Draft version July 31, 2009

ABSTRACT

The discovery of TeV emitting X-ray binaries has triggered an intense effort to better understand the particle acceleration, absorption, and emission mechanisms in compact binary systems, which provide variable conditions along eccentric orbits. Despite this, the nature of some of these systems, and of the accelerated particles producing the TeV emission, is unclear. To answer some of these open questions we conducted a multiwavelength campaign of the TeV emitting X-ray binary LS I +61 303 including the MAGIC telescope, XMM-Newton, and Swift during 60% of an orbit in 2007 September. We detect a simultaneous outburst at X-ray...
and TeV energies, with the peak at phase 0.62 and a similar shape at both wavelengths. A linear fit to the simultaneous X-ray/TeV pairs obtained during the outburst yields a correlation coefficient of $r = 0.97$, while a linear fit to all simultaneous pairs provides $r = 0.81$. The observed correlation and the lack of significant absorption towards the observer expected at TeV energies during the explored orbital phases indicate a simultaneity in the emission processes. Assuming that they are dominated by a single particle population, either hadronic or leptonic, the X-ray/TeV flux ratio favors leptonic models. This fact, together with the detected photon indexes, suggests that in LS I +61 303 the X-rays are the result of synchrotron radiation of the same VHE electrons that produce TeV emission as a result of inverse Compton scattering of stellar photons.

**Subject headings:** binaries: general — gamma rays: observations — stars: emission-line, Be — stars: individual (LS I +61 303) — X-rays: binaries — X-rays: individual (LS I +61 303)

1. INTRODUCTION

LS I +61 303 is one of the few X-ray binaries that have been detected at TeV energies (see e.g. Paredes 2008 for a recent review). It is a high mass X-ray binary system located at a distance of 2.0±0.2 kpc (Fraul & Hjellming 1991). The system contains a rapidly rotating early type B0 Ve star with a stable equatorial decretion disk and mass loss, and a compact object with a mass between 1 and 4 M⊙ orbiting it every ~2.65 d in an eccentric orbit (see Casares et al. 2005; Grundstrom et al. 2007, Aragona et al. 2009, and references therein). LS I +61 303 was classified as a microquasar based on structures detected from five to several tens of milliarcseconds with the EVN and MERLIN (Massi et al. 2004 and references therein), although analysis of later EVN and MERLIN datasets does not reveal the presence of such structures (Dhawan et al. 2006; Albert et al. 2008a). VLBA images with a resolution of one milliarcsecond (2 AU at the source distance) obtained during a full orbital cycle show an elongated structure that rotates as a function of the orbital phase (Dhawan et al. 2006). Later VLBA images show repeating structures at the same orbital phases, reinforcing the idea that the milliarcsecond structure depends on the orbital phase (Albert et al. 2008a). This may be consistent with a model based on the interaction between the relativistic wind of a young non-accreting pulsar and the wind/decretion disk of the stellar companion (Dubus 2006a), as occurs in PSR B1259−63 (but confining the pulsar wind may be problematic, see Bogovalov et al. 2008).

LS I +61 303 shows periodic non-thermal radio outbursts on average every $P_{\text{orb}}=26.4960±0.0028$ d, with the peak of the radio emission shifting progressively from phase 0.45 to 0.95, using $P_{0}=JD 2,443,366,775$, with a modulation period of 1667±8 d (Gregory 2002). According to the most precise orbital parameters, the periastron takes place at phase 0.275 and the eccentricity of the orbit is 0.537±0.034 (Aragona et al. 2009).

LS I +61 303 has been observed several times in X-rays (see Smith et al. 2009 and references therein). It generally displays quasi-periodic X-ray outbursts, with the maximum occurring between orbital phase 0.4 and 0.8 (Goldoni & Mereghetti 1995; Taylor et al. 1996; Paredes et al. 1997; Harrison et al. 2000; Esposito et al. 2007), although the lack of a sensitive long-term monitoring has prevented to search for a super-orbital modulation. The source also shows short-term variability on timescales of hours (Sidoli et al. 2006).

