C2 Domain Proteins

Thomas A. Leonard
Max F. Perutz Laboratories, Vienna, Austria

Synonyms

2nd conserved domain of protein kinase C; C2 domain; Calcium-binding region; CBR; Endocytosis; Exocytosis; Intracellular signaling; LH2 domain; Lipoxygenase homology domain; Membrane trafficking; Second messenger signaling; Signal transduction; Vesicle fusion

Definition

C2 domain proteins are proteins containing the second conserved domain of protein kinase C. The C2 domain is an all-beta domain, consisting of a beta-sandwich of two antiparallel four-stranded beta sheets. C2 domains are found in a wide range of both enzymatic and non-enzymatic proteins involved in signal transduction and membrane trafficking.

Introduction

Comprising approximately 130 amino acids, the C2 domain was first identified as a conserved domain of the calcium-dependent protein kinases C (PKC). 233 C2 domains are predicted in 127 human proteins, making the C2 domain, after the pleckstrin homology (PH) domain, the second most abundant lipid-binding domain found in eukaryotic proteins. Since the original identification of the C2 domain as the calcium sensor in PKC, both Ca^{2+}-binding and non-Ca^{2+}-binding C2 domains have been characterized in a wide variety of lipid signal transduction enzymes and membrane-trafficking proteins. By sensing the lipid microenvironments within cells, C2 domains, coupled to a variety of effector domains, spatially and temporally regulate both lipid second messenger signaling and membrane fusion events.

To date, there are structures available for 31 C2 domains from 24 proteins; the C2 fold is a β-sandwich of two four-stranded antiparallel β-sheets (Fig. 1). Three loops at the top of the domain and four at the bottom connect the β-strands. Topologically, the C2 domain comes in two flavors that differ in the connectivity of their β-strands: By fusing the N- and C-termini and cutting the loop between strands β1 and β2, type I topology can be converted into type II. A third C2 topology, called the LH2 domain, will be discussed later in more detail. Despite adopting two different topologies, the C2 domains of synaptotagmin (C2A; type I) and phospholipase C-δ1 (PLC-δ1) (type II) differ by a root mean square deviation of only 1.4 Å. It is, as yet, unclear why C2 domains exist in two

C2 Domain Proteins, Fig. 1 *C2 domain structure and topology*. The structures of type I (I, synaptotagmin), type II (II, PKCε), and type III (III, *Clostridium perfringens* alpha toxin LH2 domain) topology C2 domains are illustrated in the *upper panels*. The beta sandwich fold is highlighted by the coloring of the two antiparallel β-sheets in *blue* and *orange*. Strand β1 of the type I topology C2 domain and the equivalent β-strands in type II and type III C2 domains are colored in *red* to orient the viewer. The Ca^{2+}-binding regions (CBRs) are shown in *green*, together with the bound Ca^{2+} ions, represented as *spheres*. The corresponding topology diagrams (*middle panels*) illustrate the connectivity of the β-strands. The strand numbers, colors, and annotation of the topology diagrams correspond to the structural representations shown in the *upper panels*. Numbers in *circles* reflect the CBRs. The topologically distinct CBR3 of the LH2 domain is highlighted with *yellow circles*. Below each topology diagram and structure is a list of representative proteins containing the respective topology C2 domain

distinct topologies, but it has been speculated that the topology could influence the relative orientation of a C2 domain with respect to its neighboring domains; in type I C2 domains (synaptotagmin, PKCβII), the N- and C-termini are on the top surface of the domain, whereas in type II C2 domains (PLC-δ1, cPLA2), the termini are at the bottom. Despite a high degree of structural conservation in the core β-sandwich of the C2 domain, there is low sequence conservation between the C2 domains of different proteins. The type I C2 domains of synaptotagmin and PKCβII exhibit only 30% sequence identity over 126 equivalent residues, while the type II C2 domains of PLC-δ1 and PLA2 are only 18% sequence identical (Nalefski and Falke 1996; Rizo and Sudhof 1998).

Ca^{2+}-Binding C2 Domains

Intracellular signaling elicited by external stimuli is often mediated by an increase in cytosolic Ca^{2+} concentration. Release of intracellular stores of Ca^{2+} in response to agonist activation of G protein–coupled receptors or growth factor activation of receptor tyrosine kinases recruits C2 domain–containing proteins to the membrane. The recruitment of effectors to the membrane by small molecules, which diffuse freely in the cytosol, enables signals originating at the membrane to be propagated in a rapid and synchronous manner. The involvement of C2 domains in metal ion binding was first postulated on the basis that the calcium-independent PKCs apparently lacked this

domain (in fact, they do contain a non-Ca^{2+}-binding C2 domain with an alternate topology, but this was not discovered until later). Subsequent studies on PKCs and other C2 domain–containing proteins such as synaptotagmins and cytosolic phospholipase A2 (cPLA2) identified the C2 domain as being responsible for Ca^{2+}-dependent membrane binding. Ca^{2+} binding is mediated exclusively by residues in the loops connecting the β-strands at the top of the domain (e.g., PKCβII, Fig. 1 I); these loops were thus designated the Ca^{2+}-binding regions (CBRs), although this designation is somewhat misleading as a number of C2 domains do not bind calcium (e.g., PKCε, Fig. 1 II). Of those that do, however, both C2 domain topologies mediate binding to calcium in identical ways, since the circular permutation that converts the two topologies does not affect the CBRs. The Ca^{2+} binding sites are primarily formed by aspartate side chains that serve as bidentate ligands for two or three Ca^{2+} ions (Nalefski and Falke 1996; Rizo and Sudhof 1998). The intrinsic affinities for Ca^{2+} at each of the binding sites vary dramatically between C2 domains and are up to three orders of magnitude higher in the presence of phospholipids. Half-maximal binding of C2 domains to lipid vesicles typically occurs at 5-50 μM; Ca^{2+} has been shown to simultaneously increase the association rate constant (k_a) of C2 domains with membranes, and decrease the dissociation rate constant, (k_d). Electrostatic interactions mediated by Ca^{2+} primarily accelerate the rate of association with anionic membranes, while penetration of the hydrophobic core of the membrane has been proposed as the primary mechanism by which dissociation from the membrane is slowed. Ca^{2+} ions have been observed in four distinct positions in isolated C2 domain structures, but in the absence of structural information on lipid binding for the majority of these domains, it is unclear whether all four sites are capable of playing functionally equivalent roles. However, the structural arrangement of the Ca^{2+}-binding motifs provides an unambiguous explanation for the cooperativity that is observed in Ca^{2+} binding. Hill coefficients of 2 have been reported for the isolated C2A domains of the DOC2β (double C2 domain) C2A domain and the C2 domain of PKCβ, while synaptotagmin 1, which binds 3 Ca^{2+} ions, exhibits a Hill coefficient of 3. The affinity for Ca^{2+} at site III in synaptotagmin 1 is considerably lower than the respective affinities of sites I and II, and calcium is not observed at this position in the C2 domains of PKCs α and βII, cPLA2, and PLCδ1. In synaptotagmin I, the coordination sphere of the bound Ca^{2+} ion is incomplete, explaining the low affinity of this site. It has been speculated that anionic phospholipids may fill unsatisfied coordination sites at site III, increasing the affinity for Ca^{2+}. Ca^{2+} is observed at site I in cPLA2 and PLCδ1, but not at sites II and III. Instead, a second binding site, site IV, is created by the juxtaposition of two conserved aspartates in CBR1. While equivalent aspartates exist in CBR1 of synaptotagmin and PKCs α and βII, Ca^{2+} is not observed at this site. Structurally, there is no impedance to Ca^{2+} binding at site IV, and variations in Ca^{2+} occupancy may be due to its observation in the absence of membranes. Only lanthanum (La^{3+}) was observed at site II of PLCδ1, despite an identical arrangement of the Ca^{2+}-binding residues to that found in synaptotagmin 1. It seems likely, however, that Ca^{2+} is bound at site II in the presence of phospholipids. In cPLA2, conservative substitutions of calcium-chelating aspartates in CBR3 probably reduce the affinity for Ca^{2+} at site III, though since the binding of Ca^{2+} is cooperative and since site II is not occupied in the absence of phospholipids, it is conceivable that all of these C2 domains contain a total of four Ca^{2+}-binding sites. The structures of Ca^{2+}-free and Ca^{2+}-bound C2 domains show that Ca^{2+} does not induce a substantial conformational change, suggesting that the C2 domain acts as a calcium sensor in the cell. NMR studies have shown that Ca^{2+} induces a stabilization and reduction in conformational flexibility in the CBRs. In this way, Ca^{2+} binding by the C2 domain differs markedly from another class of Ca^{2+} effector domains, EF-hands, in which binding of a single Ca^{2+} ion to a contiguous helix-turn-helix motif induces a conformational change that exposes hydrophobic surfaces. Ca^{2+} causes an increase in the thermal denaturation temperature and confers resistance to proteolytic degradation of the C2A domain of synaptotagmin I. Ca^{2+} binding contributes to membrane binding of C2 domains in two distinct ways: first, Ca^{2+} dramatically alters the electrostatic landscape of the C2 domain surface that favors interaction with anionic membranes; secondly, Ca^{2+} provides a stereospecific bridge between the C2 domain and anionic phospholipids. The bridge model is supported by the crystal structure of the C2 domain of PKCα in complex with Ca^{2+} and a short chain phosphatidylserine (PS) molecule. Ca^{2+} binding has been

