large-radius jets in QCD multijet events to be misidentified as $\tau_h\tau_h$ final states (lower right), as a function of the large-radius jet p_T . Vertical bars correspond to the statistical uncertainties (the 68% Clopper-Pearson intervals), while horizontal bars indicate the bin widths.

used to form vertices. If no vertex is found, the τ_h jet is passed to the following step for more detailed scrutiny. If, on the other hand, at least one vertex is found, the one with highest $\sum p_T^2$ of its tracks is assumed to be the primary hard-scattering vertex in the event. Tracks originating from within $d_z < 0.1$ cm of the hard-scattering vertex, in an annulus of $0.15 < \Delta R < 0.4$ centered on the τ_h jet direction, and with at least three hits in the pixel detector, are used in the computation of the τ_h jet isolation. An L2 τ_h jet is considered isolated if the scalar sum of the p_T of the associated pixel tracks $\sum p_T^{\text{track}}$ is less than 1.85 GeV.

Finally, at Level 3 (L3), full track reconstruction, using both pixel and strip detectors, is executed using rectangular regions of size $\Delta\eta \times \Delta\phi = 0.5 \times 0.5$ around the L2 τ_h jets, followed by the PF reconstruction. Both components are tuned specifically for the fast processing at HLT, as discussed in Ref. [55].

The L3 τ_h algorithm starts with jets clustered from PF particles by the anti- k_T algorithm using a distance parameter of 0.4. First, photons, contained in a jet, within a fixed $\Delta\eta \times \Delta\phi$ area of 0.05×0.2 are clustered into the strips, and assigned the π^0 mass. A variable signal-cone size of $\Delta R_{\text{sig}}^{L3} = (3.6 \text{ GeV})/p_T^{\text{jet}}$, with $\Delta R_{\text{sig}}^{L3}$ limited to the range of 0.08–0.12, and an isolation cone of $\Delta R = 0.4$, are defined around the direction of the charged hadron in the jet with highest p_T . The L3 τ_h candidate is then constructed from the following constituents found within the signal cone: up to three charged hadrons that are ordered in decreasing p_T , and assumed to be charged pions, and all the available π^0 candidates. To recover possible tracking inefficiencies, neutral hadrons within a distance of $\Delta R = 0.1$ from the leading charged hadron are also considered as being part of the τ_h candidate. The vertex with smallest d_z relative to the track of the leading charged hadron is considered as the vertex of the τ_h production. To maximize the HLT reconstruction efficiency, these identification criteria are chosen to be fairly inclusive, not requiring strict consistency with the τ_h decay modes, with the respective sizes of the signal and isolation cones chosen to be larger and smaller than the sizes of the corresponding cones in the offline algorithm.

Two types of isolations were defined for L3 τ_h candidates in 2016. First is the charged isolation ($\sum p_T^{\text{charged}}$), computed by summing the scalar p_T of charged hadrons (other than those constituting the L3 τ_h candidate) with $d_z < 0.2$ cm relative to the τ_h vertex, located within the isolation cone; defining the loose, medium, and tight WPs through $\sum p_T^{\text{charged}}$ being smaller than 3.0, 2.0, and 1.5 GeV, respectively.

The second type is the combined isolation, I_τ^{L3} , defined as

$$I_\tau^{L3} = \sum p_T^{\text{charged}} + 0.3 \max\left(0, \sum p_T^\gamma - p_T^{\text{PU}}\right), \quad (8)$$

where $\sum p_T^\gamma$ is the sum of the scalar p_T of photons within an annulus between the signal and isolation cones that do not belong to the signal strips, and p_T^{PU} is the neutral contribution to the isolation from PU, estimated using the jet area method [56]. The respective loose, medium, and tight WPs of the combined isolation require I_τ^{L3} to be smaller than 3.0, 2.3, and 2.0 GeV.

The absolute isolation cutoff values (for both isolation types) are often relaxed by a few percent, depending on the trigger, as a function of $p_T^{\tau_h}$, starting at values of about twice the trigger threshold. This relaxation increases the reconstruction efficiency for genuine τ_h candidates, and is possible because of the number of misidentified τ_h candidates decreases with p_T , providing thereby a control of the trigger rates.

Finally, the scalar p_T sum of photons that are included in the strips of the L3 τ_h candidate, but are located outside of its signal cone (R_{sig}^{L3}), is defined as for offline τ_h candidates in Eq. (7). This

variable was not used for τ_h triggers in 2016, but is included in triggers during data taking in 2017.

The τ_h reconstruction and identification algorithms described in this section are employed to define a set of triggers for data taking during 2016. The triggers and their performance are discussed in Section 13.

8 Event selection and systematic uncertainties

This section describes the selection requirements employed to define event samples used in the following measurements of the performance of τ_h reconstruction and identification in data and simulation, as well as their related systematic uncertainties. Differences between data and simulated events in trigger, identification, and isolation efficiencies are taken into account through the reweighting of simulated events. In addition, the number of PU interactions in simulation is reweighted to match that measured in data.

8.1 The $Z/\gamma^* \rightarrow \tau\tau$ events

A sample of Z/γ^* events decaying into $e\tau_h$ or $\mu\tau_h$ final states is selected by requiring at least one well-identified and isolated electron or muon, referred to as the “tag”, and one τ_h candidate that passes loose preselection criteria, which corresponds to the “probe”.

The events in the $e\tau_h$ final state are required to pass an isolated single-electron trigger with $p_T > 25$ GeV. Offline, the electron candidate is required to have $p_T > 26$ GeV and $|\eta| < 2.1$, pass the tight WP of the MVA-based electron identification (with an average efficiency of 80%) [21, 67], and have $I_{\text{rel}}^e < 0.1$, as defined in Eq. (1). In the $\mu\tau_h$ final state, events are required to pass an isolated single-muon trigger with $p_T > 22$ GeV. Offline, the muon candidate is required to have $p_T > 23$ GeV and $|\eta| < 2.1$, pass the medium identification WP [22], and have $I_{\text{rel}}^\mu < 0.15$. The τ_h candidate is preselected to have $p_T > 20$ GeV, $|\eta| < 2.3$, no overlap with any global muon [22] with $p_T > 5$ GeV, to pass the against-lepton discriminant selection requirements defined in Sections 5.3 and 5.4, and to have at least one charged hadron with $p_T > 5$ GeV. The τ_h and electron or muon are required to be separated by at least $\Delta R = 0.5$, and to carry opposite electric charges. If several $e\tau_h$ or $\mu\tau_h$ pairs in one event pass this set of selection criteria, the pair formed from the most isolated τ_h and the most isolated electron or muon is selected. The events are rejected if they contain an additional electron or muon passing relaxed selection criteria. The relaxed selection requires that an electron satisfies the very loose WP of the MVA-based identification (with an average efficiency of 95%), a muon has to be reconstructed as a global muon, and both the electron or muon must have $p_T > 10$ GeV and $I_{\text{rel}}^{e/\mu} < 0.3$. To reduce the W +jets background contribution, the transverse mass of the electron or muon and \vec{p}_T^{miss} , $m_T \equiv \sqrt{2p_T^{e/\mu} p_T^{\text{miss}} (1 - \cos \Delta\phi)}$, is required to be less than 40 GeV, where $\Delta\phi$ is the difference in azimuthal angle between the electron or muon \vec{p}_T and \vec{p}_T^{miss} . In addition, a linear combination of the variables $P_\zeta^{p_T^{\text{miss}}}$ and P_ζ^{vis} , originally developed by the CDF experiment [68], namely $D_\zeta = P_\zeta^{p_T^{\text{miss}}} - 0.85 P_\zeta^{\text{vis}}$, is used to benefit from the fact that in $Z/\gamma^* \rightarrow \tau\tau$ events the \vec{p}_T^{miss} from the neutrinos produced in τ decays typically forms a small angle with the visible τ_h decay products. The D_ζ is required to be greater than -25 GeV.

8.2 The $\mu\tau_h$ final states in $t\bar{t}$ events

The $t\bar{t} \rightarrow \mu\tau_h$ +jets events are selected in the same way as the $Z/\gamma^* \rightarrow \tau\tau \rightarrow \mu\tau_h$ events, except for the requirements on m_T and D_ζ , which are not applied. The events are also required to have

at least one b-tagged jet to enrich the content in $t\bar{t}$ events.

8.3 The $Z/\gamma^* \rightarrow \mu\mu$ events to constrain the $Z/\gamma^* \rightarrow \ell\ell$ normalization

A high purity sample of $Z/\gamma^* \rightarrow \mu\mu$ events is selected to constrain the normalization of the Drell–Yan (DY, $q\bar{q} \rightarrow Z/\gamma^* \rightarrow \ell^+\ell^-$) events in the measurement of τ_h efficiency through the tag-and-probe method [69], described in detail in Section 9.1. The events are required to have a pair of well-separated ($\Delta R > 0.5$), oppositely-charged muons. The leading (in p_T) muon is required to pass the same selection as used in the $\mu\tau_h$ final states of Z/γ^* events. The subleading muon is required to pass the same selection as the leading muon, except for the η requirement, which is relaxed to $|\eta| < 2.4$. The invariant mass of the dimuon pair is required to be within 60–120 GeV. Events are rejected if they contain an additional electron or muon passing the relaxed selection criteria.

8.4 Off-shell $W \rightarrow \tau\nu$ events

Here, we use events in which a virtual W boson that decays into a τ_h and a ν is produced with small p_T (and no accompanying hard jet). The \vec{p}_T of the τ_h and the \vec{p}_T^{miss} are expected to be well balanced in such events.

Events are required to pass a trigger where $p_{T,\text{no}\mu}^{\text{miss}}$ and $H_{T,\text{no}\mu}^{\text{miss}}$ are both greater than 110 GeV, with $p_{T,\text{no}\mu}^{\text{miss}}$ being the magnitude of \vec{p}_T^{miss} computed using all particles in an event except muons, and $H_{T,\text{no}\mu}^{\text{miss}}$ being the magnitude of \vec{p}_T^{miss} computed using jets with $p_T > 20$ GeV, reconstructed from all particles except muons. Offline, events are required to have one τ_h candidate with $p_T > 100$ GeV, and $p_T^{\text{miss}} > 120$ GeV. To ensure back-to-back topologies between the τ_h candidate and p_T^{miss} , we require $\Delta\phi(\tau_h, p_T^{\text{miss}}) > 2.8$ rad. The event is discarded if it has at least one jet with $p_T > 30$ GeV and $|\eta| < 4.7$, except the one corresponding to the τ_h , or an additional electron or muon passing the relaxed selection criteria.

8.5 Off-shell $W \rightarrow \mu\nu$ events to constrain the $W \rightarrow \tau\nu$ normalization

This event sample is used to constrain the normalization of off-shell W boson production for $m_W > 200$ GeV, used in the τ_h efficiency measurement, as described in Section 9.3. Events are selected with an isolated single-muon trigger with $p_T > 22$ GeV and $|\eta| < 2.1$. Offline, the muon candidate must have $p_T > 120$ GeV and $|\eta| < 2.1$; it must also pass the medium identification WP, and have a relative isolation of less than 0.15. The event must also have $p_T^{\text{miss}} > 120$ GeV and $\Delta\phi(\mu, p_T^{\text{miss}}) > 2.8$ rad. The event is discarded if it has at least one jet with $p_T > 30$ GeV and $|\eta| < 4.7$, or an additional electron or muon passing the relaxed selection criteria.

8.6 Events from $W \rightarrow \mu\nu$ +jet production

These events are triggered using a single isolated-muon trigger with $p_T > 24$ GeV and $|\eta| < 2.1$. Offline, we require one well-identified and isolated muon with $p_T > 25$ GeV. Events with additional electrons or muons passing the relaxed selection criteria are rejected. In addition, the transverse mass of the muon and \vec{p}_T^{miss} is required to be greater than 60 GeV, to suppress events with genuine τ_h candidates, in particular from Z/γ^* bosons. Events should contain exactly one jet with $p_T > 20$ GeV and $|\eta| < 2.4$, and there should be no additional jets (in $|\eta| > 2.4$) with $p_T > 20$ GeV. To ensure that the W boson is balanced in p_T with the jet, the following selections are applied: $\Delta\phi(W, \text{jet}) > 2.4$ rad, and the ratio of jet p_T and W boson p_T must be between 0.7 and 1.3, where the p_T of the W boson is reconstructed from the vector sum of muon \vec{p}_T and \vec{p}_T^{miss} .

8.7 The $e\mu$ final states in $t\bar{t}$ events

These events are triggered using a single isolated-muon trigger with $p_T > 24$ GeV, and are required to have one well-identified and isolated electron and one well-identified and isolated muon both of $p_T > 26$ GeV and $|\eta| < 2.4$. Events with additional electrons or muons passing the relaxed selection criteria are rejected.

8.8 The $Z/\gamma^* \rightarrow ee, \mu\mu$ events for measuring the $e/\mu \mapsto \tau_h$ misidentification probability

High-purity samples of $Z/\gamma^* \rightarrow ee$ and $Z/\gamma^* \rightarrow \mu\mu$ events are selected for measuring their respective $e \mapsto \tau_h$ and $\mu \mapsto \tau_h$ misidentification probabilities. Consequently, again, we require at least one well-identified, isolated electron or muon (tag) and one isolated τ_h candidate (probe).

The $Z/\gamma^* \rightarrow ee$ events are selected by requiring a single-electron trigger to have fired. Offline, the electron candidate must match the trigger object (within $\Delta R < 0.5$), have $p_T > 26$ GeV and $|\eta| < 2.1$, pass the most-restrictive electron-identification criteria, and have an $I_{\text{rel}}^e < 0.1$. The $Z/\gamma^* \rightarrow \mu\mu$ events are collected using a single isolated-muon trigger with $p_T > 24$ GeV. Offline, the muon candidate must match the trigger object (within $\Delta R < 0.5$), be selected with $p_T > 26$ GeV and $|\eta| < 2.1$, after passing medium muon-identification criteria, and $I_{\text{rel}}^\mu < 0.15$.

The τ_h candidate is required to satisfy $p_T > 20$ GeV and $|\eta| < 2.3$, be reconstructed in one of the decay modes $h^\pm, h^\pm\pi^0, h^\pm\pi^0\pi^0$, or $h^\pm h^\mp h^\pm$, and pass the tight WP of the MVA-based isolation discriminant described in Section 5.2.2. It must also be separated from the electron or muon by $\Delta R > 0.5$, and have an electric charge opposite to that of the electron or muon. The τ_h candidate must pass the loose WP of the against- μ discriminant described in Section 5.4 when selecting $Z/\gamma^* \rightarrow ee$ events. The purity of the sample is increased by requiring the invariant mass of the tag-and-probe pair to be between 60–120 or 70–120 GeV for $Z/\gamma^* \rightarrow ee$ and $Z/\gamma^* \rightarrow \mu\mu$ events, respectively.