At very high energy (VHE) gamma rays, LS I +61 303 has been clearly detected several times both by MAGIC (Albert et al. 2006, 2008a, 2009) and VERITAS (Acciari et al. 2008, 2009). The source also displays TeV periodicity, with minima taking place near periastron, where only upper limits were found in MAGIC observations, and maxima occurring on average at phase 0.6−0.7, although the source has also shown a second peak at phase 0.84 in one of the cycles (Albert et al. 2009). There are indications of correlated X-ray/TeV emission, based on non-simultaneous data taken more than six hours apart (Albert et al. 2009), and one day apart (Albert et al. 2008a).

The lack of a systematic behavior from cycle to cycle at X-ray and TeV energies, and the occurrence of short-term variability in the X-ray flux, has hampered the definitive detection of an X-ray/TeV correlation from the comparison of non-simultaneous data. We therefore conducted a multiwavelength campaign in 2007 September, covering the epoch of maximum TeV emission. Here we report the first simultaneous TeV and X-ray observations of LS I +61 303 obtained with the MAGIC Cherenkov telescope and the XMM-Newton and Swift X-ray satellites that show correlated emission in both energy bands. We also briefly comment on radio and optical spectroscopic observations obtained during the campaign.

2. OBSERVATIONS AND DATA ANALYSIS

2.1. VHE Gamma Rays

The TeV observations were performed from 2007 September 4 to 21 using the MAGIC telescope on the Canary Island of La Palma (28.75°N, 17.86°W, 2225 m a.s.l.), from where LS I +61 303 is observable at zenith angles above 32°. The essential parameters of MAGIC are a 17 m diameter segmented mirror of parabolic shape (currently the largest dish for an air Cherenkov telescope), an f/D of 1.05 and an hexagonally shaped camera of 576 hemispherical photo multiplier tubes with a field of view of 3.5° diameter. MAGIC can detect gamma rays from 60 GeV to several TeV, and with a special setup the trigger threshold can be reduced to 25 GeV (Aliu et al. 2008). Its energy resolution is $\Delta E / E = 20\%$ above energies of 200 GeV. The current sensitivity is 1.6% of the Crab Nebula flux for a 5$\sigma$ detection in 50 h of on-source time. The improvement compared to the previous sensitivity was achieved by installing new 2 GHz FADCs (Albert et al. 2008b).

The total observation time was 58.8 h, including 39.6 h in dark conditions and 19.2 h under moonlight or twilight (Britzger et al. 2009). The range of zenith angles for these observations was [32°, 50°], with 96% of the data having zenith angles below 43°. The final effective total observation time is 54.2 h. Table 1 gives the MJD, the effective observation time, and the orbital phase for each of the MAGIC observations. The observations were carried out in wobble mode (Fomin et al. 1994), i.e. by alternately tracking two positions at 0.4° offset from the source position. This observing mode provides a reliable background estimate for pointlike sources such as LS I +61 303.

The data analysis was performed using the standard
Correlated X-ray and TeV emission in the gamma-ray binary LS I +61 303

The MAGIC analysis and reconstruction software (Albert et al. 2008c). The quality of the data was checked and data taken with anomalous event rates (very low atmospheric transmission, car light flashes, etc.) were rejected following the standard procedure, as previously done in Albert et al. (2009). From the remaining events, image parameters were calculated (Hillas 1985). In addition, the time parameters described in Aliu et al. (2009) were calculated as well. For the γ/hadron separation, a multidimensional classification procedure based on the image and timing parameters with the Random Forest method was used (Albert et al. 2008d). We optimized the signal selection cuts with contemporaneous Crab Nebula data taken at the same zenith angle range. The energy of the primary γ-ray was reconstructed from the image parameters using also a Random Forest method. The differential energy spectrum was unfolded taking into account the full instrumental energy resolution (Albert et al. 2009). We estimate the systematic uncertainty to be about 30% for the derived integral flux values and ±0.2 for the obtained photon index. For more details on the systematic uncertainties present in the MAGIC data see Albert et al. (2008c).