postulated to induce local conformational changes that could perturb inter-domain interactions in C2 domain–containing proteins, but such conformational changes have only been observed in a splice variant of the C2A domain of the active zone protein piccolo, which contains a unique nine-amino acid insertion in the loop opposite the Ca^{2+}-binding loops. It remains to be seen whether this phenomenon is a property of C2 domains in general or a characteristic peculiar to piccolo (Cho and Stahelin 2006).

C2 domains exhibit a diversity of membrane-recognition motifs, which has drawn comparison with the complementarity determining regions (CDRs) of immunoglobulins. The similarity does not end there, either, since the immunoglobulin fold is the same β-sandwich of two antiparallel β-sheets. Three variable loops between β-strands in the immunoglobulin domain are responsible for antigen recognition in a manner analogous to the Ca^{2+}- and lipid-binding CBRs of C2 domains. Indeed, the β-sandwich scaffold appears to have been utilized for the evolution of an enormous diversity of recognition modules with capacities for lipid binding (C2 domains), antigen recognition (immunoglobulins), and protein-protein interaction.

Lipid Selectivity of C2 Domains

Lipid selectivity in the presence of Ca^{2+} is determined by the residues of the CBRs; C2 domains containing cationic residues in the CBRs prefer anionic lipids over zwitterionic ones, while those containing aliphatic and aromatic residues in their CBRs (cPLA2 and 5-lipoxygenase) strongly favor neutral phosphatidylcholine (PC) membranes over anionic ones. Penetration of hydrophobic side chains into PC membranes may be favored because the desolvation penalty is less than that for penetration into anionic membranes. Stereospecific binding of L-α-PS by PKCα and PLC-δ1 is mediated by two Ca^{2+} ions and depends on residues in the CBRs that specifically recognize the serine head group of PS. The C2A domain of JFC1, a membrane-trafficking protein, has been reported to bind 3′-phosphoinositides both in vivo and in vitro (Cho and Stahelin 2006).

In addition to Ca^{2+}-dependent lipid binding, Ca^{2+}-independent phospholipid binding is highlighted by the C2B domains of synaptotagmins II and IV, which bind soluble inositol polyphosphates. Multiple structures of C2 domains have contained ordered phosphate or sulfate ions in the vicinity of a patch of basic residues, suggesting that the domain might be able to associate electrostatically, but nonspecifically, with anionic membranes. A large number of C2 domains contain this cationic patch on the concave surface of the β-sandwich, which has been designated as the β-groove. Although the size and electrostatic potential of this patch varies widely among C2 domains, its functional significance was highlighted by the recent observation that this constitutes a second phospholipid-binding site in the C2 domain of PKCα; the phosphates of the phosphatidylinositol-4,5-bisphosphate (PIP_2) head group are coordinated by a cluster of conserved lysine residues. However, despite structural validation of PIP_2 binding to the β-groove of PKCα, there are conflicting reports as to the specificity of this interaction. In the synaptotagmins, it is believed that the β-groove is key to their fusion activity. In addition to the synaptotagmins and PKCα, Ca^{2+}-independent lipid binding of C2 domains through their β-grooves has been reported for cPLA2, class II PI3Ks, and PKCs θ and ε. It is likely that these C2 domains engage multiple membrane components simultaneously, and that their membrane-bound orientations are a product of these interactions. The diversity in membrane and lipid recognition, both Ca^{2+} dependent and independent, of C2 domains suggests a complexity of membrane targeting that likely has well-defined signaling consequences (Lemmon 2008). Modulating the ability of C2 domains to bind phospholipids by posttranslational modification can also regulate the membrane targeting of C2 domains. WNK1 phosphorylates synaptotagmin 2 within its C2 domain, increasing the amount of Ca^{2+} required for membrane binding. Mutations in WNK1 have been linked to a heritable form of hypertension, pseudohypoaldosteronism. Whether posttranslational modification of C2 domains is a universal mechanism employed by cells is yet to be determined.

Membrane-Bound Orientation of C2 Domains

The orientation of C2 domains with respect to the membrane is dependent on a number of factors, not

least the nature and specificity of the interaction between the CBRs and phospholipid. Dual phospholipid-binding sites in some C2 domains and C2-protein interactions are also expected to play significant roles. Monolayer penetration studies of PKCα and cPLA2 C2 domains show that electrostatic interactions between cationic residues in the CBRs of PKCα and anionic phospholipid head groups maintain PKCα at the membrane surface, whereas hydrophobic residues in the CBRs of cPLA2 actually penetrate PC membranes. Electron paramagnetic resonance (EPR) and X-ray reflectivity analyses have also confirmed that the depth of membrane penetration from the phosphate group varies between the C2 domains of cPLA2, PKCα, and synaptotagmin I. The orientation of the PKCα C2 domain takes into account its ability to interact simultaneously with PS and PIP_2, but, noting that the β-groove is found in many other C2 domains, this orientation is not expected to be unique to PKCα (Cho and Stahelin 2006).