The W +jets and $t\bar{t}$ backgrounds are reduced by requiring the selected events to have m_T (of the tag electron or muon and \vec{p}_T^{miss}) not exceeding 30 GeV.

8.9 Systematic uncertainties affecting all studied final states

The generic systematic uncertainties affecting most of the measurements presented in Sections 9–12 are discussed in this section. Uncertainties concerning particular analyses are not covered here, but are discussed in their corresponding sections. The same is true for deviations in the values of the systematic uncertainties.

The uncertainty in the measured integrated luminosity is 2.5% [70], and affects the normalization of all processes modelled via MC simulation. The combination of trigger, identification, and isolation efficiencies for electrons and muons, measured using the tag-and-probe technique, result in normalization uncertainties of 2% that also affect the normalization of processes modelled in simulation. Uncertainties in the normalization of production cross sections [45–48, 50, 71, 72] or in the method used to extract the normalization of $t\bar{t}$ (3–10%), diboson (5–15%), and DY (2–4%) production, are also taken into account. Uncertainties in the τ_h energy scale, affecting the distributions in simulated events that depend on E_{τ_h} , and range between 1.2% (as determined in Section 12) and 3% for high- p_T τ_h candidates. Furthermore, to account for statistical fluctuations caused by the limited number of simulated events, we use the ‘‘Barlow-Beeston light’’ approach [73, 74], which assigns a single nuisance parameter per bin that rescales the total bin yield. Most of the analyses discussed in the following sections correct the simulated p_T distributions of the Z/γ^* boson in DY events and of the top quark in $t\bar{t}$ events to the

spectra observed in data through measured weights. This reweighting corrects only the differential distributions without changing their normalization. Uncertainties in these weights are propagated through the analyses, where the downward changes by one standard deviation are computed as a difference between the weighted distribution and the one without weight, while the upward changes by one standard deviation are computed as a difference between weighted distributions with nominal weight and with the square of that weight. Finally, the uncertainty related to the PU distribution is estimated by changing the minimum-bias pp cross section by $\pm 5\%$.

A comprehensive overview of these uncertainties is given in Table 2.

Table 2: Systematic uncertainties affecting the measurements described in Sections 9–12. Given are the source of the uncertainty and whether the distribution in question is affected.

Uncertainty	Value	Affecting distribution?
Integrated luminosity	2.5%	No
e trigger, identification, and isolation efficiency	2%	No
μ trigger, identification, and isolation efficiency	2%	No
DY normalization	2–4%	No
$t\bar{t}$ normalization	3–10%	No
Diboson normalization	5–15%	No
τ_h energy scale	1.2–3%	Yes
Limited number of events	Statistical uncertainty in individual bin	Yes
DY p_T	(Weight) ² – no weight	Yes
$t\bar{t}$ p_T	(Weight) ² – no weight	Yes
Number of PU events	5%	Yes

9 Measurement of the τ_h identification efficiency

The measurements of τ_h reconstruction and identification efficiencies in data use approaches similar to those of Ref. [24], and provide data-to-simulation scale factors and their uncertainties that can be used to correct the simulated predictions in analyses. The efficiency is measured in different $p_T^{\tau_h}$ regions: small $p_T^{\tau_h}$ between 20 and ≈ 60 GeV, using the $\mu\tau_h$ final state of $Z/\gamma^* \rightarrow \tau\tau$ events, as discussed in Section 9.1; intermediate $p_T^{\tau_h}$ of up to ≈ 100 GeV, using the $\mu\tau_h$ final states in $t\bar{t}$ events, as discussed in Section 9.2; and high $p_T^{\tau_h}$ of > 100 GeV, using a selection of highly virtual W bosons ($m_W > 200$ GeV) decaying into τ leptons, as presented in Section 9.3. The data-to-simulation scale factors obtained through these measurements are combined, as described in Section 9.4, to extrapolate to higher- $p_T^{\tau_h}$ regions not covered by these measurements. Finally, the identification efficiency for τ_h candidates reconstructed using the algorithm dedicated to highly boosted τ lepton pairs is measured using the tag-and-probe method, as described in Section 9.5.

9.1 Using the tag-and-probe method in Z/γ^* events

The τ_h identification efficiency for $p_T^{\tau_h}$ up to ≈ 60 GeV is estimated in $\mu\tau_h$ final states of Z/γ^* events, selected as described in Section 8.1. The events are subdivided into passing (“pass” region) and failing (“fail” region) categories, depending on whether the τ_h candidate passes or fails the appropriate working point of the τ_h isolation discriminant. The data-to-simulation scale factor for the τ_h identification efficiency is extracted from a maximum likelihood fit of the invariant mass distribution of the reconstructed (visible) $\mu\tau_h$ system, referred to as m_{vis} . The expected SM contributions are fitted to the observed data simultaneously in both categories.

The predictions for SM processes contributing to the distribution in m_{vis} consist of a signal sample of $Z/\gamma^* \rightarrow \tau\tau \rightarrow \mu\tau_h$ events, where the reconstructed τ_h candidate is required to be matched to the generated one, and a set of backgrounds. All background events, except for QCD multijet production, rely on simulated m_{vis} distributions. Diboson, single top quark, and $t\bar{t}$ samples are normalized to their theoretical cross sections. A sample of dimuon events, as described in Section 8.3, is used to constrain the normalization of the DY process, by using them simultaneously in the fit, along with the events in the passing and failing categories. The DY processes, other than the $Z/\gamma^* \rightarrow \tau\tau \rightarrow \mu\tau_h$ signal, where τ_h candidates from the misidentification of e , μ , or jets, contribute to the background, and are denoted as “other DY”.

The normalization of the contribution from W+jets events is estimated using control samples in data. A data-to-simulation scale factor is estimated in a sample enriched in W+jets events, defined in a way similar to the signal sample, but without the D_ζ requirement having been applied, and with $m_T > 80$ GeV, where small contributions from other processes are subtracted from data, based on their estimated cross sections. The scale factor is then applied to the simulation of the W+jets events in the low- m_T signal sample.

The distribution and normalization of the QCD multijet background is estimated from control samples in data. The distribution is extracted from a sample selected using the nominal selection criteria discussed previously, but requiring the μ and τ_h candidates to have the same-sign (SS) electric charge. All other processes contributing to this sample are estimated using the procedures detailed above, and are subtracted from the data. The normalization is controlled using the ratio of events found in two separate control samples requiring same- and opposite-sign (OS) charge for the μ and τ_h candidates, respectively. Otherwise, both samples are defined in ways similar to that of the signal sample, but with an inverted muon isolation criterion.

The following uncertainties are considered in addition to the ones outlined in Section 8.9, that is, uncertainties in the W+jets background normalization that arise from a possible difference between the low- and high- m_T regions and from the uncertainties in p_T^{miss} , which are used in computing m_T . The uncertainty in the yield of W+jets events is estimated to be about 10%. The uncertainty in the OS/SS scale factor, used in the estimation of the QCD multijet background is $\approx 5\%$, which is mostly due to the limited number of events in the OS and SS control regions. The normalization of the DY process is extracted from the dimuon control region. An extrapolation uncertainty of 2% is used for the $\mu\tau_h$ sample to account for the differences in lepton kinematics (mostly in p_T).

The results obtained for different working points of the MVA-based discriminant with $\Delta R = 0.5$ are shown in Table 3. An uncertainty of 3.9% is added in quadrature to the one returned by the fit, to account for the uncertainty associated with the track reconstruction efficiency [26]. The scale factors obtained for different working points of the isolation sum discriminants are found to be close to 90%, with uncertainties of 5%, and the scale factors obtained for the MVA-based discriminants trained using 2016 simulations as well as for $\Delta R = 0.3$, are found to be compatible with those presented in Table 3. The measured scale factors vary from 0.92 to 0.99, depending on the working point, with uncertainties of about 5%. The fitted distributions that maximize the likelihood for the tight WP of the MVA-based isolation are shown in Fig. 7. The scale factors are also measured in different ranges of $p_T^{\tau_h}$ for the tight WP of the MVA-based isolation discriminant with $\Delta R = 0.5$, and enter the extrapolation to high $p_T^{\tau_h}$, as discussed in Section 9.4.

The efficiency for τ_h candidates to pass the working points of the discriminants used to reject electrons and muons, described in Sections 5.3 and 5.4, respectively, are also measured in the $\mu\tau_h$ final states of $Z/\gamma^* \rightarrow \tau\tau$ events, which are selected as described above. The τ_h candidates

Table 3: Data-to-simulation scale factors for different MVA-based isolation working points with $\Delta R = 0.5$, measured using Z/γ^* events. An uncertainty of 3.9% is added in quadrature to the uncertainty returned by the fit to account for the uncertainty in track reconstruction efficiency.

Working point	Scale factor
Very loose	0.99 ± 0.05
Loose	0.98 ± 0.05
Medium	0.97 ± 0.05
Tight	0.95 ± 0.05
Very tight	0.92 ± 0.05
Very-very tight	0.93 ± 0.05

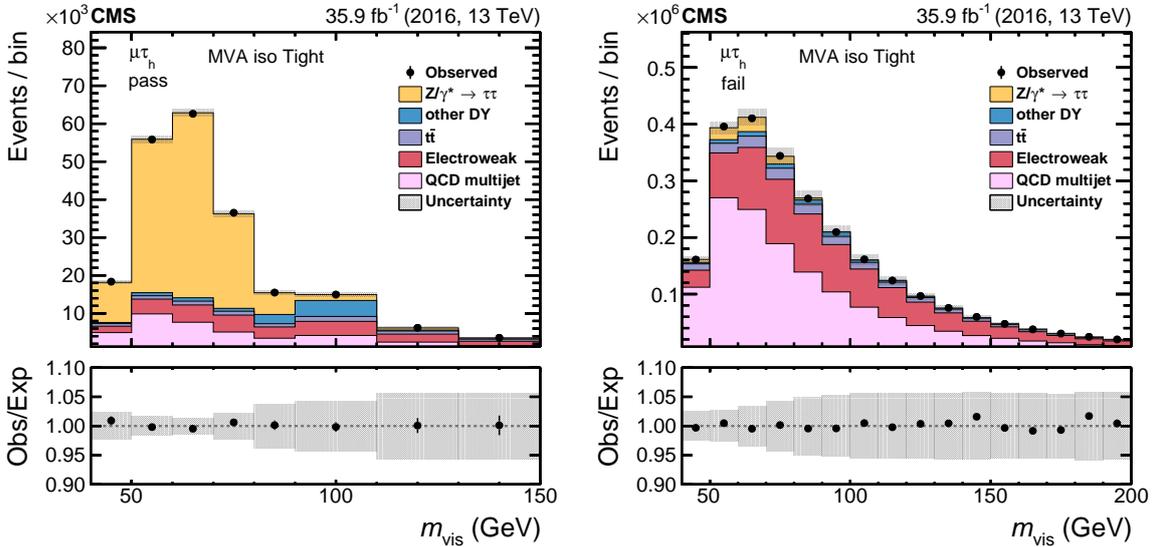

Figure 7: The fitted distribution in m_{vis} in the passing (left) and failing (right) categories for the tight WP of the MVA-based isolation. The electroweak background includes contributions from W+jets (dominating), diboson, and single top quark events. Vertical bars correspond to the statistical uncertainties in the data points (68% frequentist confidence intervals), while shaded bands to the quadratic sum of the fitted statistical and systematic uncertainties.

are required to have $p_T > 20 \text{ GeV}$, $|\eta| < 2.3$, and to pass the tight WP of the MVA-based τ_h isolation discriminant. The events are again subdivided into passing and failing categories, depending on whether the τ_h candidate passes or fails the appropriate working points of the discriminants used against electrons or muons. The data-to-simulation scale factor is obtained from a maximum likelihood fit to the m_{vis} distribution. The scale factors are compatible with unity to within the uncertainty in the measurements that range between 1 and 3%.

9.2 Using $t\bar{t}$ events

A sample of $t\bar{t}$ events with a muon and a τ_h in the final state is used to measure the τ_h identification efficiency for $p_T^{\tau_h}$ up to 100 GeV. The selection requirements are described in Section 8.2. The selected τ_h candidate must be accepted using the appropriate working point of the τ_h isolation discriminant. The distribution in m_T of the muon and \vec{p}_T^{miss} is used to determine the data-to-simulation scale factors.

Contributions to m_T distribution from $Z/\gamma^* \rightarrow \tau\tau$, single top quark, diboson, and W+jets events are modelled using simulations normalized to theoretical cross sections. Background from QCD multijet production is determined as described in Section 9.1. The major background contribution is from $t\bar{t}$ events where a jet is misidentified as a τ_h candidate. The distribution is taken from simulation and a dedicated sample of events is selected to constrain the normalization of this background, as well as the probability of a jet to be misidentified as a τ_h candidate. Events have to pass the same criteria as discussed in Section 8.2, but must also contain an additional isolated electron of electric charge opposite to that of the selected muon. This selects the $e\mu$ final state of $t\bar{t}$ events with an additional jet which can be misidentified as a τ_h candidate. These $e\mu$ events are then subdivided into passing and failing categories, based on whether the requirements imposed on the τ_h candidate are met in the τ_h isolation discriminant. A simultaneous likelihood fit is performed to the m_T distribution in all three samples, constraining thereby the $t\bar{t}$ contribution and the probability for jets to be identified as τ_h candidates, as well as measuring the efficiency of the τ_h identification relative to that expected in simulation.

The systematic uncertainties are similar to those listed in Section 8.9, except for additional uncertainties related to the b tagging performance (3% effect on the normalization), and the cross section for $Z/\gamma^* + \text{jet}$ process (30%), given that the $Z/\gamma^* + b$ jet cross section is not well measured. A 3.9% uncertainty in the track reconstruction efficiency is added to the signal processes. The uncertainty in the jet $\mapsto \tau_h$ misidentification probability is correlated between the signal and the control sample, where the τ_h candidate passes the identification requirement. The $e\mu$ failing category is used to further constrain both the normalization for $t\bar{t}$ production as well as the uncertainty in b tagging performance. Figure 8 shows the fitted distributions in m_T for the tight WP of the MVA-based isolation.