2.2. X Rays

We observed LS I +61 303 with XMM-Newton during seven runs from 2007 September 4 to 11, lasting from 12 to 18 ks (see Table 2), amounting to a total observation time of 104.3 ks. The EPIC pn detector used the Large Window Mode, while the EPIC MOS detectors used the Small Window Mode. All detectors used the medium thickness optical blocking filter. Data were processed using version 8.0.0 of the XMM-Newton Science Analysis Software (SAS). Known hot or flickering pixels were removed using the standard SAS tasks. Further cleaning was necessary to remove from the dataset periods of high background corresponding to soft proton flares, reducing the net good exposure durations to 67.0 and 92.6 ks for the pn and MOS detectors, respectively. Cleaned pn and MOS event files were extracted for spectral analysis. Source spectra were extracted from a ∼70′′ radius circle centered on the source (PSF of 15′′) while background spectra were taken from a number of source-free circles with ∼150′′ radius (three for the pn detector, four for MOS1 and five for MOS2). The extracted spectra were analyzed with XSpec v12.3.1 (Arnaud 1996). The spectra were binned so that a minimum of 20 counts per bin were present and energy resolution was not over-sampled by more than a factor 3. An absorbed power-law function (wabs*powerlaw) yielded satisfactory fits for all observations. De-absorbed fluxes in the 0.3–10 keV range were computed from the spectral fits.

Additional observations of 2–5 ks each, consisting of several pointings of 0.2–1.0 ks, were obtained with the Swift/XRT from 2007 September 11 to 22. The total observation time was 28.5 ks. The Swift data were processed using the FTOOLS task xrtpipeline (version 0.12.1 under HEASoft 6.6). The spectral analysis procedures were the same as those used for the XMM-Newton data. Since the hydrogen column density was poorly constrained, with typical values of (0.5 ± 0.2) × 10^{22} cm^{-2}, we fixed it to 0.5 × 10^{22} cm^{-2}, a typical value for LS I +61 303 also found in the XMM-Newton fits and close to the average value for the Swift fits.

To search for short-term X-ray variability we also extracted 0.3–10 keV background-subtracted lightcurves for each observation, binned to 100 s for XMM-Newton and at half-time of the sparse 0.2 to 1.0 ks Swift pointings within each observation. For XMM-Newton we considered the sum of the count rate in the three detectors. From these lightcurves we computed the degree of variability as the standard deviation with respect to the mean of the count rate divided by this mean, and the significance of this variability computed from the χ^2 probability of the count rate being constant. We also computed hardness ratios as the fraction between the count rates above and below 2 keV.

3. RESULTS

3.1. VHE Gamma Rays

The measured fluxes of LS I +61 303 at energies above 300 GeV are listed in Table 1, and the corresponding lightcurve is shown in Fig. 1-top. The periodically modulated peak emission (Albert et al. 2009) is prominently seen as the peak emission (Albert et al. 2006, 2009). We fixed it to 0.247 ± 0.023 keV and at half-time of the sparse 0.2 to 1.0 ks Swift pointings within each observation. For XMM-Newton we considered the sum of the cound rate in the three detectors. De-absorbed fluxes in the 0.3–10 keV range were computed from the spectral fits.

We also determined the differential energy spectrum from the ∼10 h of observations conducted from orbital phase 0.6 to 0.7. A power-law fit yields:

\[
\frac{dN}{dE} = \left(2.0 \pm 0.3_{\text{stat}} \pm 0.6_{\text{syst}}\right) \times 10^{-12} \left(\frac{E}{1 \text{ TeV}}\right)^{-2.7 \pm 0.3_{\text{stat}} \pm 0.2_{\text{syst}}},
\]

compatible within errors with our previous measurements (Albert et al. 2006, 2009).