C2 Domain–Containing Proteins

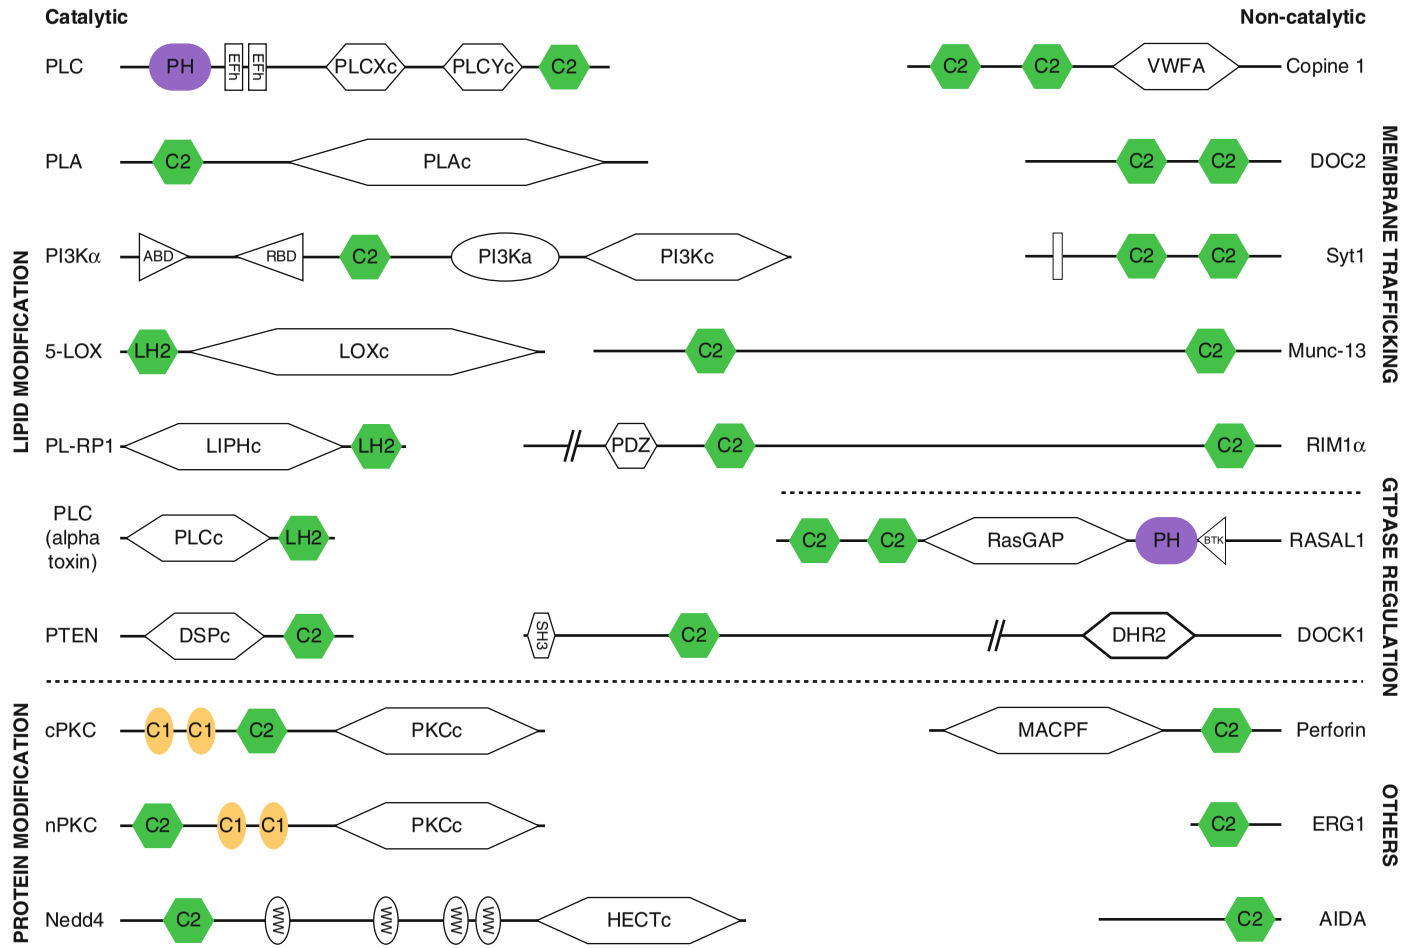
C2 domains contain neither catalytic activity nor the capacity to undergo gross conformational rearrangements in response to ligand binding. Furthermore, C2 domains have never been found to constitute individual proteins, consistent with the notion that they are sensor domains. The flow of information in a system dictates that sensors must talk to effectors such that a physiological response can be elicited. C2 domains, therefore, are of much greater significance within the context of their full-length proteins. C2 domains are found in enzymes generally involved in signal transduction (PLC, PKC, lipoxygenase, PI3K, phosphatase and tensin homolog (PTEN), ubiquitin ligases) as well as in membrane-trafficking proteins without catalytic activity (synaptotagmins, rabphilin, regulating synaptic membrane exocytosis protein (RIM), Munc-13) (Fig. 2). Despite a wealth of structural data on isolated C2 domains, there are relatively few structures of full-length, C2 domain–containing proteins.

Catalytic C2 Domain–Containing Proteins

C2 domains are found in proteins with phospholipase, ubiquitin ligase, lipid kinase and phosphatase, protein kinase and phosphatase, and lipid peroxidizing activities. Structures of a number of these holoenzymes provide a framework for a discussion of the role of their C2 domains. The structure of the original C2 domain–containing protein, PKC, was recently published, but the C2 domain adopts two positions in the crystal lattice that are the result of lattice packing interactions and are not deemed physiologically relevant. The Ca^{2+}-dependent C2 domains of the conventional PKCs bind PS with high specificity and affinity, but do not measurably penetrate the hydrophobic layer. Conventional and novel PKCs contain type I and II C2 domains, respectively, perhaps with consequences for the orientation of their catalytic domains with respect to the membrane.

The type II C2 domain of PI3Kα makes a number of intramolecular contacts with both the p110α and p85α subunits. The putative membrane-binding CBRs contact the helical domain of p85α, while a 22-amino acid insertion in the loop connecting strands β7 and β8 mediates extensive intramolecular contacts with the p110α kinase domain. The PI3Kα C2 domain does not contain a cationic β-groove. Removal of the p85α nSH2 domain from inhibitory constraints with the kinase domain is required for activation, but it is unclear whether this is also coupled to displacement of the C2 domain from its intramolecular contacts. However, somatic mutations in the interface between the p110α C2 domain and the helical domain of p85α, as well as between the C2 domain and the nSH2 domain of p85α, have been detected in a number of diverse tumor types; PI3KCA, the gene encoding the catalytic subunit of PI3Kα, is one of the most frequently mutated oncogenes in human cancer (Huang et al. 2007).

PLCβ and δ1 contain type II C2 domains that are sandwiched between the lipase and EF-hand domains in the full-length proteins. The interface buries 1106 Å, or 40%, of C2 domain surface area, partially occluding the β-groove. However, neither of the PLC C2 domains contain a cationic patch in the β-groove and the CBRs are free to engage the membrane. While the architecture of the two holoenzymes is highly conserved, the principal differences are found between the C2 domains. PLCδ-1 C2 binds PS in a Ca^{2+}-dependent manner, whereas the C2 domain of PLCβ interacts with activated $G\alpha_q$ subunits of heterotrimeric G proteins with nanomolar affinity. Binding of GTP-bound $G\alpha_q$ results in PLCβ activation at the membrane. Membrane association of the $G\alpha_q$ subunit via



C2 Domain Proteins, Fig. 2 *C2 domain–containing proteins*. On the *left* of the figure are C2 domain–containing proteins containing effector domains with catalytic activity, grouped into those that catalyze lipid modifications and those that catalyze protein modifications. C2 domains are colored *green*; other membrane-targeting domains are colored in *purple* (PH domains) and *yellow* (C1 domains)

prenylation of its carboxy terminus may compensate for the apparent lack of membrane binding by the C2 domain of PLCβ. The C2 domain of PLCs has been proposed to help orient the catalytic domain with respect to the membrane in order to facilitate hydrolysis of PIP_2. Like the C2 domain of PI3Kα, a loop between strands β7 and β8 mediates a number of crucial intramolecular contacts with both the lipase and PH domains. The type I C2 domains of PKCα and βII superimpose well with that of PLCδ1, suggesting that perhaps the C-terminal α-helix that follows strand β8 (which is topologically equivalent to the β7-β8 loop in type II C2 domains) plays a similar role in mediating intramolecular contacts in conventional PKCs. Despite diverse modes of activation, including by protein-protein interactions, the basal activity of all PLCs is low relative to their maximal activation; it is likely, therefore, that inter-domain conformational changes, which may or may not involve dissociation of the C2 domain from intramolecular contacts, play an important role in PLC activation (Rhee 2001).

In the dual specificity phosphatase, PTEN, the C2 domain and phosphatase domain interact across an extensive interface. Both the C2 domain and the phosphatase domain are necessary for membrane recruitment. The C2 domain has been proposed to play a dual role in targeting PTEN to the plasma membrane and assisting a productive orientation of the phosphatase domain at the membrane surface. As such, truncation of the C-terminus of the C2 domain results in a complete loss of phosphatase activity. The type II C2 domain can be superimposed on the C2 domain of cPLA2 with a r.m.s.d. of just 1.9 Å over 85 Cα atoms. However, the ligands for Ca^{2+} binding are absent in PTEN, in which membrane binding appears to be mediated by electrostatic interactions between the cationic surfaces of both the C2 and phosphatase domains and hydrophobic residues in the CBR3 loop; equivalent hydrophobic residues in the CBR3 loop are known to insert into the lipid bilayer in the C2 domain of synaptotagmin. The basic surface of the C2 domain and the CBR3 loop are on the same face as the phosphatase active site, consistent with a role in orienting the phosphatase domain with respect to the membrane and its lipid substrate, phosphatidylinositol-3,4,5-phosphate (PIP_3). Mutation of PTEN is a common event in about 50% of gliobastomas, endometrial and prostate carcinomas, and melanomas. Tumor mutations map evenly to both the phosphatase and C2 domains and reduce or eliminate PTEN's growth suppression activity (Leslie and Downes 2002).

The Nedd4 E3 ubiquitin ligases contain an N-terminal Ca^{2+}-binding type II topology C2 domain, superimposable on the C2 domains of Munc-13, PKCs ε and η, and synaptotagmin. Ca^{2+} binding to the C2 domain of Nedd4 promotes its interaction with acidic lipids. In addition to its role in membrane binding, the Nedd4 C2 domain interacts with the SH2 domain of Grb10, which recruits Nedd4 to IGFR1 (insulin-like growth factor receptor 1) for ubiquitin-mediated degradation. Ca^{2+} binding activates Nedd4 by displacing the C2 domain from autoinhibitory interactions.