The measurement is repeated for different isolation working points of the MVA-based discriminant, as well as for the tight WP in different regions of $p_T^{\tau_h}$, and individually for each reconstructed decay mode. Although the mean value of the scale factor in the $h^\pm h^\mp h^\pm$ decay mode is slightly below those of the other decay modes, no significant differences are observed between the three decay modes. The measured scale factors in different $p_T^{\tau_h}$ regions enter the extrapolation as outlined in Section 9.4, and Table 4 summarizes the results for the working points of the MVA-based isolation discriminants. The scale factors measured from the inclusive $t\bar{t}$ events are slightly lower than those from $Z/\gamma^* \rightarrow \tau\tau$. This is because the jet $\mapsto \tau_h$ misidentification probability is slightly higher in simulation than in data, causing the τ_h identification efficiency scale factor to be pulled down towards lower values, where the distributions of the $t\bar{t}$ events with genuine τ_h and the misidentified jet $\mapsto \tau_h$ candidates become similar. However, this is

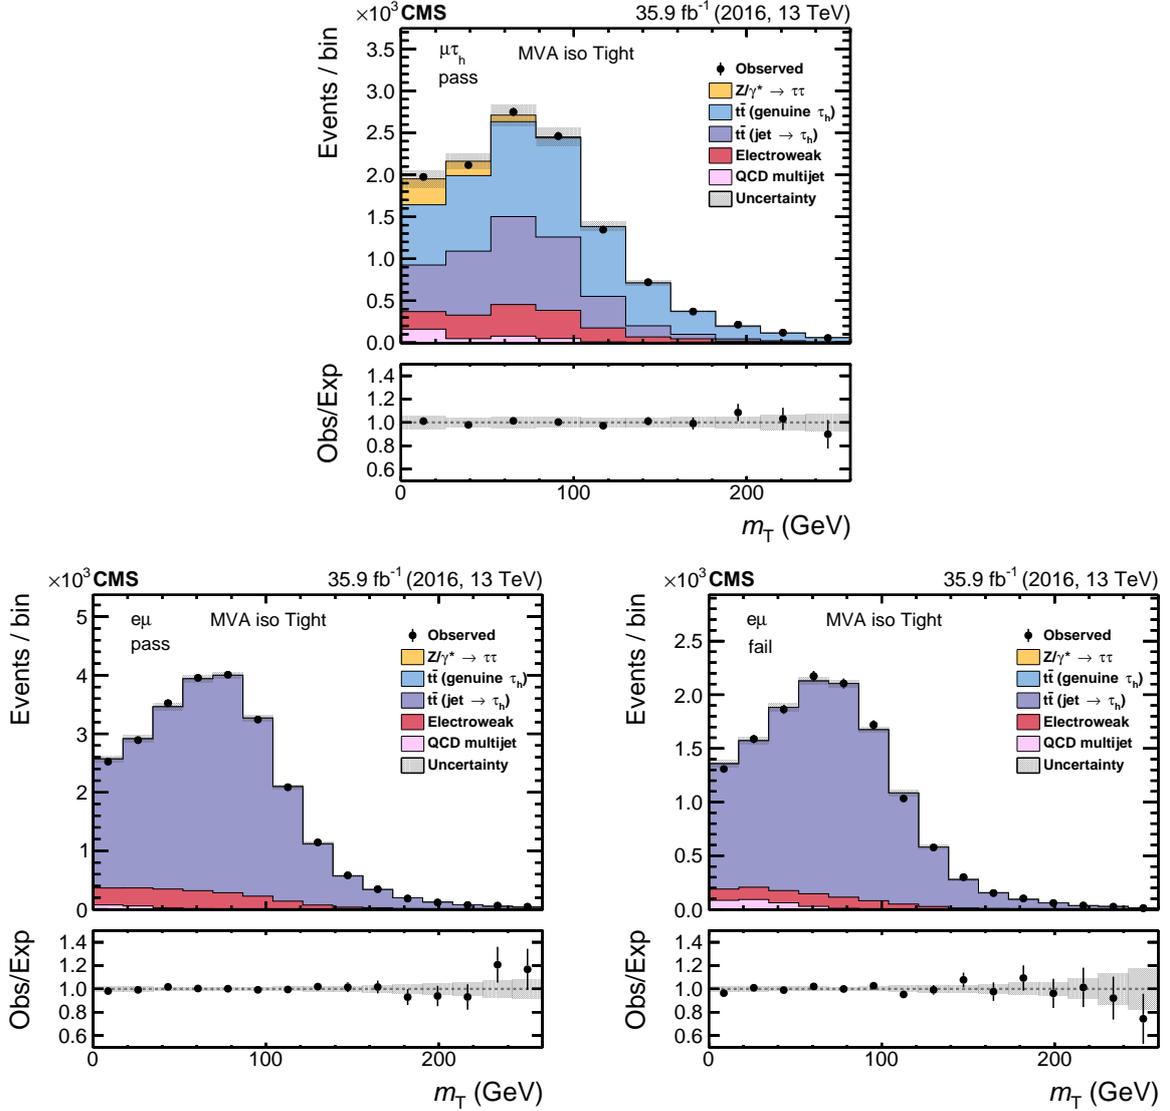

Figure 8: Fitted distributions for the signal (upper), $e\mu$ passing (lower left), and the $e\mu$ failing (lower right) categories, using the m_T for the \vec{p}_T^H and \vec{p}_T^{miss} vectors as observables for the tight WP of the MVA-based isolation with p_T^H between 30 and 40 GeV. The electroweak background includes contributions from W +jets (dominating), diboson, and single top quark events. Vertical bars correspond to the statistical uncertainties in the data points (68% frequentist confidence intervals), while the shaded bands reflect the quadratic sum of the statistical and systematic uncertainties after the fit.

mitigated for the measurement in bins of $p_T^{\tau_h}$, by constraining the normalization of the $t\bar{t}$ background with a jet misidentified as a τ_h candidate, using the $e\mu$ passing sample, as discussed above.

Table 4: Data-to-simulation scale factors for different MVA-based isolation working points obtained from $t\bar{t}$ events.

Working point	Scale factor
Very loose	0.99 ± 0.07
Loose	0.94 ± 0.07

Very tight	0.89 ± 0.06
Very-very tight	0.86 ± 0.06

9.3 Using off-shell $W \rightarrow \tau\nu$ events

The identification efficiency for τ_h leptons with $p_T > 100$ GeV is measured using a sample of events in which a highly virtual W boson ($m_W > 200$ GeV) is produced at small p_T (and often without an accompanying hard jet), and decays into a τ lepton and ν_τ . The signature for such events consists of a single τ_h decay and \vec{p}_T^{miss} balanced by the $\vec{p}_T^{\tau_h}$.

The selection requirements for the $W \rightarrow \tau\nu$ sample are described in Section 8.4. A large fraction of events selected in this channel originate from processes where a jet is misidentified as a τ_h candidate. The main processes contributing to this kind of background are QCD multijet, $Z/\gamma^* \rightarrow \nu\bar{\nu}$ +jets, and $W \rightarrow \ell\nu$ +jets events.

The background from events where a jet is misidentified as a τ_h candidate is estimated using a control sample obtained by applying the same set of requirements as used in the selection of the $W \rightarrow \tau\nu$ events, except for the τ_h isolation criterion, which is inverted. Events in this control sample are then extrapolated to the signal region using the ratio of probabilities for a jet to pass to that to fail the τ_h isolation. The $W \rightarrow \mu\nu$ +1 jet and QCD dijet events are utilized to estimate the extrapolation factor. The method is verified with simulated samples of $W \rightarrow \ell\nu$ +jets and $Z/\gamma^* \rightarrow \nu\bar{\nu}$ +jets events.

The study shows that the set of requirements outlined in Section 8.4, selects $W \rightarrow \tau\nu$ events with an invariant mass of the $\tau\nu$ pair $m_{\tau\nu} \equiv m_W > 200$ GeV. A dedicated auxiliary sample of $W \rightarrow \mu\nu$ events is used to constrain the normalization of virtual W boson production with $m_W > 200$ GeV. The $W \rightarrow \mu\nu$ events are selected as described in Section 8.5, and verified using MC simulation that the phase space covered by the $W \rightarrow \mu\nu$ and $W \rightarrow \tau\nu$ samples tend to largely overlap.

The signal is extracted using a simultaneous maximum likelihood fit to the m_T (of the $\vec{p}_T^{\tau_h/\mu}$ and \vec{p}_T^{miss}) distribution for both the $W \rightarrow \tau\nu$ signal and $W \rightarrow \mu\nu$ control samples. This procedure minimizes the uncertainties related to the normalization of W boson events. The fit is performed using two freely floating parameters:

1. the scale factor in the τ_h identification efficiency, i.e., the ratio of the measured value of the τ_h identification efficiency to the value predicted by simulation, and
2. the normalization for W production with $m_W > 200$ GeV, relative to the theoretical prediction (r_W).

In addition to the uncertainties listed in Section 8.9, the following systematic uncertainties are also taken into account in the fit. An uncertainty of 1% in the momentum scale of the muon that also alters the differential distributions. The energy scale of the p_T^{miss} is taken into account in propagating the uncertainty in the jet energy scale, as well as in the scale of the unclustered energy depositions. Uncertainties in the extrapolation factor used in the estimation of background from jets misidentified as τ_h is also taken into account. The backgrounds with genuine τ leptons in $W \rightarrow \tau\nu$ events are dominated by diboson events, which are estimated via MC simulation. The normalization of the diboson background is verified in dedicated control regions, indicating discrepancies of up to 30%. An uncertainty of 30% is therefore used in the normalization of backgrounds containing genuine τ leptons.

Figure 9 shows the fitted m_T distributions for the $W \rightarrow \tau\nu$ signal and $W \rightarrow \mu\nu$ control samples. The scale factor in the τ_h identification efficiency, the parameter r_W , and the correlation coefficient between the two quantities obtained from the fits, are detailed in Table 5 for different working points of the MVA-based τ_h isolation discriminants. The data-to-simulation scale factors range between 0.89 for the very tight WP and 0.96 for the loose WP. The fitted value of the W boson production cross section for $m_W > 200$ GeV is consistent with theoretical predictions. The W boson sample normalization factor is anticorrelated with the scale factor for τ_h identification efficiency, as an increase in the W boson yield is compensated in the fit by a reduction in the scale factor. The correlation between the scale factor and r_W increases with tighter τ_h isolation, as expected, due to an increase in the purity of the signal region.

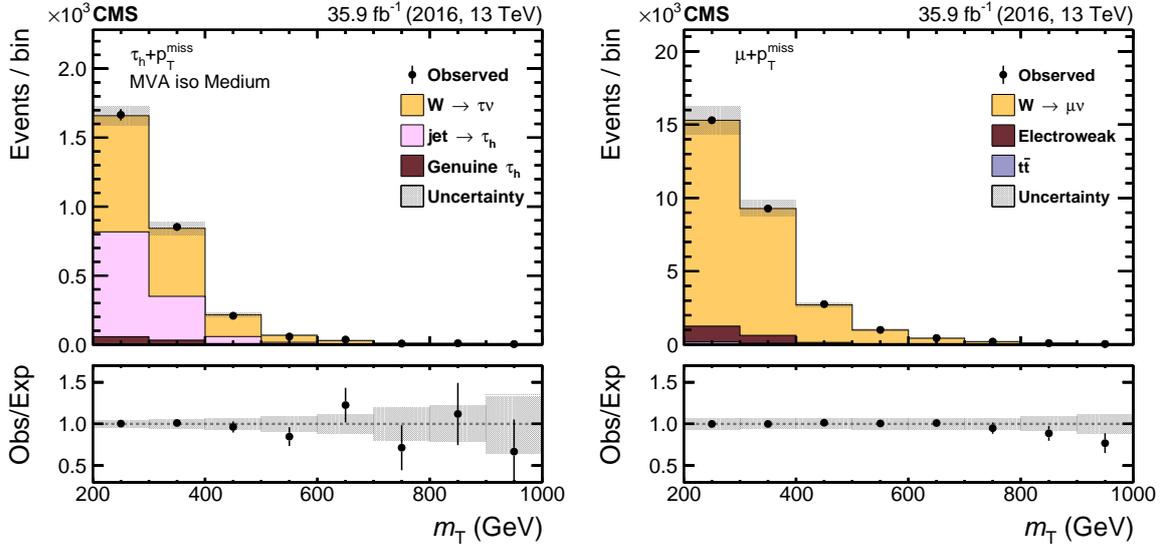

Figure 9: The m_T distribution for selected $W \rightarrow \tau\nu$ (left) and $W \rightarrow \mu\nu$ (right) events after the maximum likelihood fit. The medium WP of the MVA-based isolation discriminant is applied to select $W \rightarrow \tau\nu$ events. The electroweak background contribution includes diboson and single top quark events. Vertical bars correspond to the statistical uncertainties in the data points (68% frequentist confidence intervals), while the shaded bands to the quadratic sum of the statistical and systematic uncertainties after the fit.

We also measure the τ_h identification efficiencies in bins of $p_T^{\tau_h}$, with the data-to-simulation scale factors extracted in a simultaneous fit to the m_T distribution in four signal samples, corresponding to four bins of $p_T^{\tau_h}$, and of p_T^μ in the $W \rightarrow \mu\nu$ control sample. The results enter in the extrapolation of the scale factor to high $p_T^{\tau_h}$, as discussed in Section 9.4.

Table 5: The scale factor in the τ_h identification efficiency, the normalization of W boson production with $m_W > 200$ GeV, r_W , and the correlation coefficient between the two quantities obtained from the fit, measured for MVA-based discriminants using $\Delta R = 0.5$ in $W \rightarrow \tau\nu$ events.

Working point	Scale factor	r_W	Correlation

9.4 Extrapolation of the τ_h identification efficiency to large $p_T^{\tau_h}$

To extrapolate the scale factors for the τ_h identification efficiency to high $p_T^{\tau_h}$, a fit is performed to the values obtained in Sections 9.1, 9.2, and 9.3, as a function of $p_T^{\tau_h}$. These measurements cover a $p_T^{\tau_h}$ range between 20 and ≈ 300 GeV, with the mean value in each $p_T^{\tau_h}$ bin used as a representative number for that bin. Fits to a zero- (constant) and first-order polynomial are performed, without considering the uncertainty in track reconstruction efficiency, as it is correlated among the individual measurements. Nevertheless, it is found to contribute very little to the overall uncertainty, with the exception of measurements at low $p_T^{\tau_h}$, where other uncertainties are small because of the large number of events and the high purity of the event samples. Despite having other possible correlations between $p_T^{\tau_h}$ bins in a single measurement, or between different measurements, all measurements entering the fit are assumed to be uncorrelated.