3.2. X Rays

We summarize in Table 2 the parameters of the spectral fits and variability obtained for both the XMM-Newton and Swift/XRT data sets. All X-ray fluxes quoted hereafter are de-absorbed. Since there is significant X-ray count-rate variability within each observation, we have to consider it to provide...

Note. — * The central MJD and half-span of each observation is quoted. * Fluxes are de-absorbed. The uncertainties in parentheses include the uncertainties due to intrinsic X-ray variability during the observations.

More realistic values for the flux uncertainties than those directly obtained from the spectral fits. We note that there is no significant hardness ratio change within each of the observations, in contrast to what was found in the XMM-Newton observations reported by Sidoli et al. (2006). In principle this implies that, for each observation, the flux and corresponding uncertainty obtained from the spectral fit is a good estimate of the flux during the whole observation. However, moderate count-rate variability is present in most observations, ranging from 6 to 17% for the XMM-Newton data and from 9 to 25% for the Swift data (see Table 2), yielding to additional uncertainties that should be considered when providing a measurement spanning several ks. We converted this count-rate variability into flux variability by multiplying the degree of variability defined in Sect. 2.2 with the fluxes coming from the spectral fits. Since no spectral change is detected within each observation, we added this flux variability (as an estimate of flux uncertainty) in quadrature to the spectral fits flux errors. This procedure provides the more realistic total flux uncertainties quoted in parentheses in Table 2, and used hereafter.

We show in Fig. 1—bottom the 0.3–10 keV lightcurve of LS 1+61 303. The source displays a steady flux during the first four observations and shows a steep increase at phase 0.62, which is followed by a slower decay up to phase 0.69 (XMM-Newton) and probably up to phase 0.72 (Swift). The behavior is very similar to the one seen at TeV energies, although at X-ray energies the baseline has a significant flux. Later on there is a significant increase of the X-ray flux up to phase 0.8. This high flux is detected with a sparse sampling up to phase 0.9, and the source goes back to its baseline flux at phase 1.0. This high X-ray flux between phases 0.8 and 1.0 occurs when the source is also detected at TeV energies.

3.3. X-Ray/TeV Correlation

A clear correlation between the X-ray and TeV emissions is seen during the outburst, with a simultaneous peak at phase 0.62 (see Fig. 1). To study the significance of this correlation, we selected the X-ray datasets that overlap with MAGIC observations. There are six overlapping MAGIC/XMM-Newton datasets, for which strictly simultaneous observations range from 3.3 to 3.9 h. For the four overlapping MAGIC/Swift datasets the strictly simultaneous observations range from 2.2 to 4.1 h (although the Swift runs have gaps). We plot in Fig. 2 the X-ray fluxes against the TeV fluxes for all ten simultaneous pairs, which are marked with arrows in Fig. 1. The linear correlation coefficient for the six simultaneous MAGIC/XMM-Newton pairs that trace the outburst is r = 0.97. For the ten simultaneous pairs we find r = 0.81 (which for a double tail test has a probability of about 5 × 10^{-3} to be produced from independent X-ray and TeV fluxes). Minimizing $\chi^2$ we obtain $\chi^2 = 7.68$ for 8 degrees of freedom and the fol-

Relation coefficient to be ous observations, yielding the uncertainties for the linear correlation function (ZDCF), which determines 68% confidence level interval. The X-ray and TeV lightcurves reported (Krolik 1988, Alexander 1997). The Fisher z-transform of the sampled data as a function of time lags (see e.g. Edelson & Krolik 1988, Alexander 1997). The Fisher z-transform of the linear correlation coefficient is used to estimate the 68% confidence level interval. The X-ray and TeV lightcurves reported here lead to the highest correlation coefficient for simultaneous data with a TeV sampling that is not dense enough (Acciari et al. 2009). Although a similar X-ray/TeV correlation has been obtained for the TeV emitting X-ray binary LS 5039, this result was based on non-simultaneous data acquired years apart (Aharonian et al. 2005, 2006; Takahashi et al. 2009).