The lipoxygenase family of lipid-peroxidizing enzymes metabolizes arachidonic acid to produce both pro-inflammatory leukotrienes and anti-inflammatory lipoxins. Lipoxygenases comprise a C2-like N-terminal LH2 (lipoxygenase homology) domain (Fig. 1, III) and a C-terminal, predominantly α-helical, catalytic domain containing a non-heme iron (Allard and Brock 2005). The LH2 domains of 5-, 8-, and 12-lipoxygenases, like many C2 domains, mediate Ca^{2+}-dependent association with the nuclear membrane. Three Ca^{2+} ions are observed bound to the LH2 domain of 8-lipoxygenase, chelated by conserved aspartate residues; however, due to the topological change in CBR3 that distinguishes the LH2 domain from the type I and type II topology C2 domains (Fig. 1, yellow circles), the sites are structurally distinct from those in synaptotagmin, PKCs, and PLCs. Mutation of the Ca^{2+}-ligating residues results in both impaired membrane binding and Ca^{2+}-dependent enzyme activity. Mutation of surface-exposed hydrophobic residues in the CBRs of 5- and 8-lipoxygenase also impairs membrane binding. Since the Ca^{2+}-binding loops are found on the same side as the putative entrance into the substrate-binding pocket, the LH2 domain likely orients the catalytic domain to facilitate fatty acid acquisition from the membrane. The LH2 domain is a third permutation of the canonical C2 domain that is generated from C2 type II topology by connecting strand β5 to strand β8 and β8 to β7 (Fig. 1, II and III). The C2 β-sandwich fold of two four-stranded antiparallel β-sheets is maintained by breaking and rejoining strands on the same side of the domain, but in contrast to type I and II C2 domains, the LH2 domain starts and ends in different β-sheets.

This has topological consequences for the connection of LH2 domains to their various effector domains. There are 19 human proteins predicted to contain LH2 domains, of which only lipoxygenase homology domain 1 contains multiple LH2 domains (seven). Lipoxygenases and pancreatic lipases are the principal members of this family (Chahinian et al. 2000; Allard and Brock 2005). However, the LH2 domain is also found in bacterial alpha toxins, critical virulence factors that have phospholipase activity. The *Clostridium perfringens* alpha toxin LH2 domain has significant structural homology with the LH2 domains of nonbacterial lipoxygenases and pancreatic lipases, as well as with the C2 domain of synaptotagmin. Moreover, eukaryotic phospholipases also contain membrane-targeting C2 domains. Membrane targeting of bacterial alpha toxins, like that of the lipoxygenases and pancreatic lipases, is mediated by Ca^{2+}-dependent phospholipid binding. The Ca^{2+}-binding loops of the LH2 domain are oriented on the same face of the alpha toxin as the catalytic site, supporting the notion that LH2 domains, just like their related C2 domains, assist the productive orientation of the catalytic domain at the interface with the membrane. Indeed, the LH2 domain of the bacterial alpha toxins is required for their hemolytic activities (Popoff and Bouvet 2009). The LH2 domain of pancreatic lipase is also oriented with respect to the catalytic domain such that the putative membrane-binding CBRs are on the same face of the molecule as the active site (Chahinian et al. 2000). While lipoxygenases, pancreatic lipases, and bacterial alpha toxin C2 domains all appear to facilitate a productive orientation of their catalytic domains with respect to their membrane-bound substrates, the inter-domain contacts are different in each family. The LH2 domains of the three proteins superimpose with r.m.s.d.s of less than 2.8 Å over 110 matching Cα atoms, but the effector domains of each protein contact three distinct surfaces of the LH2 domain, of which two only partially overlap.

Non-Catalytic C2 Domain Containing Proteins

Of the non-enzymatic C2 domain–containing proteins, the remainder are primarily involved in membrane trafficking. The prototypical C2 domain–containing proteins in trafficking are the approximately 400-amino acid synaptotagmins, which contain tandem type I C2A and C2B domains C-terminal of a transmembrane α-helix. There are 15 members of the mammalian synaptotagmin family, of which eight bind Ca^{2+}. Ca^{2+} binding to synaptotagmin 1 triggers the displacement of complexin from "primed" SNARE complexes, resulting in the high speed and synchronicity of Ca^{2+}-mediated neurotransmitter release. In addition to Ca^{2+}-dependent membrane binding to PS, the C2 domains of synaptotagmins bind phosphoinositides via their cationic β-grooves. Synaptotagmins have been shown to lower the energy needed for membrane fusion; membrane insertion of residues in the CBRs of the two C2 domains has been postulated to induce positive membrane curvature under the SNARE complex ring, causing buckling of the plasma membrane towards the vesicle, therefore reducing the distance between the two membranes and reducing the energy barrier for hemifusion (Sudhof 2004). Other multiple C2-containing monotopic transmembrane proteins involved in membrane trafficking include the ferlins, tricalbins, and MCTPs.

RIM, Munc-13, rabphilin, and DOC2 are non-transmembrane soluble C2-containing proteins that regulate membrane fusion. The active zone protein RIM1α is a 190 kDa protein containing two type I C2 domains widely separated in primary sequence. Munc-13 is a multidomain protein found in presynaptic active zones where it mediates the priming of synaptic vesicle fusion, although the mechanism is as yet unclear. Munc-13 contains three C2 domains also widely separated in primary sequence. The type II C2B domain of Munc-13 contains an unusual amphipathic helix in one of the Ca^{2+}-binding loops that confers on it a preference for phosphoinositides. Mutation of Ca^{2+} binding to this domain does not block neurotransmitter release in response to isolated action potentials, but depresses the release evoked by action potential trains. Rabphilin is a regulator of synaptic vesicle recovery from use-dependent depression. Like the synaptotagmins, rabphilin contains tandem type I C2A and C2B domains C-terminal of the rabphilin effector domain, a binding domain for the small G protein Rab3A (Nalefski and Falke 1996; Sudhof 2004). The DOC2 family of synaptic proteins also contains tandem C2A and C2B domains C-terminal of the DOC2 effector MID (Munc-13 interacting domain). The C2A domain of DOC2B binds membranes containing PS in a Ca^{2+}-dependent manner. The copine family of proteins, found to be associated with secretory vesicles, also contains tandem Ca^{2+}-binding C2 domains in front of a C-terminal von Willebrand factor type A (VWFA) domain.

It is not fully understood why many of the proteins involved in membrane trafficking contain multiple C2 domains; in cell signaling proteins, multiple C2 domains are the exception rather than the rule. Multiple C2 domains may increase the avidity of the host protein for the membrane. However, the tandem C2 domains of synaptotagmin, rabphilin, and DOC2 are nonequivalent sensor modules, suggesting that they have evolved functional specialization. As such, the C2 domains of synaptotagmin have different structural features and exhibit different lipid selectivities. Since the membrane fusion reaction is dependent on bringing the vesicle and target membranes into close juxtaposition, an attractive hypothesis is that multiple C2-containing proteins evolved to bridge two separate membranes. Ca^{2+}-mediated synchronous exocytosis of neurotransmitter presumably requires simultaneous local remodeling of both the vesicle and presynaptic membranes, which would be consistent with distinct roles for the C2A and C2B domains of synaptotagmin in membrane binding.

Natural killer cells and cytotoxic T lymphocytes are critical for the elimination of virus-infected and neoplastic cells. The pore-forming protein perforin is necessary for the delivery of pro-apoptotic granzymes into the cytosol of the target cell. Perforin contains a C-terminal Ca^{2+}-binding type II topology C2 domain that targets perforin to membranes; the C2 domain is important for the activity of perforin: at low Ca^{2+} concentrations, perforin is not activated, but upon granule exocytosis, elevated Ca^{2+} and neutral pH promote membrane binding. The recently determined structure of the perforin monomer shows a limited inter-domain interface between the bottom of the C2 domain and the C-terminal and EGF domains, but, significantly, a number of mutations linked to familial hemophagocytic lymphohistiocytosis (FHL) map to this region (Pipkin and Lieberman 2007).