The fit to a first-order polynomial provides a smaller goodness-of-fit per degree of freedom, χ^2/dof , than that to a constant, indicating that the scale factor for τ_h identification efficiency may decrease with $p_T^{\tau_h}$; but, given that the slope of the fitted first-order polynomial barely deviates from zero (by only about one standard deviation), the scale factor is compatible with being constant. As there are no indications that components of τ_h reconstruction or identification behave abnormally at high $p_T^{\tau_h}$, a constant scale factor with an asymmetric uncertainty that increases with $p_T^{\tau_h}$ is defined by adding in quadrature the uncertainty in the fit to a constant, and the difference between the fit to a first-order polynomial and to a constant for the downward deviation. In addition, this also takes into account the uncertainty in the efficiency of track reconstruction, yielding the total (asymmetric) uncertainty of $+5\% \times p_T^{\tau_h}$ (TeV) and $-35\% \times p_T^{\tau_h}$ (TeV). The fit to a constant using the combined uncertainty is shown in Fig. 10.

9.5 Using the tag-and-probe method in Z/γ^* events for highly boosted τ lepton pairs

The identification efficiency for highly boosted τ lepton pairs in τ_h final states is measured using the same tag-and-probe method as described in Section 9.1. The selection is optimized to have a pure sample of τ leptons from the decay of high- p_T Z bosons, where one τ lepton decays leptonically and the other one into hadrons and a neutrino. As the trigger thresholds for non-isolated leptons are very high, too few events are available to reliably measure the identification efficiency for very high p_T τ lepton pairs. Single isolated-lepton triggers with lower thresholds are used therefore to select $e\tau_h$ and $\mu\tau_h$ events. However, events in which a τ_h is within the isolation area around a triggering lepton ($\Delta R < 0.4$) are not accessible in this measurement.

The selection requires one isolated electron or muon fulfilling tight identification criteria, and satisfying $p_T > 40$ or > 26 GeV, respectively. Furthermore, as discussed in Section 6, at least one τ_h candidate must be reconstructed with $p_T > 20$ GeV and $|\eta| < 2.3$, in compliance with relaxed decay mode criteria. The ΔR between the selected lepton and τ_h candidate must be

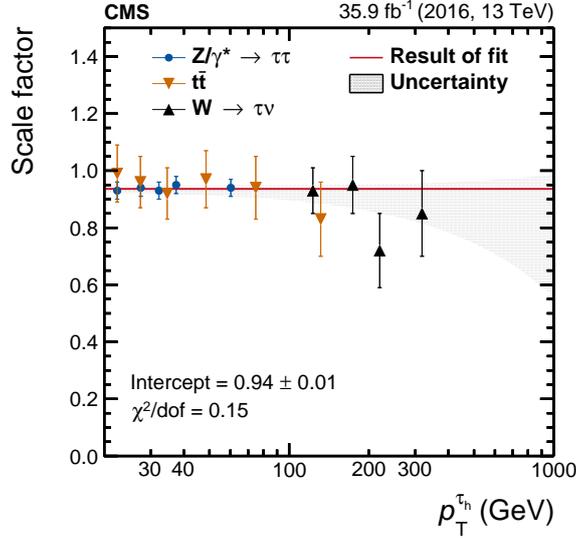

Figure 10: Fit of the measured scale factors to a constant value in the τ_h identification efficiency, for the tight WP of the MVA-based isolation discriminant in Z/γ^* , $t\bar{t}$, and W events, as a function of $p_T^{\tau_h}$. The shaded band represents the uncertainties in the fit, where the result is combined with the difference obtained using a first-order polynomial instead of a constant for the downward deviations, which also contain an additional contribution from the uncertainty in track-reconstruction efficiency.

between 0.4 and 0.8, and the m_T of the \vec{p}_T^ℓ and \vec{p}_T^{miss} system must be < 40 GeV. Moreover, p_T^{miss} must exceed 75 GeV, the scalar p_T sum of all measured particles has to be greater than 200 GeV, and there cannot be any identified b jets in the event. If more than one $e\tau_h$ or $\mu\tau_h$ pair is present, the one with the largest p_T is chosen for further analysis.

The contribution from DY events is modelled using MC simulation. It is split into the signal contribution by matching the reconstructed leptons to those generated and those contributing via misidentified Z boson decays. The distributions of the backgrounds from W +jets and $t\bar{t}$ production are also modelled using simulation, but their normalizations are obtained from dedicated control data samples. The control sample for W +jets production is defined by inverting the requirement on m_T . The control sample for $t\bar{t}$ production is established by demanding at least one b -tagged jet.

The background from QCD multijet production is estimated from a sample selected in the same way as the signal, except for the requirement on p_T^{miss} , which is inverted to $p_T^{\text{miss}} < 75$ GeV. Contributions from other processes are subtracted based on simulation. The extrapolation factor from the sample with an inverted p_T^{miss} requirement to the signal region is obtained from the ratio of events in two other control samples, where the ΔR between the lepton and the τ_h candidate is between 0.8 and 2.0, one which uses the nominal and the other an inverted p_T^{miss} requirement, respectively. Contributions from other processes are also subtracted from data using MC simulation in these two control regions.

The systematic uncertainties discussed in Section 8.9 are taken into account in the procedure, as are the additional uncertainties in the estimation of the QCD multijet background, which are dominated by the limited number of events in the control samples. Finally, the uncertainties in the normalization of background from $t\bar{t}$ and W +jets production are determined from their respective control samples, and amount to 3 and 13%, respectively.

The data-to-simulation scale factors are evaluated in the same way as outlined in Section 9.1.

The passing and failing events are defined by requiring the τ_h to pass or fail a given working point of the MVA-based isolation discriminant. The scale factors for the six MVA-based working points are shown in Table 6. The values are compatible with unity, as well as with the scale factors obtained through the measurements described in Sections 9.1–9.3. The dependence of the scale factor on the ΔR between τ_h and the lepton, is studied without revealing a significant effect. The fitted distributions corresponding to the medium isolation WP are shown in Fig. 11.

Table 6: Data-to-simulation scale factors for different working points of the MVA-based isolation discriminant, using highly boosted Z/γ^* events decaying to τ lepton pairs.

Working point	Scale factor
Very loose	0.97 ± 0.09
Loose	0.99 ± 0.09
Medium	0.98 ± 0.09
Tight	0.96 ± 0.08
Very tight	0.95 ± 0.09
Very-very tight	0.90 ± 0.08

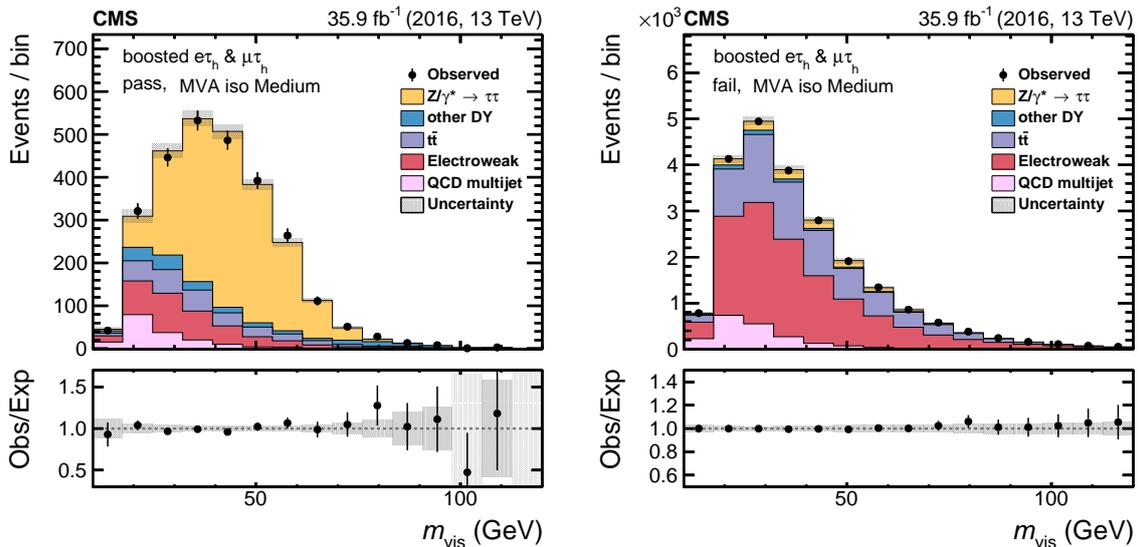

Figure 11: Fitted distributions to the passing (left) and failing (right) events for τ_h from highly boosted τ lepton pairs that pass the medium WP of the MVA-based isolation discriminant. The electroweak background includes contributions from W +jets (dominating), diboson, and single top quark events. Vertical bars correspond to the statistical uncertainties in the data points (68% frequentist confidence intervals), while the shaded bands provide the quadratic sum of the statistical and systematic uncertainties after the fit.

10 Measurement of the jet $\mapsto \tau_h$ misidentification probability

10.1 Using $W \rightarrow \mu\nu$ +jet events

The probability to misidentify a quark or gluon jet as a τ_h candidate is measured as a function of jet p_T and η in a sample of $W \rightarrow \mu\nu$ +jet events, selected as described in Section 8.6. In addition to p_T^{jet} and η^{jet} , the misidentification probability also depends on parton flavour, as well as whether the parton initiating the jet and the reconstructed τ_h have the same or opposite charge. These factors cause differences of up to a factor of four between misidentification probabilities for c quark and gluon jets, and up to a factor of two for whether the initiating parton has the

same or opposite charge as the τ_h candidate. This means that the misidentification probabilities given in this section are indicative, in that they are mainly valid for $W \rightarrow \mu\nu + \text{jet}$ events, which contain a large fraction of light-quark jets, and therefore have a relatively high misidentification probability.

The misidentification probability is given by the ratio of the number of jets that are identified as τ_h candidates with $p_T > 20 \text{ GeV}$, $|\eta| < 2.3$, and passing any one of the working points of the discriminants described in Section 5.2, to the total number of jets with $p_T > 20 \text{ GeV}$ and $|\eta| < 2.3$. It should be recognized that p_T^{jet} differs from $p_T^{\tau_h}$ because the four-momentum of the jet is computed by summing the momenta of all its constituents, while the τ_h four-momentum is computed only from the charged hadrons and photons used in the reconstruction of the specified decay mode of the τ_h candidate. For $p_T^{\text{jet}} < 300 \text{ GeV}$, the $p_T^{\tau_h}$ constitutes on average only 40% of the jet p_T . Furthermore, p_T^{jet} is subject to additional jet energy corrections, whereas $p_T^{\tau_h}$ is not.

In the measurement of the misidentification probability, backgrounds with genuine τ_h are subtracted, based on the expectations from simulated events. The fraction of events with genuine τ_h candidates in the sample passing the τ_h identification criteria is well below 10% for τ_h with $p_T < 100 \text{ GeV}$, but reaches up to 50% for $p_T \approx 300 \text{ GeV}$. Furthermore, backgrounds with prompt electrons and muons giving rise to τ_h candidates are also subtracted based on expectations from simulated events. To reject events from $Z/\gamma^* \rightarrow \mu\mu$ production, the loose WP of the against- μ discriminant described in Section 5.4 is applied to the reconstructed τ_h candidates.

The subtraction of backgrounds containing genuine τ_h is subject to an uncertainty of 30%, leading to an uncertainty of up to 15% in the jet $\mapsto \tau_h$ misidentification probability. Because of threshold effects, the jet energy scale also leads to a significant uncertainty, especially in the lowest bin of p_T^{jet} . Additional uncertainties are considered for probabilities with which electrons are reconstructed as τ_h candidates (with $\approx 100\%$ relative values), and with which muons are reconstructed as τ_h candidates that pass the loose WP of the against- μ discriminant (at 50%). These lead to uncertainties in the measured misidentification probabilities of at most a few percent.

The observed and simulated jet $\mapsto \tau_h$ misidentification probabilities for the loose, medium, and tight WPs of the MVA-based isolation discriminant are shown in Fig. 12, as a function of p_T^{jet} and η^{jet} . The probabilities are observed to be almost constant as a function of η^{jet} , while they decrease monotonically with increasing p_T^{jet} from $\approx 40 \text{ GeV}$, as the absolute isolation increases for quark- and gluon-initiated jets with increasing jet p_T . The values of the misidentification probability as a function of p_T^{jet} range between 2.0 and 0.1% for the loose WP of the MVA-based isolation discriminant, and between 1.0 and less than 0.1% for the tight WP. The observed probabilities show a difference of 10–20% relative to expectations from MC simulation. This difference is well within the range of the misidentification probabilities obtained under variations of the parton shower models and underlying-event tunes, and reflects precision of modelling untypical, narrow and low multiplicity, quark and gluon jets being able to pass τ_h identification criteria.

10.2 Using $e\mu$ +jets events

The probability to misidentify quark and gluon jets as τ_h candidates is also measured in the $e\mu$ final state of $t\bar{t}$ events using the same methodology and uncertainties outlined in Section 10.1. The events are selected as described in Section 8.7, with the largest contributions being from $t\bar{t}$ and single top quark events, where the misidentified τ_h candidates are dominated by b quark