The TeV emission within a binary system can suffer photon-photon absorption via pair creation, mainly with the stellar optical/ultraviolet photons. In LS I +61 303 this absorption is only expected to be significant towards the observer for $E > 300$ GeV just before periastron (Dubus 2006b; Bednarek 2006; Sierpowska-Bartosik & Torres 2009), a phase range not explored here. On the other hand, the quoted X-ray fluxes are already de-absorbed (and the hydrogen column densities and the associated errors are low). Therefore, the X-ray/TeV correlation we have found for LS I +61 303 indicates that the emission processes at both wavelengths occur at the same time and are probably the result of a single physical mechanism. In this context, it is reasonable to assume that the X-ray and TeV emissions are produced by a single particle population.

It is interesting to note that the MAGIC spectrum in the 0.6–0.7 phase range yields $\sim 11 \times 10^{-12} \text{ erg cm}^{-2} \text{s}^{-1}$ for $E > 300$ GeV, while the X-ray flux is $\sim 19 \times 10^{-12} \text{ erg cm}^{-2} \text{s}^{-1}$. Therefore, the total X-ray flux approximately doubles the TeV flux. However, if we subtract an apparent baseline X-ray flux of $10 \times 10^{-12} \text{ erg cm}^{-2} \text{s}^{-1}$, the resulting X-ray flux is similar to the total TeV flux in the phase range 0.6–0.7. If the radiation mechanisms are dominated by a single particle population, the X-ray/TeV correlation and the smaller/similar TeV fluxes favor leptonic models. In hadronic models, the X-ray emitting $e^\pm$ and the TeV photons would come from the same protons (for reasonable values of the magnetic field), and the luminosity of the $e^\pm$ radiation should be $\lesssim 1/2$ that of TeV gamma-rays (Kelner et al. 2006) unlike it is observed. In addition, the IC cooling channel is less efficient than the synchrotron channel to produce the detected X-ray emission for reasonable values of the magnetic field (see Takahashi et al. 2009 for a similar discussion for LS 5039). This clearly suggests that the X rays are the result of synchrotron radiation of the same VHE electrons that produce TeV emission as a result of inverse Compton scattering of optical/ultraviolet stellar photons.

The observed photon indexes of the simultaneous X-ray and VHE spectra are consistent with one population of electrons following a power-law energy distribution with index $\sim 2.1$. These electrons would produce X-rays via synchrotron and VHE photons via IC with an interaction angle $\lesssim \pi/2$. We note that an electron index of $\sim 2.1$ is too hard if synchrotron cooling dominates in the X-ray range, since it implies an injected electron index of 1.1. On the other hand, dominant adiabatic cooling implies an injection index of 2.1, a more reasonable value (see for example the discussion in Takahashi et al. 2009). Although small changes in the VHE spectrum would be expected due to variations in the IC interaction angle or the electron index (as seen in X-rays), at present they are not detectable due to the large uncertainties of the VHE photon index.

Finally, we note that contemporaneous radio lightcurves obtained with RATAN, VLBA images, and Hα spectroscopy are consistent with previous results (Gregory 2002; Dhawan et al. 2006; Zamanov et al. 1999). Details on these observations will be reported elsewhere. Therefore, the X-ray/TeV correlation occurred when the source was showing a standard behavior in both its outflow (radio) and decretion disk (Hα line).

![Fig. 2.— De-absorbed X-ray fluxes as a function of TeV fluxes. Only the 10 simultaneous fluxes, marked with arrows in Fig. 1, have been considered. Error bars correspond to a 1σ confidence level in all cases. The solid line represents a χ2 linear fit to all data points.](image-url)
We would like to thank the Instituto de Astrofisica de Canarias for the excellent working conditions at the Observatorio del Roque de los Muchachos in La Palma. The support of the German BMBF and MPG, the Italian INFN and Spanish MICINN is gratefully acknowledged. This work was also supported by ETH Research Grant TH 34/043, by the Polish MNiSzW Grant N 203 390834, and by the YIP of the Helmholtz Gemeinschaft.