Other non-catalytic C2-containing proteins include the DOCK (dedicator of cytokinesis) family of Rho family guanine nucleotide exchange factors (GEFs) and the RASAL (RasGAP-activating-like) family of Ras GTPase–activating proteins. The surface loops (CBRs) of the DOCK type II C2 domain create a basic pocket for the recognition of the PIP_3 head group. A 40 amino acid segment between strands β7 and β8 forms a helical scaffold that, by comparison to the β7–β8 loop insertions of PI3Kα and PLCβ/δ C2 domains, could mediate intramolecular or protein-protein interactions. The tandem C2 domains of the RASAL proteins are homologous to the C2 domains of synaptotagmin and PKCβII; the C2 domains bind to PS- and PC-containing membranes in a Ca^{2+}-dependent manner in vitro. RASAL responds to oscillations in intracellular Ca^{2+} concentration via its type I C2 domains to regulate the activation state of Ras. The AIDA (axin interaction dorsal-associated) family of cytoskeleton-interacting proteins contains a C2 domain of type II topology. Putative C2 domains have additionally been detected bioinformatically in ciliary basal body–associated proteins (annotated in the PFAM database as B9 domains), as well as in several microfilament and endocytosis-related proteins. Finally, C2 domains are also found in plant proteins; rice ERG1 (elicitor-responsive gene) contains a single type II topology C2 domain that translocates to the plasma membrane in response to fungal pathogen elicitors. ERG1 C2 is structurally most similar to the C2B domain of Munc-13 and binds to PS-containing vesicles in a Ca^{2+}-dependent manner (Zhang and Aravind 2010).

Subcellular Targeting of C2 Domain–Containing Proteins

Subcellular targeting studies of GFP-tagged C2 domains have shown that their behaviors in vivo largely mimic their in vitro binding properties. The C2 domains of PKCα and PLCδ1, which preferentially bind anionic membranes containing PS, translocate to the plasma membrane in response to Ca^{2+} while the C2 domains of cPLA2 and 5-lipoxygenase, which bind neutral and PC-containing membranes, translocate preferentially to the PC-rich perinuclear region. The calcium concentrations reported for the half-maximal binding of many C2 domains to membranes in vitro are in the micromolar to millimolar range, yet cytosolic calcium concentrations are typically submicromolar in both resting and stimulated cells. The C2 domains of conventional PKCs, cPLA2, and RASAL all respond linearly to cellular calcium oscillations, suggesting that translocation is a function of calcium concentration in the cell. However, membrane residence is not simply a function of Ca^{2+} concentration considering that all C2 domain–containing proteins are coupled to effector domains, many of which exert their catalytic function on membrane-bound substrates (PI3K, PLC, cPLA2, lipoxygenase) and potentially interact with

other proteins at the membrane. Furthermore, many proteins contain membrane-binding modules in addition to C2 domains, including PKC and Munc-13 (C1 domains), PLC (PH domain), and rabphilin (FYVE domain) (Fig. 2), which extend the duration of their residence at cellular membranes. It is likely, therefore, that apparent in vitro affinities are artificially lower due to a higher k_d than is physiologically the case in vivo, rather than any change in k_a.

Conclusions

Since the discovery, 23 years ago, that the second conserved domain (C2) of PKC was a calcium sensor, biochemical, cell biological, and structural studies of these domains and their host proteins have contributed enormously to efforts aimed at understanding the processes of signal transduction and membrane trafficking. The C2 domain has been widely described as having one of two topologies, though the LH2 domain can be classified as a third topology of the C2 domain. Indeed, the LH2 domains of the lipoxygenases and pancreatic lipases have been widely discussed in the context of C2 domain properties. The C2 domain is regarded as an exclusively eukaryotic domain, and a SMART search of bacterial genomes fails to find C2 domain–containing proteins; in fact, there is at least one example of a bacterial C2 domain–containing protein in the alpha toxins. C2 domains, like their immunoglobulin counterparts, have an enormous repertoire of ligand-binding capabilities, whether those ligands are calcium, phospholipids, or other proteins. Within the context of signal transduction enzymes, C2 domains recruit the proteins to the appropriate cellular membrane while simultaneously ensuring the productive orientation of the catalytic domain. In at least a subset of these enzymes, calcium and phospholipid binding is also coupled to the relief of autoinhibitory intramolecular interactions between the C2 domain and the remainder of the protein. Multiple C2 domain–containing proteins, on the other hand, appear to have employed the C2 domain to regulate membrane fusion. One of the most fundamental processes in life, membrane fusion is critical to intracellular trafficking pathways, synaptic transmission, and fertilization. Inherently complex and very tightly regulated, the mechanisms governing membrane fusion are still unclear. While it is evident that the C2 domain plays a significant role, much more work is needed to define the contributions of individual C2 domain–containing proteins and, within that framework, the contributions of each C2 domain.

Definitions

Genuine *cadherins* are metazoa-specific, calcium-dependent transmembrane (TM) proteins that generally mediate cell–cell adhesion or cell–cell recognition and are characterized by the presence of at least two consecutive extracellular cadherin-specific motifs in their extracellular domains. Each motif, called a cadherin repeat (EC), is about 110 amino acid residues (AA) long and comprises highly conserved calcium-binding AA.

All members of the major cadherin (CDH) gene family encode proteins with an ectodomain comprising at least five consecutive calcium-binding ECs. There is strong sequence conservation within the family. The family includes the paradigmatic type-I "classical" cadherin genes, encoding proteins with five ECs and a single TM domain. Comprehensive phylogenetic analysis of related cadherins (Hulpiau and van Roy 2009) identified several more branches

in this major family, including the closely related type-II cadherins, also called atypical cadherins; the type-III and type-IV cadherins, which have elongated ectodomains with about ten ECs and at least one LamG domain (a 180-AA long globular domain originally found at the C-terminus of laminin-α chains), and which are not anymore present in mammals; the desmogleins and desmocollins, present in mammalian desmosomes; and the CELSR/Flamingo cadherins having, besides an ectodomain of nine ECs, a seven-transmembrane domain, which is exceptional for cadherins. Cadherins of types I to IV all have a cytoplasmic domain containing two conserved motifs for binding to members of the armadillo protein family.

The *protocadherin* (PCDH) gene family encodes proteins with an ectodomain comprising six or seven calcium-binding ECs with high sequence conservation within the family but weaker homology to the ECs of members of the CDH family. Further, protocadherins have a single TM domain and a distinct, protocadherin-specific cytoplasmic domain. Protocadherins can be further subdivided into clustered and non-clustered protocadherins on the basis of particular genomic organizations.

The *cadherin-related* (CDHR) genes do not fit into the above two families because they are clearly separated phylogenetically. The encoded proteins comprise at least two typical, consecutive, calcium-binding ECs, but often many more than the typical members of the CDH and PCDH families. Their overall domain organization is more diverse and also includes unique cytoplasmic domains.

Armadillo proteins have a central armadillo domain composed of tandemly arranged armadillo repeats. These repeats are about 40 AA long and were originally identified in the Armadillo protein, which is the β-catenin ortholog in *Drosophila melanogaster*. The armadillo domain has a typical curved structure and functions for multiple specific protein–protein interactions.

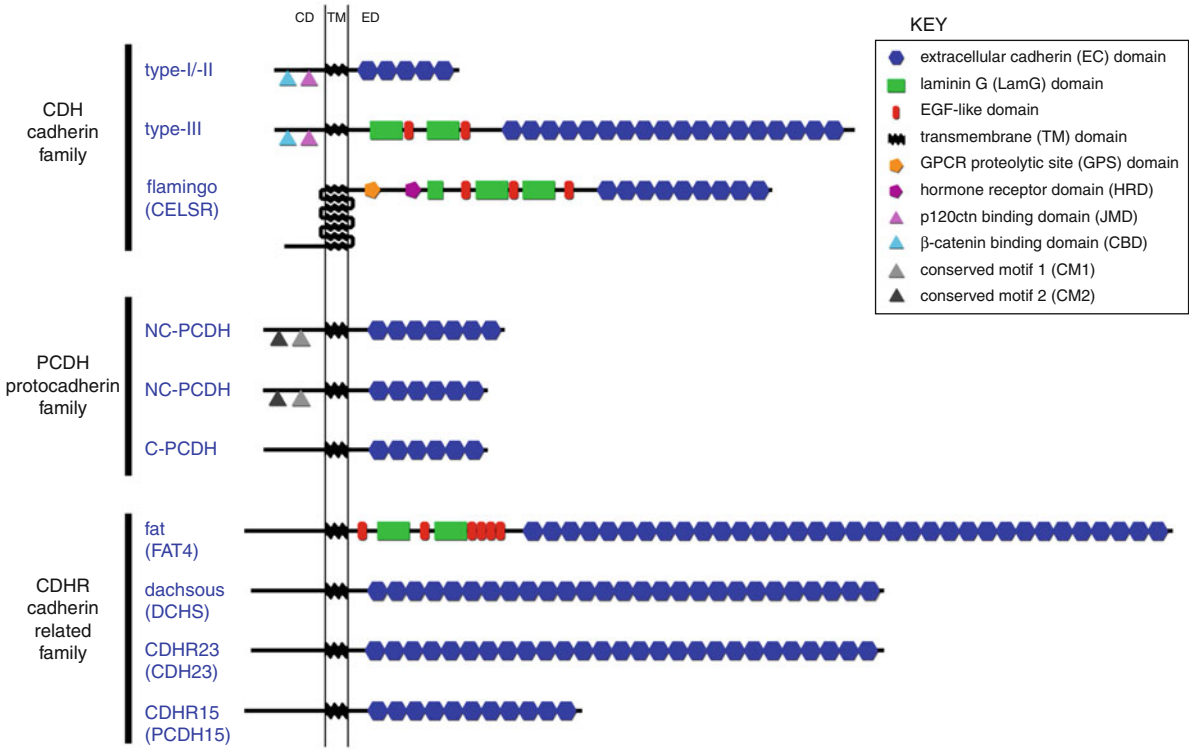
Orthologs are genes in different species that are closely homologous to each other because they represent the divergent copies of a single gene in the last common ancestor. During evolution, orthologs were separated by a speciation event, in contrast to paralogs, which were separated by a gene duplication event.