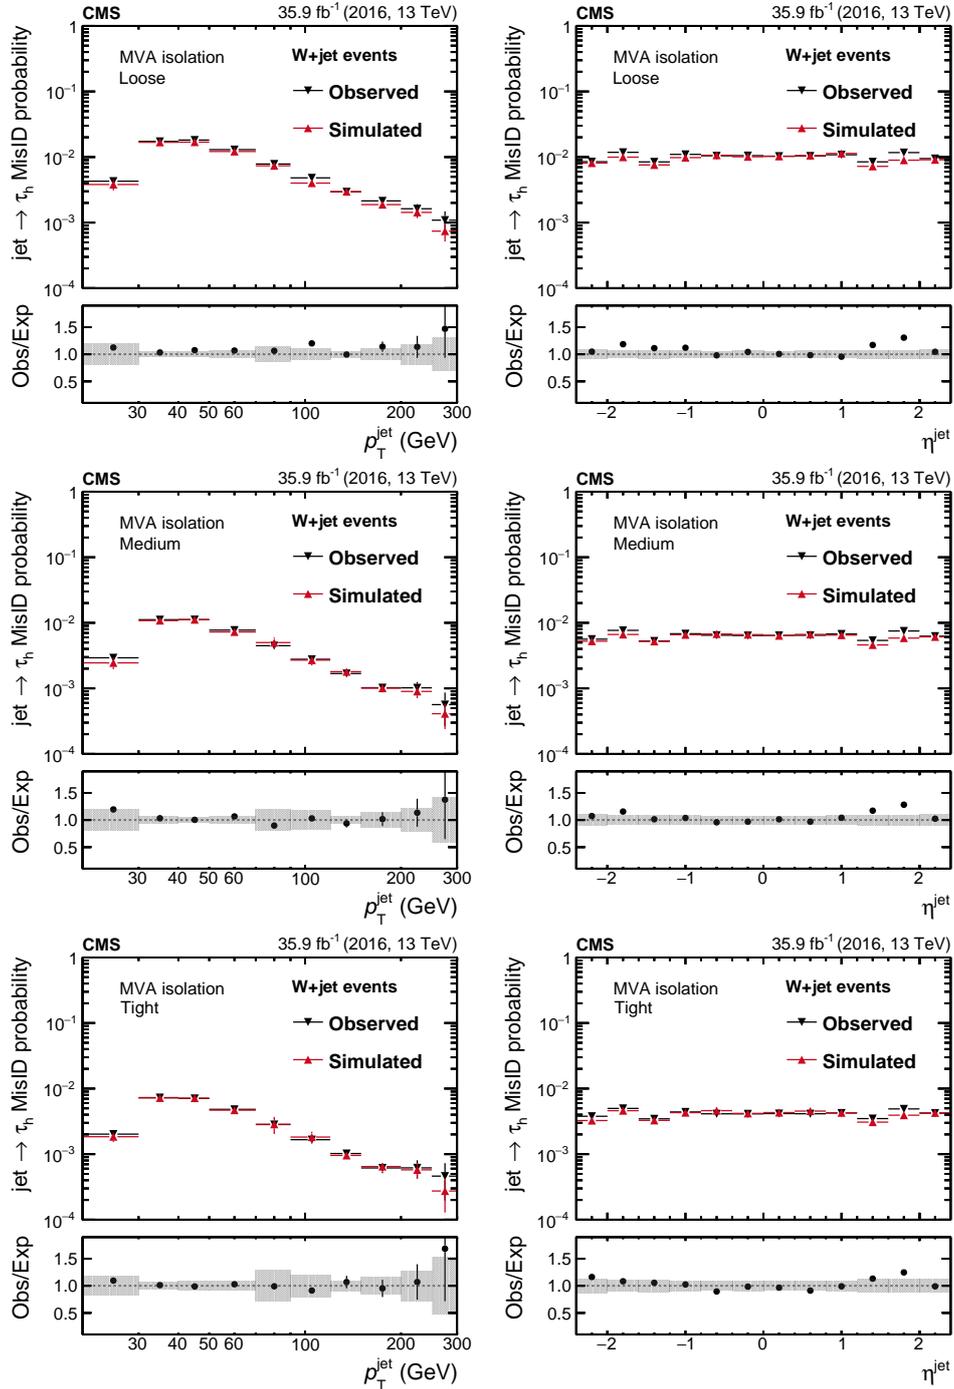

Figure 12: Probabilities for quark and gluon jets in W +jet events to pass the loose (uppermost), medium (middle), and tight (lowest) WPs of the MVA-based isolation discriminant as a function of p_T^{jet} (left) and η^{jet} (right). The misidentification probabilities in data are compared to expectations from simulation. The vertical bars in the simulated and observed misidentification probabilities include statistical uncertainties from the limited event count in both data and simulated samples, including the background subtraction. The shaded bands contain the systematic uncertainties related to background subtraction and the jet energy scale.

jets. The contribution from other processes is $<10\%$. The observed and simulated jet $\mapsto \tau_h$ misidentification probabilities for the loose, medium, and tight WPs of the MVA-based isolation discriminant are shown in Fig. 13, as a function of p_T^{jet} and η^{jet} . The observed probabilities show a 10–20% difference relative to expectations from simulation, except in a few η^{jet} bins where the differences are as large as 50%. The jet $\mapsto \tau_h$ misidentification probabilities in $e\mu$ +jets events are found to be smaller than those for W +jet events because of the larger fraction of b quark jets. The b quark jets are typically less collimated than the light-quark jets, providing thereby smaller probabilities to pass the τ_h isolation discriminant selection requirements.

11 The $e/\mu \mapsto \tau_h$ misidentification probability

11.1 Measurement of the $e \mapsto \tau_h$ probability

The $e \mapsto \tau_h$ misidentification probability is obtained from data using a tag-and-probe method in $Z/\gamma^* \rightarrow ee$ events selected as described in Section 8.8.

Depending on whether the probe passes or fails a given working point of the against- e discriminant, the event enters the passing or failing category, respectively. The $e \mapsto \tau_h$ misidentification rate is then measured in a simultaneous fit to the number of $Z/\gamma^* \rightarrow ee$ events in both categories. The m_{vis} distribution in the range $60 < m_{\text{vis}} < 120$ GeV is used in the passing category, obtained from the templates for $Z/\gamma^* \rightarrow ee$ signal and for the $Z/\gamma^* \rightarrow \tau\tau$, W +jets, $t\bar{t}$, single top quark, diboson (WW , WZ , ZZ), and QCD multijet backgrounds. In the failing category, the total number of events in the same range of m_{vis} is used to constrain the normalization of the $Z/\gamma^* \rightarrow ee$ process.

The differential templates for signal and all background distributions, except for QCD multijet, are taken from MC simulation. The normalization is performed according to the cross section for the specific sample of events, with the exception of the W +jets background, which is obtained from data, using an enriched sample of W +jets events with $m_T > 70$ GeV. The scale factor between the sideband and the signal region is extracted from simulation. The differential distribution and normalization of the QCD multijet background is obtained from data in a control sample where the tag and the probe are of SS . The contributions from all other backgrounds are estimated using simulation, and are subtracted from the SS control sample in this procedure.

Systematic uncertainties are represented through nuisance parameters in the fit, and account for the effects listed in Section 8.9, as well as for the energy scale of tag electrons, which is changed by its uncertainty of $\pm 1\%$ in the barrel region ($|\eta| < 1.46$) and $\pm 2.5\%$ in the endcap regions ($|\eta| > 1.56$), with the difference in the m_{vis} template considered as an uncertainty in the differential distribution. Similarly, the energy scale of probe electrons and τ_h are changed by ± 1.5 and $\pm 3\%$, respectively. The energy scale of leptons have been measured using the method described in Ref. [75]. Uncertainties in the normalization of W +jets and QCD multijet production are dominated by number of events in the relevant control regions, and each amount to 20%. Finally, an additional 3% uncertainty is associated with the $Z/\gamma^* \rightarrow ee$ normalization because of the need to disentangle possible differences between the $Z/\gamma^* \rightarrow ee$ and $Z/\gamma^* \rightarrow \tau\tau$ normalizations. Separate fits are used for probes in the barrel and in the endcap regions.

The fitted m_{vis} distributions in the passing category are shown in Fig. 14 for the medium and very tight WPs of the against- e discriminant in the barrel region of the ECAL, while the $e \mapsto \tau_h$ misidentification probabilities are displayed in Fig. 15. In the barrel region, the measured misidentification probabilities in data exceed those in the simulations. The difference between

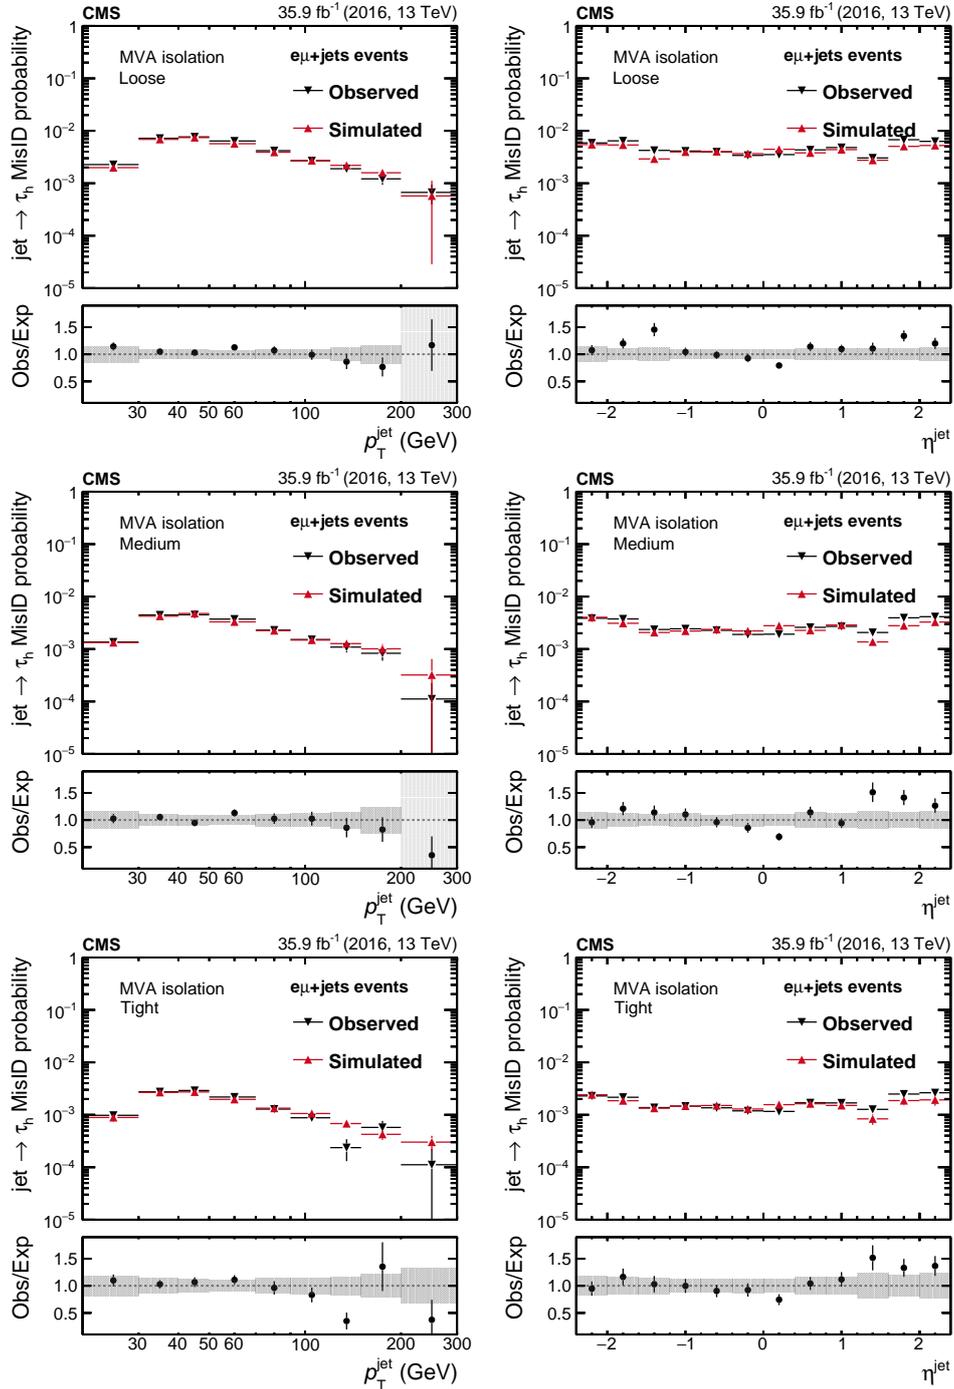

Figure 13: Probabilities for quark and gluon jets in $e\mu$ +jets events to pass the loose (uppermost), medium (middle), and tight (lowest) WPs of the MVA-based isolation discriminant as a function of p_T^{jet} (left) and η^{jet} (right). The misidentification probabilities in data are compared to expectations from simulation. The vertical bars in the simulated and observed misidentification probabilities include statistical uncertainties from the limited event count in both data and simulated samples, including the background subtraction. The shaded bands contain the systematic uncertainties related to background subtraction and the jet energy scale.

data and simulation increases for the tight and very tight WPs of the discriminant, and a similar trend is observed for the probes in the endcap regions. The observed misidentification probabilities range from $\approx 5\%$ for the very loose WP to less than 0.1% for the very tight WP in the barrel region, while in the endcap regions, the probabilities are larger, ranging between 0.1 and 10%.

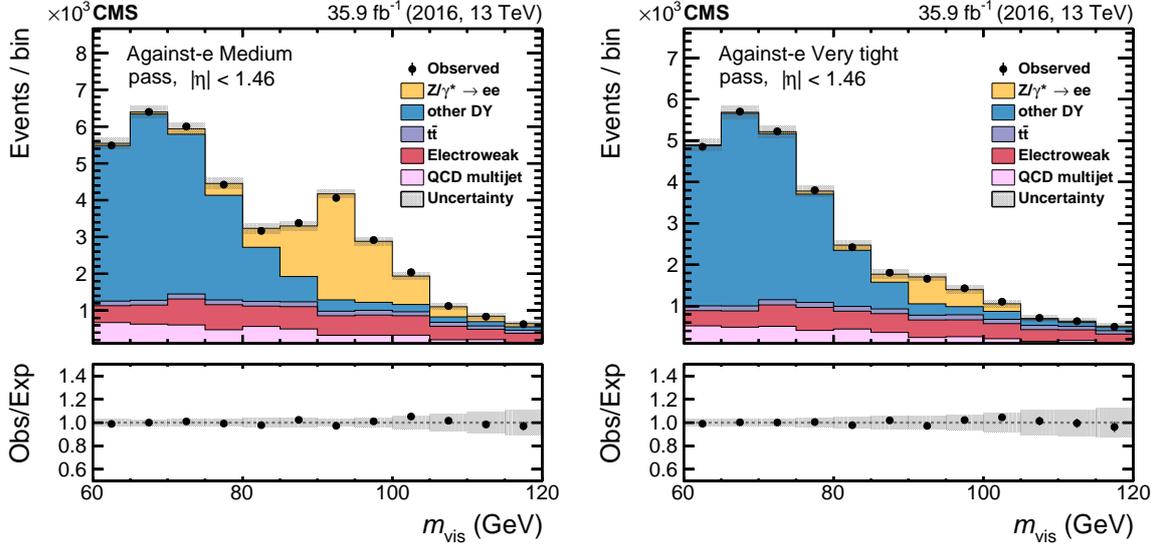

Figure 14: Fitted distributions in m_{vis} in the passing category for the medium (left) and very tight (right) WPs of the against-e discriminant in the barrel region. The electroweak background includes contributions from W +jets (dominating), diboson, and single top quark events. Vertical bars correspond to the small (not visible) statistical uncertainties in the data points (68% frequentist confidence intervals), while the shaded bands provide the quadratic sum of the statistical and systematic uncertainties after the fit.

11.2 Measurement of the $\mu \mapsto \tau_h$ probability

The $\mu \mapsto \tau_h$ misidentification probability is also measured using a tag-and-probe method, following an approach similar to that used to measure the $e \mapsto \tau_h$ misidentification probability discussed in Section 11.1. For this, we select $Z/\gamma^* \rightarrow \mu\mu$ events, as described in Section 8.8, and again divide these into two categories, depending on whether the probe passes or fails the specific working point of the against- μ discriminant. The number of $Z/\gamma^* \rightarrow \mu\mu$ signal events in each category is then extracted from a simultaneous maximum likelihood fit to the mass of the tag-and-probe pair, in the range $70 < m_{\text{vis}} < 120$ GeV. Separate fits are performed for probes in five $|\eta|$ regions of <0.4 , $0.4\text{--}0.8$, $0.8\text{--}1.2$, $1.2\text{--}1.7$, and >1.7 , corresponding to the geometry of the CMS muon spectrometer.