PDZ is a protein interaction domain of about 70–90 AA, named after a common structure found in the Post-Synaptic Density protein PSD-95, in Discs Large and in Zona Occludens 1 proteins. A PDZ domain in one protein generally interacts with a PDZ recognition motif at the C-terminus of another protein. Such sequence-specific interactions contribute to the formation of protein scaffolds leading to signaling networks.

Further Classification and Phylogenetics of Cadherin Superfamily Members

In mammals, the cadherin superfamily comprises more than 100 different types of cadherins, but ancestral proteins with similar structures were present in the most ancestral metazoans (Hulpiau and van Roy 2009). As the complexity of newly emerging organisms increased, the cadherin superfamily expanded and diverged. As defined above, the cadherin superfamily can be phylogenetically divided into three major families (CDH, PCDH, and CDHR) merely on the basis of ectodomain homologies (Fig. 1) (Hulpiau and van Roy 2009). These families are subdivided mainly on the basis of the domain composition and sequence homology of the ectodomains, TM, and cytoplasmic regions.

The cadherin family consists of classical cadherins (CDH) and flamingo cadherins (CELSR). Each type had an ancient ancestor in early metazoan life, which evolved into about 31 members in mammals by two rounds of whole genome duplications and several individual gene duplications throughout evolution. In addition to the type-I "classical" cadherins, the CDH branch includes type-II or atypical cadherins, the desmosomal cadherins, and several cadherins with longer ectodomains containing additional motifs besides ECs. The latter cadherins are the type-III and type-IV classical cadherins and have additional non-EC calcium-binding motifs in their ectodomain. These motifs consist of alternating epidermal-growth-factor-like (EGF-like) and laminin G (LamG) domains localized between the N-terminal EC repeats and the single TM domain (Fig. 1). The cytoplasmic domains of classical cadherins contain two conserved motifs for binding to proteins with a central armadillo domain, that is, p120ctn and β-catenin. Three other cadherins



Cadherins, Fig. 1 Classification and domain composition of representative members of the cadherin superfamily. The molecules are depicted as mature mammalian proteins with their N-terminal ends on the right. Their sizes range between about 800 and 5000 amino acid residues. On *top*: the cadherin family (CDH) represented by a type-I/-II classical cadherin with five EC domains, a type-III classical cadherin with at least 13 EC domains, and a flamingo (CELSR) cadherin with 9 EC domains. Other typical domains are indicated and explained in the key. In the *middle*: the protocadherin family with non-clustered protocadherins (NC-PCDH) with seven or six ECs, and clustered protocadherins (C-PCDH) with six ECs. At the *bottom*: major members of the cadherin-related (CDHR) family. *CD* cytoplasmic domain, *ED* extracellular domain or ectodomain, *TM* transmembrane domain, *JMD* conserved cadherin-specific juxtamembrane domain

belonging to the CDH family are exceptional. Kidney-specific (Ksp) cadherin-16 and liver intestine (LI) cadherin-17 have seven ECs as a result of duplication of the first two ECs. Cadherin-13, also called T-cadherin (truncated) or H-cadherin (heart) stands out because it is the only known cadherin lacking a TM domain and is instead linked to the cell surface by a glycosylphosphatidylinositol (GPI) anchor (reviewed by Berx and van Roy in Nelson and Fuchs 2010). Cadherin-16, -17, and -13 also lack in their N-terminal region the conserved Trp residue(s) important for the classical adhesion mechanism described below. Finally, the family includes Flamingo/CELSR proteins, which typically have a longer ectodomain with nine ECs, a seven-pass TM domain, and a cytoplasmic domain not related to those of other cadherins.

Most non-vertebrate metazoans have only one type-III classical cadherin with 13 or more ECs, and one flamingo/CELSR cadherin with nine ECs (Hulpiau and van Roy 2009). Vertebrates have many more classical cadherins of type-I and type-II, and they have only five ECs due to the evolutionary loss of N-terminal EC repeats and internal loss of the EGF-like and LamG domains (Hulpiau and van Roy 2009). The desmosomal cadherin genes, comprising clustered desmoglein (DSG) and desmocollin (DSC) genes, evolved from classical cadherin genes in gnathostomes fairly recently.

The largest cadherin family, the protocadherins (PCDH), represents more than half of the cadherin repertoires. They emerged independently and expanded greatly in vertebrates. This expansion is

consistent with their important role in the nervous system. Based on their genomic structure, they can be divided into clustered and non-clustered protocadherins. Humans have over 50 clustered protocadherin genes pooled in neighboring α, β, and γ clusters. Whereas the β cluster consists of repeats of single-exon genes only, mature transcripts of α- and γ-protocadherins are generated from one of several variable exons spliced to a set of three constant exons (Morishita and Yagi 2007). This generates a large number of unique protocadherins with homologous but different N-terminal domains comprising six ECs, one TM, and a short cytoplasmic domain. The latter is elongated in α- and γ-protocadherins by a shared sequence encoded by the constant exons. The non-clustered protocadherins have been called δ-protocadherins and comprise ten members in vertebrates (Hulpiau and van Roy 2009). They have ectodomains with six or seven ECs and are generally expressed as either short or long isoforms, the latter having an elongated cytoplasmic domain with conserved sequence motifs (CM-1 to -3).

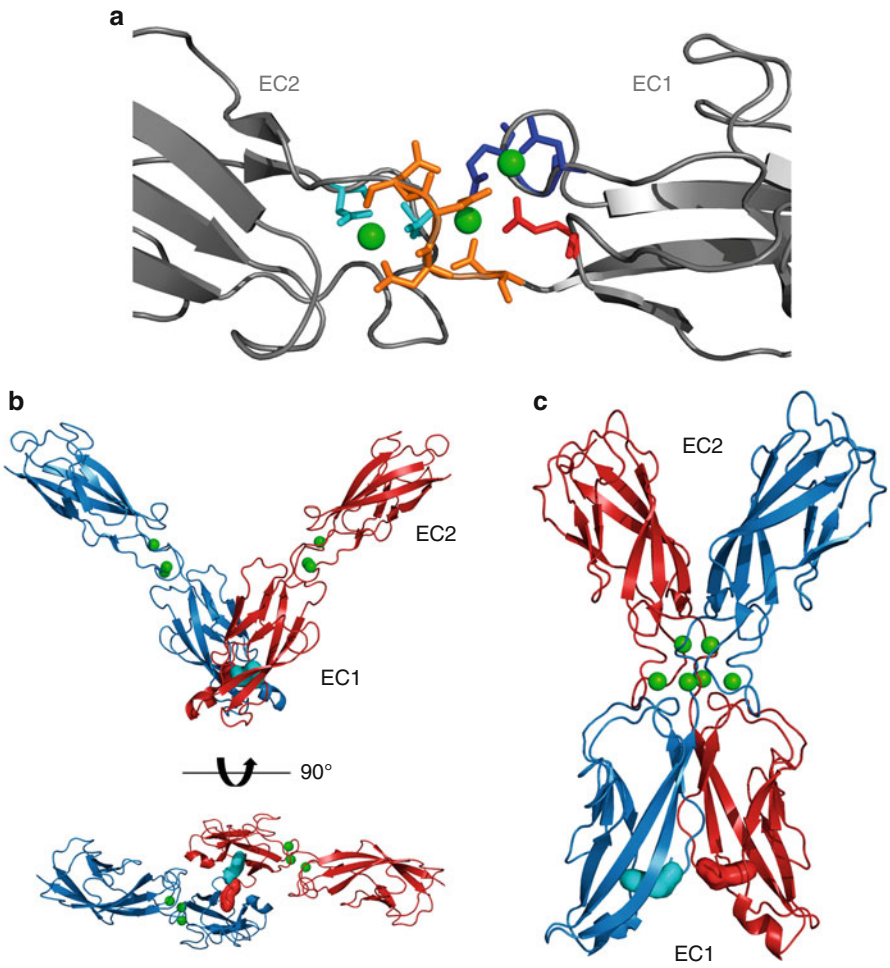
Of the remaining cadherin-related (CDHR) proteins in the superfamily, the best studied are Dachsous (DCHS) and fat/FAT4, which were present in the most ancient multicellular animals (Hulpiau and van Roy 2009). Mammals express four proteins, named FAT1 to FAT4, but only FAT4 is the genuine ortholog of the fruit fly protein fat and a heterophilic interaction partner of DCHS. Indeed, although all mammalian FAT proteins share a long ectodomain with 34 ECs, FAT1 to FAT3 are in fact homologs of *Drosophila* fat-like (ftl or fat2). In mammalian auditory hair cells, cadherin-related-23 (often called cadherin-23 or CDH23) has 27 ECs in its ectodomain and makes heterophilic contact with cadherin-related-15 (often called protocadherin-15 or PCDH15), which has 11 ECs in its ectodomain. This interaction is very important for correct functioning of the inner ear (see below). The cadherin-related proteins with the smallest number of ECs are the proto-oncogene Ret (four ECs) and the calsyntenins (two ECs).

Molecular Structures of Cadherin Domains

Basic structure of the classical cadherin domain (EC). Structural studies on the adhesion mechanisms of cadherins have focused mainly on the vertebrate classical cadherins ([reviewed by Shapiro and Weis in Nelson and Fuchs 2010]; Hulpiau and van Roy 2009; van Roy and Berx 2008). One cadherin repeat (EC domain) folds into a structural unit consisting of seven β-strands forming an immunoglobulin-like Greek key topology. Two consecutive EC domains are stabilized by three calcium ions binding to a cluster of specific AA situated in the interdomain linker. In the primary structure of each EC, these calcium-binding AA are arranged as four conserved motifs: a Glu (E) residue around position 11, a DRE motif in the center, a DxNDxxPxF motif near the C-terminal of the EC, and a DxD motif further downstream in the next EC (Fig. 2a). However, in each cadherin ectodomain, the membrane-proximal last EC typically lacks the C-terminal motif because there is no subsequent EC domain to support binding of a calcium ion at the end of this last one. For that reason, this atypical sequence was also named MPED (membrane-proximal extracellular domain). The *Xenopus* C-cadherin ectodomain, which has five EC domains, has three calcium ions bound in each interdomain region, which fully agrees with the presence of 12 calcium ions in classical cadherin proteins.

Homophilic adhesion mode. The ectodomains of cadherins form a molecular layer composed of two interfaces involved in the assembly of junctions: *trans* adhesive interfaces between cadherins on apposed cell surfaces and *cis* interactions between cadherins in the same cell surface (Harrison et al. 2011).

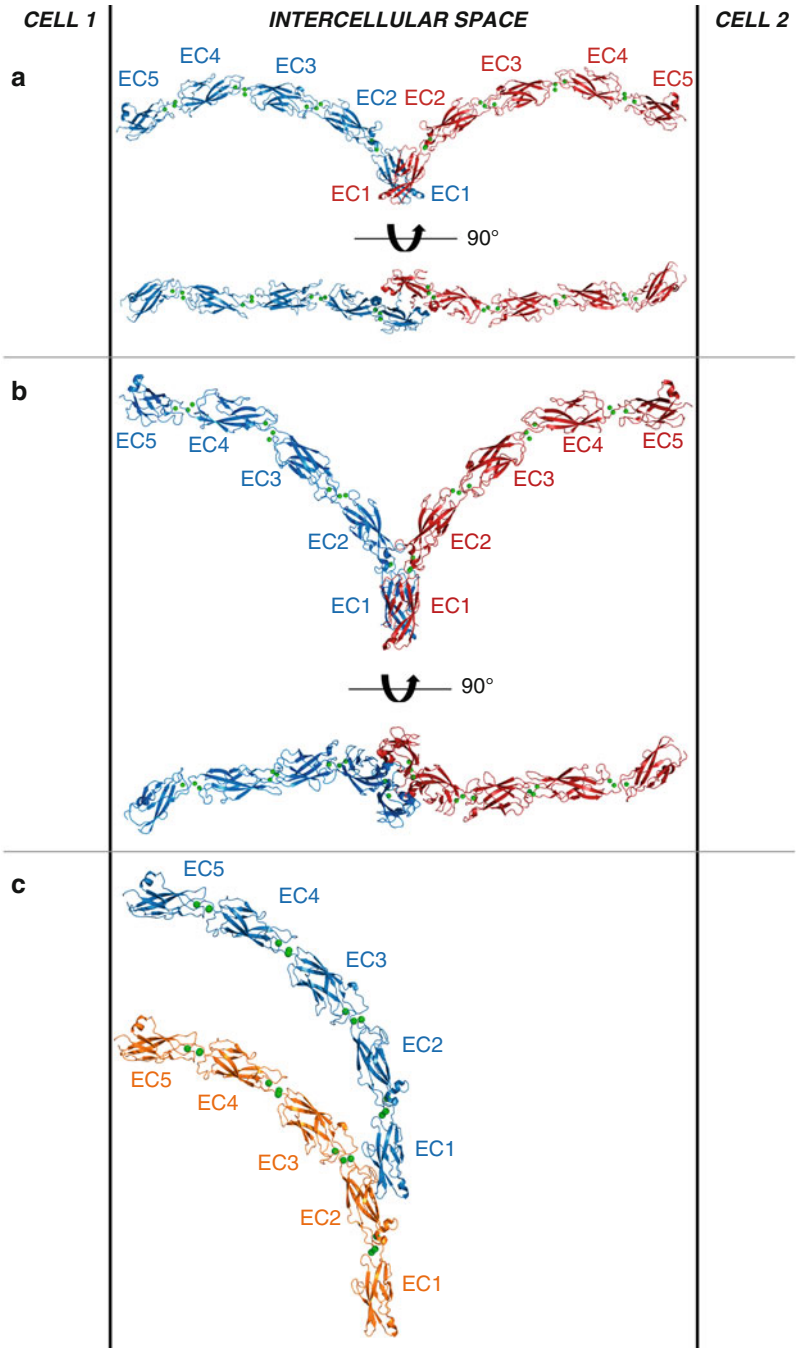
It is widely accepted that there are two dimeric homophilic binding modes in *trans*. Both of them are based on free N-terminal ends of opposing EC1 domains; this occurs when a signal peptide and a prodomain are removed from the preproprotein. In the first binding configuration, the EC1 structures of two cadherin molecules on apposed cells exchange their N-terminal β-strands. For type-I cadherins, a Trp residue docks into a hydrophobic pocket generated by a conserved His-Ala-Val sequence in the apposed EC. For type-II cadherins, this anchoring occurs by two Trp residues. This type of adhesive *trans* interface is called the strand swapping dimer (Figs. 2b and 3a). The second *trans* binding mode is called the X-dimer mode and is considered an intermediate form in type-I and type-II cadherins. Here, the apposed cadherin molecules contact each other at the interdomain of the first and second EC domains to form an X-shaped structure (Figs. 2c and 3a). T-cadherin (CDH13) cannot form a strand swap dimer because it