The normalization and distribution in m_{vis} for signal and background processes are estimated as discussed in Section 11.1. Systematic uncertainties are also similar, except that those related to electrons are replaced by those appropriate for the muons, such as the energy scale for the probe, which is changed by ± 1.5 and $\pm 3\%$ for the misidentified $\mu \mapsto \tau_h$ and the genuine τ_h candidates, respectively, with the resulting difference in the m_{vis} template taken as an uncertainty in the differential distribution. The uncertainty in the energy scale of the tag muon is negligible compared with the energy scale of the τ_h candidates, and is therefore neglected.

Figure 16 shows the mass distribution in the $\mu\tau_h$ pair after the maximum likelihood fit, for events where the probe muon is reconstructed as a τ_h candidate, and passes the loose or tight WPs of the against- μ discriminant. The probes in these distributions lie within $|\eta| < 0.4$.

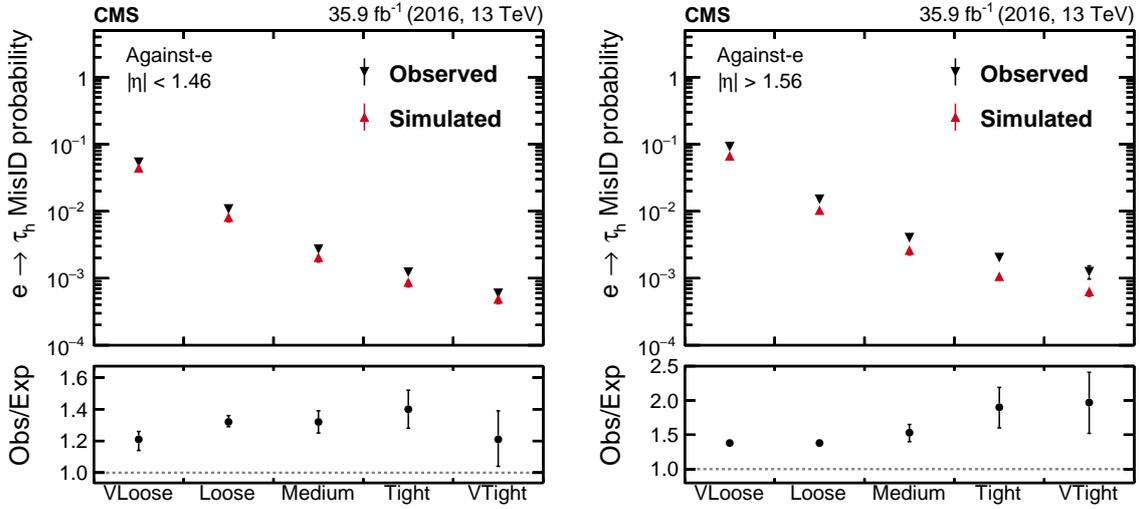

Figure 15: Probability for electrons to pass different working points of the against-e discriminator, split into the barrel (left) and endcap (right) regions. For each working point, the $e \mapsto \tau_h$ misidentification probability is defined as the fraction of probes passing that working point relative to the total number of probes. Vertical bars correspond to the statistical and the quadratic sum of the statistical and systematic uncertainties, respectively, for simulated and observed data.

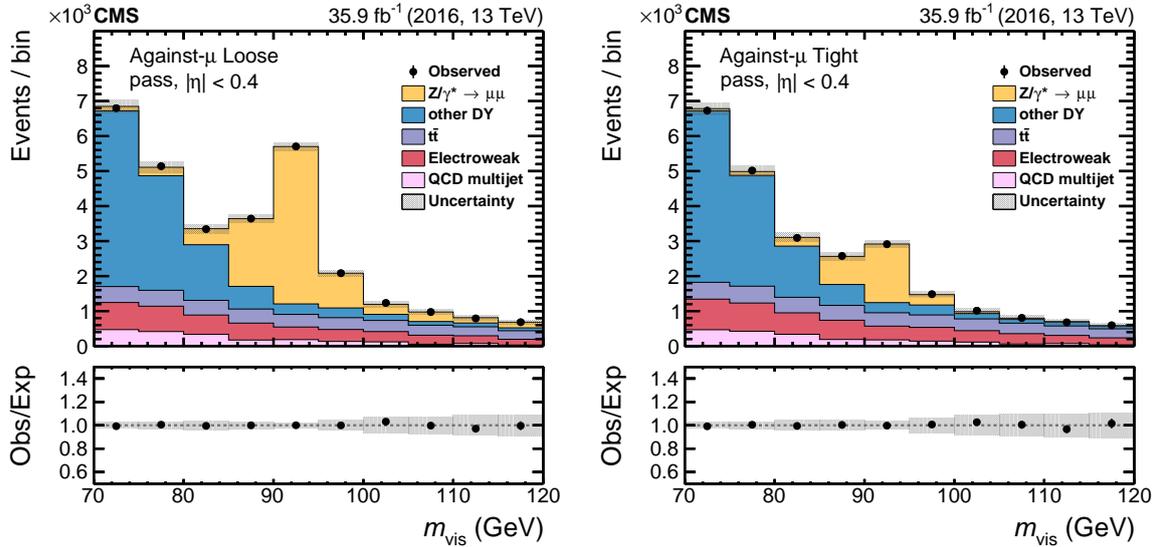

Figure 16: Fitted distribution in m_{vis} in the passing category for the loose (left) and tight (right) WPs of the against- μ discriminator in the region of $|\eta| < 0.4$. The electroweak background includes contributions from W +jets (dominating), diboson, and single top quark events. Vertical bars correspond to the small (not visible) statistical uncertainties in the data points (68% frequentist confidence intervals), while the shaded bands provide the quadratic sum of the statistical and systematic uncertainties after the fit.

The $\mu \mapsto \tau_h$ misidentification rates are given for the loose and tight WPs of the against- μ discriminant in Fig. 17. For probes passing the WPs, the measured misidentification rates in data exceed the predictions, with the difference between data and simulation possibly increasing from small to large $|\eta|$. The observed trend is more significant for probes passing the tight WP. The observed misidentification probabilities for the loose WP are in the range of 0.1–0.5%, with the highest probability lying in the $|\eta|$ range between 0.8 and 1.2 which corresponds to transition between barrel and endcap regions of the muon spectrometer. The probabilities for the tight WP range between 0.03 and 0.40%, with the highest value again falling in the same $|\eta|$ region.

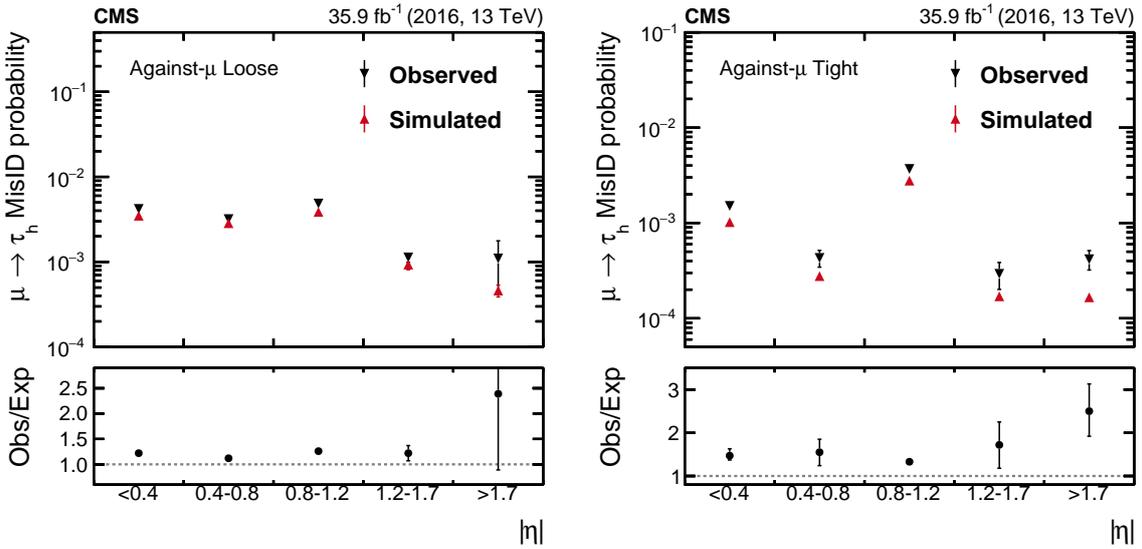

Figure 17: Probability for muons to pass the loose (left) and tight (right) WPs of the against- μ discriminant, as a function of the $|\eta|$ of the probe. For each working point, the $\mu \mapsto \tau_h$ misidentification probability is defined as the fraction of probes passing that working point relative to the total number of probes. Vertical bars correspond to the statistical and the quadratic sum of the statistical and systematic uncertainties, respectively, for simulated and observed data.

12 Measurement of the τ_h energy scale

The correction to the τ_h energy scale is defined by the deviation of the average reconstructed τ_h energy from the generator-level energy of the visible τ_h decay products. The corresponding data-to-simulation correction is obtained from a fit of the distributions of observables sensitive to the energy scale, using samples of $e\tau_h$ and $\mu\tau_h$ final states in Z/γ^* events. The distributions sensitive to the energy scale are m_{τ_h} and the mass of the $\ell\tau_h$ system, m_{vis} . These are fitted, separately for the h^\pm , $h^\pm\pi^0$, and $h^\pm h^\mp h^\pm$ decays to extract the correction factors between data and simulation.

The $e\tau_h$ and $\mu\tau_h$ final states are selected as described in Section 8.1, except that the τ_h candidates are required to pass the very tight WP of the MVA-based τ_h isolation discriminant to further reduce backgrounds from jets misidentified as τ_h candidates. Moreover, the requirement on m_T is tightened to be less than 30 GeV, and the requirement on D_ζ is removed. Finally, the τ_h candidate must satisfy the tight and loose, or very loose and tight WPs of the against- e and against- μ discriminants in the respective $e\tau_h$ or $\mu\tau_h$ final states. Templates for events in which the reconstructed τ_h is matched to some generated τ_h are obtained by changing the reconstructed τ_h energy between -6% and $+6\%$ in steps of 0.1% , with the m_{vis} and m_{τ_h} recomputed at each step.

The maximal energy shifts of $\pm 6\%$ are selected to be sufficiently away from the nominal value in the simulation such that the true value can be obtained between them. While m_{τ_h} displays higher sensitivity to the energy scale for the $h^\pm \pi^0$ and $h^\pm h^\mp h^\pm$ decay modes, it cannot be used in the h^\pm decay mode, where only m_{vis} is used. The backgrounds are modelled in the same way as described in Section 9.1, and the templates for processes in which there is no match between the reconstructed and generated τ_h candidates are not changed as a function of the τ_h energy scale.

For illustration, the m_{τ_h} templates corresponding to no shifts, and to shifts in τ_h energy scale of -6 and $+6\%$ are shown in Fig. 18 for events selected in $h^\pm \pi^0$ decay mode. The data are compared to predictions for these three energy scales.

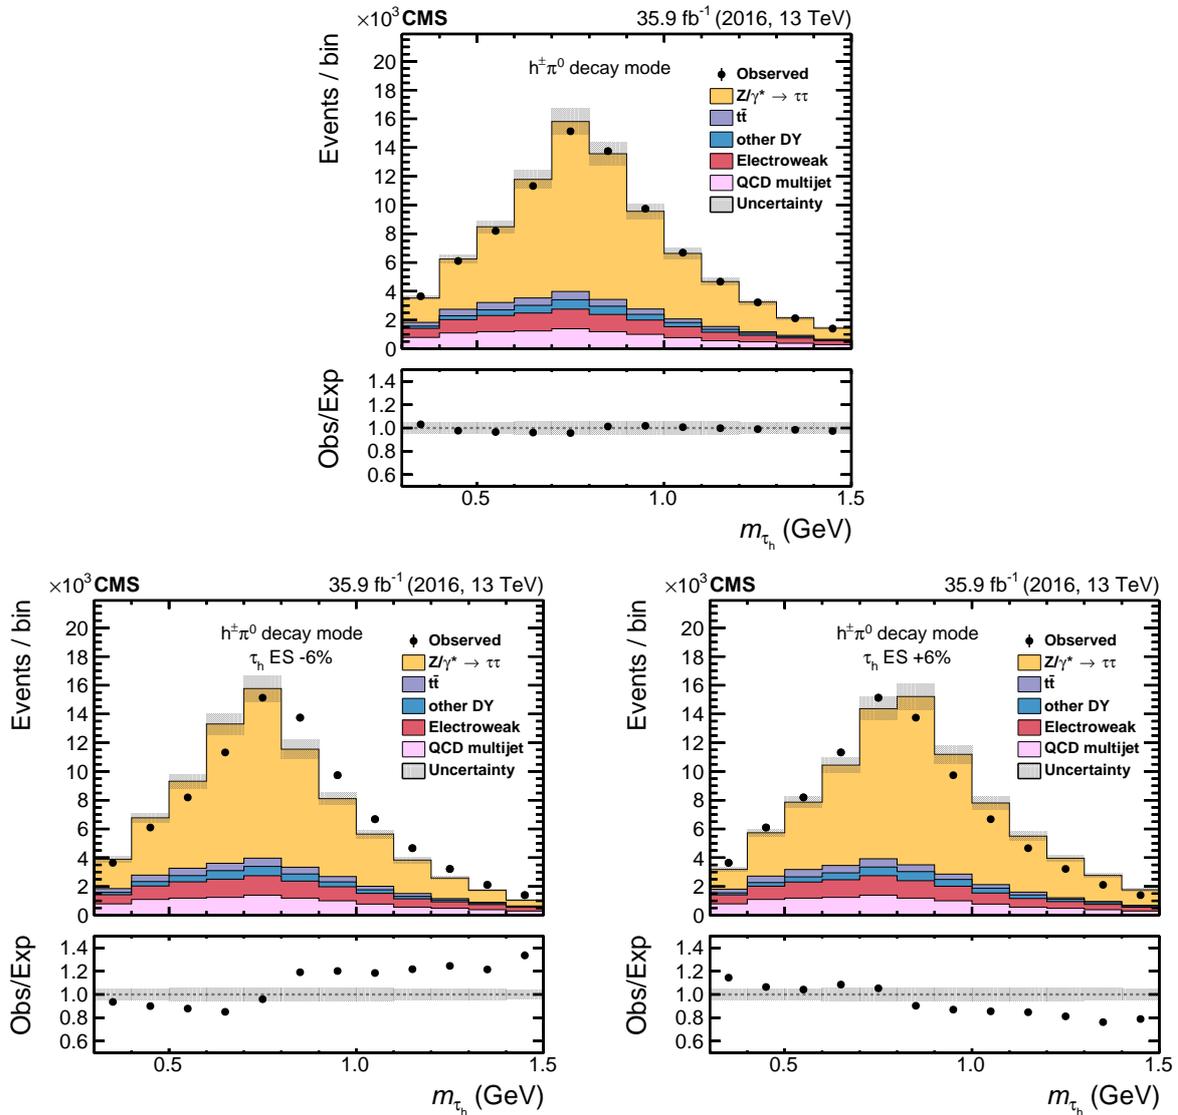

Figure 18: The distributions in m_{τ_h} for $\mu\tau_h$ events in the $h^\pm \pi^0$ decay channel. The data are compared to predictions with different shifts applied to the τ_h energy scale: 0% (upper), -6% (lower left), and $+6\%$ (lower right). The electroweak background includes contributions from W +jets (dominating), diboson, and single top quark events. Vertical bars (smaller than the symbol size) correspond to the statistical uncertainty in the data points (68% frequentist confidence intervals), while the shaded bands provide the expected systematic uncertainties.

A likelihood ratio method is used to extract the τ_h energy scale for each decay mode. In addition to those listed in Section 8.9, the following sources of systematic uncertainties are considered: uncertainties in the identification of τ_h candidates, determined in Section 9, are split into those that are uncorrelated ($\approx 2\%$) and correlated ($\approx 4.5\%$) between the $e\tau_h$ and $\mu\tau_h$ final states. The rates for electrons, muons, and jets misidentified as τ_h candidates have uncertainties of 12, 25, and 20%, respectively. Moreover, uncertainties in the energy scale of electrons (1% in the barrel and 2.5% in the endcaps) and muons (5%) identified as τ_h are taken into account in their differential distributions. The results obtained from fits to m_{vis} and m_{τ_h} distributions for each decay mode in the $e\tau_h$ and $\mu\tau_h$ final states are found to be compatible with each other, and their combination is given in Table 7. The measurement is limited by systematic rather than statistical uncertainties.

Table 7: The data-to-simulation correction for the τ_h energy scale from the combination of measurements performed in the $e\tau_h$ and $\mu\tau_h$ final states separately using m_{τ_h} and m_{vis} distributions. The correction is relative to the reconstructed energy from simulation, expressed in %.

Decay mode	m_{τ_h}	m_{vis}
h^\pm	—	-0.5 ± 0.5
$h^\pm\pi^0$	0.9 ± 0.3	1.1 ± 0.3
$h^\pm h^\mp h^\pm$	0.6 ± 0.2	0.6 ± 0.3

Additional studies performed using the $\mu\tau_h$ final state are carried out to assess the stability of the measurement. To gauge the impact of fluctuations caused by the limited number of MC events relative to the data, the simulated events used to model Z/γ^* decays are split into four samples of equal size, and the measurement is performed using each of these four subsamples. The resulting fluctuations in the measured τ_h energy scale are up to 1%. Similarly, the effect of the contamination from backgrounds that arise from misidentification of the τ_h is checked by changing the selection criteria, and found to be 0.5%. The choice of the binning is investigated by changing the number of bins up and down by a factor 2. The results are compatible to within 1%. Finally, the effect of the range of the fit is evaluated for the m_{vis} template by increasing it by 10 GeV in either direction, resulting in changes compatible within 0.5% of the original measurement. Although these checks do not guarantee that similar levels of fluctuation exist in the original measurement (especially, the assessment of the limited number of MC events), an additional uncertainty of 1.0% is added in quadrature to the uncertainty detailed in Table 7, to reflect our limited knowledge of the true fluctuations. This results in a total uncertainty of $<1.2\%$.

13 Performance of τ_h identification in the high-level trigger

The τ_h reconstruction and identification algorithm described in Section 7 for the HLT was used to define a set of triggers for 2016 data taking. These triggers cover all final states of interest, namely, τ lepton pair production in $\tau_e\tau_h$, $\tau_\mu\tau_h$, and $\tau_h\tau_h$ decays, τ_h associated with p_T^{miss} ($\tau_h p_T^{\text{miss}}$), and single τ_h with large p_T .

There are two types of HLT decision trees that use τ_h candidates and which are aimed at two different classes of final states, those that comprise other than τ_h candidates in the event, e.g., $e\tau_h$, $\mu\tau_h$, $\tau_h p_T^{\text{miss}}$, and those that include only τ_h candidates, e.g., $\tau_h\tau_h$. The first type of trigger is based on L1 seeds that require the presence of an electron, a muon, or large p_T^{miss} , possibly together with a τ_h candidate. These triggers also have their corresponding selections in e , μ , or p_T^{miss} in the HLT, thereby greatly reducing the event rates processed at later stages. This allows reconstruction of τ_h candidates directly through the resource-intensive L3 step, wherein the

PF sequence underpinning τ_h reconstruction is run using the full-detector acceptance. In the second type of trigger, only τ_h candidates are required to be identified at L1, without additional lepton or p_T^{miss} selections. At HLT, since the L3 step would be too time consuming to run at the L1 output rates, the L2 and L2.5 filtering steps are executed first. The efficiency of the L2 and L2.5 filter is $>95\%$ per τ_h candidate. In addition, this class of triggers has HLT τ_h reconstruction used only in regions of the detector centered on the direction of the L1 τ_h candidates, further reducing thereby the processing time.

The triggers for τ pair production are aimed mainly to select efficiently the SM $H \rightarrow \tau\tau$ decays that require respective p_T thresholds of 20–25 and 30–35 GeV for τ_e or τ_μ and τ_h final states. In addition, trigger rates at an instantaneous luminosity of $\mathcal{L} = 1.4 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ and PU close to 40 interactions per bunch crossing, typical for pp collisions in late 2016, were required not to exceed rates of about 10–15 and 50–65 Hz for the $e\tau_h$ or $\mu\tau_h$ and $\tau_h\tau_h$ triggers, respectively.

The $\mu\tau_h$ trigger is constructed as follows. First, we require the presence of a muon candidate with $p_T > 18 \text{ GeV}$ at L1. Then, an isolated muon, seeded by the L1 candidate, with $p_T > 19 \text{ GeV}$ is selected at the HLT. Subsequently, an unseeded L3 τ_h candidate is selected with $p_T > 20 \text{ GeV}$ that passes the loose charged-particle isolation WP. The isolation is relaxed linearly by 10%/GeV for $p_T^{\tau_h} > 50 \text{ GeV}$. Finally, the L3 τ_h candidate must be separated from the muon by $\Delta R > 0.3$. At $\mathcal{L} = 1.4 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$, the rate for the $\mu\tau_h$ trigger corresponds to $\approx 20 \text{ Hz}$.

To adapt to different conditions in instantaneous luminosity delivered by the LHC in 2016, ranging from $\approx 3 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ to $1.4 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$, and to provide highest efficiency possible within the limited rate budget, two variants of $e\tau_h$ triggers were developed. The first one is similar to the $\mu\tau_h$ trigger in that an isolated electromagnetic (e or γ) object with $p_T > 22 \text{ GeV}$ is required at L1, and is used to initiate the reconstruction of an isolated electron at the HLT that is required to have $p_T > 24 \text{ GeV}$. A seedless L3 τ_h candidate, not overlapping with the electron, is required to have $p_T > 20 \text{ GeV}$, and to pass the loose charged-particle isolation WP (linearly relaxed by 10%/GeV for $p_T^{\tau_h} > 50 \text{ GeV}$). This trigger covered instantaneous luminosities of up to $9 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$.

The second, a more stringent version of the $e\tau_h$ trigger, adds the requirement of an L1 τ_h candidate to accompany the L1 electromagnetic object. First, the p_T threshold on the L1 τ_h was set to 20 GeV, and, as the instantaneous luminosity increased, was raised to 26 GeV, and eventually the L1 isolation condition was also applied. In the latter configuration at the HLT, the p_T threshold for the L3 τ_h candidate was adjusted to 30 GeV. In the utilized ranges of instantaneous luminosity for which the $e\tau_h$ triggers were designed, the trigger rates remained below 15 Hz.

The $\tau_h\tau_h$ triggers require a pair of isolated L1 τ_h candidates, with p_T above a threshold in the range of 28–36 GeV. The threshold is dynamically adjusted to maintain a constant rate of events passing L1, independent of the instantaneous luminosity. Even after satisfying the L1 requirements, the event rate is still too high to run the L3 τ_h reconstruction. The L3 reconstruction is therefore used only if at least two τ_h candidates pass the L2 and L2.5 stages, as discussed in Section 7. At L3, the candidates have to have $p_T > 35 \text{ GeV}$, and pass the medium WP of the charged isolation (the charged isolation was replaced by the combined isolation at $\mathcal{L} > 1.3 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$). The isolation is linearly relaxed by 6%/GeV for $p_T^{\tau_h} > 73 \text{ GeV}$. Two such candidates must be present in the event, and must be separated by $\Delta R > 0.5$. At $\mathcal{L} = 1.4 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$, the rate of $\tau_h\tau_h$ triggers was below 60 Hz.

The benchmark process that guided the design of the $\tau_h p_T^{\text{miss}}$ trigger is the decay of a charged resonance $X^\pm \rightarrow \tau\nu$, e.g., for $X^\pm = H^\pm$ or W' , with a mass $m_X > 200 \text{ GeV}$. At L1, this trig-

ger requires p_T^{miss} in excess of 80–100 GeV, again with the threshold dynamically adjusted as a function of instantaneous luminosity to keep the rate of events passing L1 constant. At the HLT, the selected events must further satisfy the condition of $p_T^{\text{miss}} > 90$ GeV. After this, the L3 τ_h reconstruction step is executed, and events are finally saved when an L3 τ_h candidate with $p_T > 50$ GeV, passing the loose WP of charged isolation (relaxed by 6%/GeV for $p_T^{\tau_h} > 100$ GeV) is found, with its leading charged hadron satisfying $p_T > 30$ GeV. At $\mathcal{L} = 1.4 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$, the rate for the $\tau_h p_T^{\text{miss}}$ trigger is about 20 Hz.

Finally, a high- p_T single- τ_h trigger was developed for searches for high-mass resonances decaying into at least one τ lepton, for example W^l , H^\pm , or the heavy A or H boson in MSSM. This trigger was designed to cover portions of the phase space not covered by the more usual cross-triggers ($\tau_h \tau_h$, $\tau_h p_T^{\text{miss}}$, $e\tau_h$, and $\mu\tau_h$), e.g., H^\pm events with an energetic τ_h but small p_T^{miss} . The trigger that fulfilled those conditions required an isolated L1 τ_h candidate with $p_T > 120$ GeV. The τ_h reconstruction at the HLT consists of steps taken in L2, L2.5, and L3. The L3 requires one τ_h candidate with $p_T > 140$ GeV, and with a leading charged hadron with $p_T > 50$ GeV. The L3 τ_h candidate has to pass also the tight WP of charged isolation, which is linearly relaxed by 2%/GeV for $p_T^{\tau_h} > 275$ GeV, and is discarded for $p_T^{\tau_h} > 500$ GeV. Rates of about 30 Hz were allocated to this trigger.

The basic features of triggers with τ_h candidates used to record pp collisions in 2016 are summarized in Table 8. The efficiencies of the τ_h part of the triggers listed in Table 8 are measured via the tag-and-probe technique as a function of the offline-reconstructed $p_T^{\tau_h}$, using data enriched in τ_h leptons from $Z/\gamma^* \rightarrow \tau\tau \rightarrow \mu\tau_h$ decays. To single out this sample, the selections for the $\mu\tau_h$ final state described in Section 8.1, together with the requirement of $m_T < 30$ GeV and the additional condition of $40 < m_{\text{vis}} < 80$ GeV, are applied to data previously collected through single-muon triggers. Furthermore, to provide an efficiency measurement that is specific to the selections used in $H \rightarrow \tau\tau$ analyses, the τ_h candidates must pass the tight WP of the MVA-based isolation discriminant. The residual contamination from other objects misidentified as τ_h is subtracted statistically using SS events passing the same selections. The purity of the final sample exceeds 95%.

Table 8: Triggers with τ_h candidates used to record pp collisions in 2016: the final state (Channel), HLT p_T thresholds and τ_h isolation working point, L1 p_T thresholds, peak instantaneous luminosity ($\mathcal{L}_{\text{peak}}$) in the period of operation as main trigger, and integrated luminosity ($\int \mathcal{L}$) collected with the trigger. The $\tau_h \tau_h$ and $\tau_h p_T^{\text{miss}}$ triggers are seeded by sets of L1 triggers with thresholds dynamically adjusted as a function of the instantaneous luminosity to maintain a constant L1 rate, given by the ranges in p_T . The trigger p_T thresholds and isolation criteria were successively tightened over the data-taking period to keep the rate of events passing HLT approximately constant with increasing instantaneous luminosity.

Channel	HLT object and WP	L1 object	$\mathcal{L}_{\text{peak}} (\text{cm}^{-2} \text{ s}^{-1})$	$\int \mathcal{L} (\text{fb}^{-1})$
$\mu\tau_h$	$p_T^\mu > 19$ GeV, $p_T^{\tau_h} > 20$ GeV, loose iso	$p_T^\mu > 18$ GeV	1.5×10^{34}	35.9
	$p_T^e > 24$ GeV, $p_T^{\tau_h} > 20$ GeV, loose iso	$p_T^{e/\gamma} > 22$ GeV	0.9×10^{34}	7.5
$e\tau_h$	$p_T^e > 24$ GeV, $p_T^{\tau_h} > 20$ GeV, loose iso	$p_T^{e/\gamma} > 22$ GeV, $p_T^{\tau_h} > 20$ GeV	1.3×10^{34}	10.2
	$p_T^e > 24$ GeV, $p_T^{\tau_h} > 30$ GeV, loose iso	$p_T^{e/\gamma} > 22$ GeV, iso $p_T^{\tau_h} > 26$ GeV	1.5×10^{34}	18.2
$\tau_h \tau_h$	$2 \times p_T^{\tau_h} > 35$ GeV, medium iso	$2 \times \text{iso } p_T^{\tau_h} > 28\text{--}36$ GeV	1.3×10^{34}	27.3
	$2 \times p_T^{\tau_h} > 35$ GeV, medium comb. iso	$2 \times \text{iso } p_T^{\tau_h} > 28\text{--}36$ GeV	1.5×10^{34}	8.6
$\tau_h p_T^{\text{miss}}$	$p_T^{\text{miss}} > 90$ GeV, $p_T^{\tau_h} > 50$ GeV, $p_T^{h^\pm} > 30$ GeV, loose iso	$p_T^{\text{miss}} > 80\text{--}100$ GeV	1.5×10^{34}	35.9
τ_h	$p_T^{\tau_h} > 140$ GeV, $p_T^{h^\pm} > 50$ GeV, tight iso	$p_T^{\tau_h} > 120$ GeV	1.5×10^{34}	33.1

To provide an unbiased measurement of the efficiency of the single- τ_h part of the $\tau_h \tau_h$ and

$\tau_h p_T^{\text{miss}}$ triggers, special $\mu\tau_h$ triggers were put in place. The special triggers have one part that is required to match the nominal single-muon trigger used to select events; the other part is required to pass the τ_h trigger identification for the trigger of interest.

The passing τ_h probes correspond to those that pass the τ_h part of the special trigger, i.e., the trigger is satisfied and its τ_h part geometrically matches ($\Delta R < 0.5$) the selected offline τ_h . The efficiency of the τ_h part of the $\mu\tau_h$ and $\tau_h\tau_h$ triggers, measured using collision data relative to the DY simulation, is shown in Fig. 19. For the $\tau_h\tau_h$ trigger, we use only the portion of the 2016 data that contains the trigger employing the combined isolation. In both cases, simulation agrees well with the data. Data-to-simulation agreement is similar for the other triggers discussed in this section.

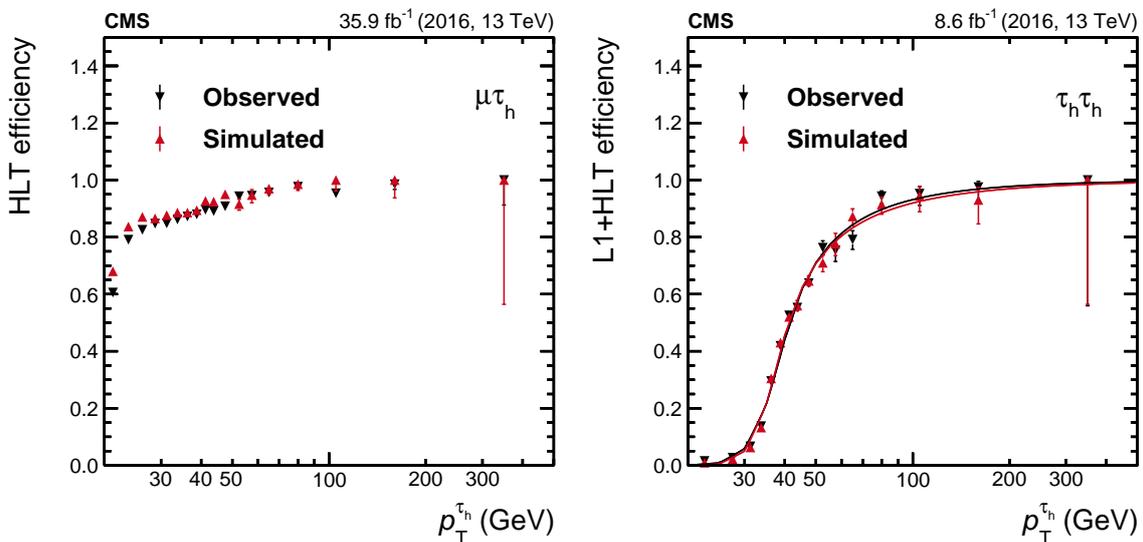

Figure 19: Single- τ_h efficiency of the $\mu\tau_h$ (left) and $\tau_h\tau_h$ (right) triggers. The efficiency is computed per single τ_h , using the tag-and-probe method as a function of the offline-reconstructed $p_T^{\tau_h}$. Observed data are compared to simulated $Z/\gamma^* \rightarrow \tau\tau$ events selected through the same procedure. Vertical bars correspond to the statistical uncertainties. The plot on the right has data points fitted using a cumulative (integral) distribution of the Crystal Ball function [76].

Figure 19 shows that the nominal p_T threshold of the τ_h triggers corresponds to an efficiency of 50%, as expected for trigger and offline objects with the same energy scale. The slow turn-on originates from two effects: in the p_T range above about twice the trigger threshold, it is caused by the relaxed isolation selection applied at HLT, but not in the offline selection; in the range just above the trigger threshold, it is caused by an asymmetric energy response of the HLT τ_h candidate relative to its offline counterpart. The asymmetry is due to a more inclusive selection of constituents of the τ_h candidate at the HLT than offline. The second effect is clearly visible in the $\mu\tau_h$ trigger with unseeded L3 τ_h reconstruction, while for the $\tau_h\tau_h$ trigger it is smeared out by the resolution of the L1- and L2- τ_h candidates (relative to offline), which is much worse than the resolution of the L3 candidates.

14 Summary

The “hadron-plus-strips” algorithm developed at the CMS experiment to reconstruct and identify $\tau \rightarrow \text{hadrons} + \nu_\tau$ decays in proton-proton collisions at $\sqrt{s} = 7$ and 8 TeV, as presented in Ref. [24], has been improved. The changes include a dynamic strip reconstruction, the recon-

struction of highly boosted τ lepton pairs, and the introduction of additional variables in the multivariate-analysis discriminants used to reject jets and electrons. The isolation discriminants have also been optimized to cope with the large pileup of events in $\sqrt{s} = 13$ TeV proton-proton runs.

The performance of the improved algorithm has been measured using 35.9 fb^{-1} of data recorded during 2016 at $\sqrt{s} = 13$ TeV. The τ_h identification efficiency in data at low, intermediate, and high transverse momenta, as well as for highly Lorentz-boosted τ lepton pairs, is similar to that expected from Monte Carlo simulation, while differences of 10–20% are found between data and simulation for the jet $\mapsto \tau_h$ misidentification probability. The $e \mapsto \tau_h$ and $\mu \mapsto \tau_h$ misidentification probabilities are smaller than those of the previous version of the algorithm under the same running conditions, while maintaining a high efficiency for the selection of genuine τ_h candidates. The corresponding data-to-simulation scale factors have also been determined. The energy scale of τ_h candidates is measured, and its response relative to Monte Carlo simulation is found to be close to unity. Finally, a specialized τ_h reconstruction and identification algorithm has been used in the high-level trigger, and its performance has been presented.

Acknowledgments

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centres and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Education, Science and Research and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, FAPERGS, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport, and the Croatian Science Foundation; the Research Promotion Foundation, Cyprus; the Secretariat for Higher Education, Science, Technology and Innovation, Ecuador; the Ministry of Education and Research, Estonian Research Council via IUT23-4 and IUT23-6 and European Regional Development Fund, Estonia; the Academy of Finland, Finnish Ministry of Education and Culture, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules / CNRS, and Commissariat à l'Énergie Atomique et aux Énergies Alternatives / CEA, France; the Bundesministerium für Bildung und Forschung, Deutsche Forschungsgemeinschaft, and Helmholtz-Gemeinschaft Deutscher Forschungszentren, Germany; the General Secretariat for Research and Technology, Greece; the National Research, Development and Innovation Fund, Hungary; the Department of Atomic Energy and the Department of Science and Technology, India; the Institute for Studies in Theoretical Physics and Mathematics, Iran; the Science Foundation, Ireland; the Istituto Nazionale di Fisica Nucleare, Italy; the Ministry of Science, ICT and Future Planning, and National Research Foundation (NRF), Republic of Korea; the Ministry of Education and Science of the Republic of Latvia; the Lithuanian Academy of Sciences; the Ministry of Education, and University of Malaya (Malaysia); the Ministry of Science of Montenegro; the Mexican Funding Agencies (BUAP, CINVESTAV, CONACYT, LNS, SEP, and UASLP-FAI); the Ministry of Business, Innovation and Employment, New Zealand; the Pakistan Atomic Energy Commission; the Ministry of Science and Higher Education and the National Science Centre, Poland; the Fundação para a Ciência e a Tecnologia, Portugal; JINR, Dubna; the Ministry of Education and Science of the Russian Federation, the Federal Agency of Atomic Energy of the Russian Federation, Russian Academy of Sciences, the Russian Foundation for Basic Research, and the National Research Center "Kurchatov Institute"; the Ministry of Education, Science and Technological Development of Serbia; the Secretaría de Estado de Investigación, Desarrollo e Innovación, Programa Consolider-Ingenio 2010, Plan Estatal de Investigación Científica y Técnica y de Innovación 2013-2016, Plan de Ciencia, Tecnología e Innovación 2013-2017 del Principado de Asturias, and Fondo Europeo de Desarrollo Regional, Spain; the Ministry of Science, Technology and Research, Sri Lanka; the Swiss Funding Agencies (ETH Board, ETH Zurich, PSI, SNF, UniZH, Canton Zurich, and SER); the Ministry of Science and Technology, Taipei; the Thailand Center of Excellence in Physics, the Institute for the Promotion of Teaching Science and Technology of Thailand, Special Task Force for Activating Research and the National Science and Technology Development Agency of Thailand; the Scientific and Technical Research Council of Turkey, and Turkish Atomic Energy Authority; the National Academy of Sciences of Ukraine, and State Fund for Fundamental Researches, Ukraine; the Science and Technology Facilities Council, UK; the US Department of Energy, and the US National Science Foundation.

†: Deceased

1: Also at Vienna University of Technology, Vienna, Austria

2: Also at IRFU, CEA, Université Paris-Saclay, Gif-sur-Yvette, France

3: Also at Universidade Estadual de Campinas, Campinas, Brazil

4: Also at Federal University of Rio Grande do Sul, Porto Alegre, Brazil

5: Also at Université Libre de Bruxelles, Bruxelles, Belgium

6: Also at University of Chinese Academy of Sciences, Beijing, China

7: Also at Institute for Theoretical and Experimental Physics, Moscow, Russia

8: Also at Joint Institute for Nuclear Research, Dubna, Russia

9: Now at Helwan University, Cairo, Egypt

10: Also at Zewail City of Science and Technology, Zewail, Egypt

11: Also at British University in Egypt, Cairo, Egypt

12: Now at Ain Shams University, Cairo, Egypt

13: Also at Department of Physics, King Abdulaziz University, Jeddah, Saudi Arabia

14: Also at Université de Haute Alsace, Mulhouse, France

15: Also at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia

16: Also at Tbilisi State University, Tbilisi, Georgia

17: Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland

18: Also at RWTH Aachen University, III. Physikalisches Institut A, Aachen, Germany

- 19: Also at University of Hamburg, Hamburg, Germany
- 20: Also at Brandenburg University of Technology, Cottbus, Germany
- 21: Also at MTA-ELTE Lendület CMS Particle and Nuclear Physics Group, Eötvös Loránd University, Budapest, Hungary
- 22: Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary
- 23: Also at Institute of Physics, University of Debrecen, Debrecen, Hungary
- 24: Also at Indian Institute of Technology Bhubaneswar, Bhubaneswar, India
- 25: Also at Institute of Physics, Bhubaneswar, India
- 26: Also at Shoolini University, Solan, India
- 27: Also at University of Visva-Bharati, Santiniketan, India
- 28: Also at Isfahan University of Technology, Isfahan, Iran
- 29: Also at Plasma Physics Research Center, Science and Research Branch, Islamic Azad University, Tehran, Iran
- 30: Also at Università degli Studi di Siena, Siena, Italy
- 31: Also at Kyunghee University, Seoul, Korea
- 32: Also at International Islamic University of Malaysia, Kuala Lumpur, Malaysia
- 33: Also at Malaysian Nuclear Agency, MOSTI, Kajang, Malaysia
- 34: Also at Consejo Nacional de Ciencia y Tecnología, Mexico city, Mexico
- 35: Also at Warsaw University of Technology, Institute of Electronic Systems, Warsaw, Poland
- 36: Also at Institute for Nuclear Research, Moscow, Russia
- 37: Now at National Research Nuclear University 'Moscow Engineering Physics Institute' (MEPhI), Moscow, Russia
- 38: Also at St. Petersburg State Polytechnical University, St. Petersburg, Russia
- 39: Also at University of Florida, Gainesville, USA
- 40: Also at P.N. Lebedev Physical Institute, Moscow, Russia
- 41: Also at California Institute of Technology, Pasadena, USA
- 42: Also at INFN Sezione di Padova ^a, Università di Padova ^b, Università di Trento (Trento) ^c, Padova, Italy
- 43: Also at Budker Institute of Nuclear Physics, Novosibirsk, Russia
- 44: Also at Faculty of Physics, University of Belgrade, Belgrade, Serbia
- 45: Also at INFN Sezione di Pavia ^a, Università di Pavia ^b, Pavia, Italy
- 46: Also at University of Belgrade, Faculty of Physics and Vinca Institute of Nuclear Sciences, Belgrade, Serbia
- 47: Also at Scuola Normale e Sezione dell'INFN, Pisa, Italy
- 48: Also at National and Kapodistrian University of Athens, Athens, Greece
- 49: Also at Riga Technical University, Riga, Latvia
- 50: Also at Universität Zürich, Zurich, Switzerland
- 51: Also at Stefan Meyer Institute for Subatomic Physics (SMI), Vienna, Austria
- 52: Also at Adiyaman University, Adiyaman, Turkey
- 53: Also at Istanbul Aydin University, Istanbul, Turkey
- 54: Also at Mersin University, Mersin, Turkey
- 55: Also at Piri Reis University, Istanbul, Turkey
- 56: Also at Gaziosmanpasa University, Tokat, Turkey
- 57: Also at Ozyegin University, Istanbul, Turkey
- 58: Also at Izmir Institute of Technology, Izmir, Turkey
- 59: Also at Marmara University, Istanbul, Turkey
- 60: Also at Kafkas University, Kars, Turkey
- 61: Also at Istanbul University, Faculty of Science, Istanbul, Turkey
- 62: Also at Istanbul Bilgi University, Istanbul, Turkey

- 63: Also at Hacettepe University, Ankara, Turkey
- 64: Also at Rutherford Appleton Laboratory, Didcot, United Kingdom
- 65: Also at School of Physics and Astronomy, University of Southampton, Southampton, United Kingdom
- 66: Also at Monash University, Faculty of Science, Clayton, Australia
- 67: Also at Bethel University, St. Paul, USA
- 68: Also at Karamanoğlu Mehmetbey University, Karaman, Turkey
- 69: Also at Utah Valley University, Orem, USA
- 70: Also at Purdue University, West Lafayette, USA
- 71: Also at Beykent University, Istanbul, Turkey
- 72: Also at Bingol University, Bingol, Turkey
- 73: Also at Sinop University, Sinop, Turkey
- 74: Also at Mimar Sinan University, Istanbul, Istanbul, Turkey
- 75: Also at Texas A&M University at Qatar, Doha, Qatar
- 76: Also at Kyungpook National University, Daegu, Korea