Cadherins, Fig. 2 Detailed view of calcium-binding motifs and adhesion interfaces in cadherins. (**a**) Binding of three Ca^{2+} ions in the linker region between successive EC domains (http://www.rcsb.org/; PDB (protein data bank) code: 1FF5). Four conserved motifs are involved: in the first EC domain, Glu11 in the PEN (Pro-Glu-Asn) motif is indicated as a *red stick*; Asp67 and Glu69 in the LDRE (Leu-Asp-Arg-Glu) motif are indicated in *blue*; Asp100 and the subsequent residues in the DxNDN (Asp-x-Asn-Asp-Asn) motif are indicated in *orange*; in the DxD motif of the second EC, Asp134 and Asp136 are shown in *cyan*. Ca^{2+} ions are shown as *green spheres*. (**b**) The strand swapping adhesion interface. The tryptophan (Trp) residues of the N-terminal adhesion arm in each EC1 are highlighted in *red* and *blue* surface representation, and they anchor into a hydrophobic pocket in the opposite EC1. (**c**) The X-dimer adhesion interface. Interaction occurs at the EC1-EC2 interdomain near the Ca^{2+} ions. The Trp residues in the adhesion arms of EC1 dock into their own protomer

has no Trp residue near its N-terminus. Instead, the X-dimer mode is used as a final adhesive interface by this GPI-anchored cadherin. Structural studies on an E-cadherin EC1–EC2 dimer have shown that the X-dimer is formed at intermediate Ca^{2+} concentrations of 500 μM to 1 mM when the Trp residue docks into its own protomer (reviewed by Hulpiau and van Roy 2009; van Roy and Berx 2008). At Ca^{2+} concentrations above 1 mM, strand swapping interactions start to predominate. Below 50 μM Ca^{2+}, an ectodomain structure of consecutive ECs is not stable. A third model, the so-called interdigitation model, involves a much more protrusive interaction of the apposed ectodomains, with the N-terminal EC1 binding to internal ECs up to EC4 (reviewed by van Roy and Berx 2008).

Further, the curved shape of the full size C-cadherin ectodomain has been fitted onto cryoelectron tomography images of mouse desmosomes (reviewed by Shapiro and Weis in Nelson and Fuchs 2010).



Cadherins, Fig. 3 Structural overview of the different adhesion mechanisms used by classical cadherins. Ectodomains of cadherins are represented by five EC domains in the intercellular space, with the EC5 proximal to the surface of the cell in which the respective cadherins reside. The 12 Ca^{2+} ions are represented by *green spheres*: four sets of three ions in between EC domains. (**a**) Structure of the strand swap dimer in *trans*. Adhesion occurs near the N-terminus of EC1. There is no *trans* contact between the EC1–EC2 interdomain regions. (**b**) Structure of the X-dimer in *trans*. The apposed cadherins contact each other at the EC1–EC2 interdomain region. (**c**) Structure of the *cis* interface. The concave side of the EC1 domain in the cadherin ectodomain (*blue*) interacts with the EC2 convex side of the neighboring cadherin (*orange*)

The visualized interactions resemble W, S, and λ shapes that are consistent with Trp swapping models. An interaction network of three molecules has been proposed for the λ shape. In this model, the Trp of the first molecule is near the hydrophobic pocket of the second one. The Trp of the second molecule is then near the hydrophobic pocket of a third molecule and the Trp of the third molecule is free. Furthermore, other molecular networks with even more cadherin molecules are conceivable, for example, a λ shape with an additional molecule in *cis* forming a desmosomal knot.

The *cis* interface found in E-, N-, and C-cadherin molecules consists of an asymmetric interaction between the EC1 domain of one molecule and the EC2 of a neighboring molecule on the same cell surface (Fig. 3c). The concave face of EC1 opposite the *trans* dimer interface interacts with the convex side of EC2 of the next protomer. This means that each cadherin ectodomain can form two *cis* interfaces by using both its EC1 concave side and its EC2 convex face. These *cis* interactions can then be further combined with the strand-swapping *trans* interaction to complete the junctional structure. Whereas mutations that interfere with the *trans* interface abolish cell–cell adhesion completely, *cis* interface mutations make junctions extremely mobile and unstable (Harrison et al. 2011).

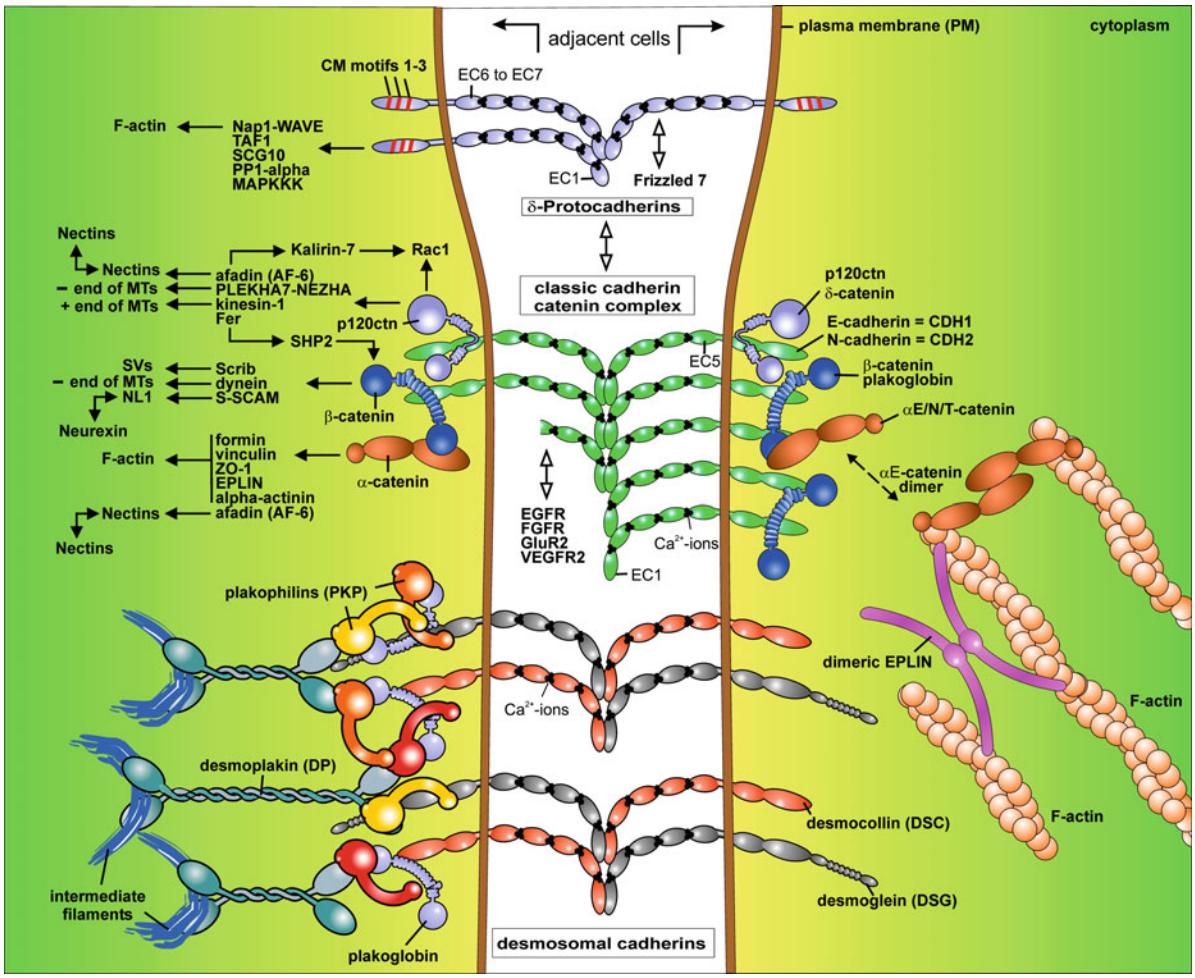
Much less is known about the homophilic adhesion mechanisms of other types of cadherins. Sequence analyses of protocadherins, cadherin-related proteins, and invertebrate classical cadherins point to a mechanism other than the strand swapping binding mode. Future studies might reveal whether their interfaces resemble that of the X-dimer or of another unknown adhesion mechanism. Initial structures have already been determined for the EC1 of one protocadherin (PCDH-α4) and one cadherin-related protein (CDH23), but not in homophilic adhesion mode. EC1 of PCDH-α4 lacks a Trp near its N-terminus and consequently the hydrophobic pocket in which Trp can dock is also absent.

Heterophilic adhesion mode. Until recently, little was known about cadherin-mediated heterophilic adhesions. N-cadherin (CDH2) and R-cadherin (CDH4), both of which are classical type-I cadherins, can form *cis* heterodimers, presumably by adapting a strand swapping conformation using their single Trp residue nearby the N-terminal end (reviewed by Shapiro and Weis in Nelson and Fuchs 2010). A specific *trans* interaction has been reported between E-cadherin (CDH1) and LI-cadherin (CDH17), which are prominently present in intestinal epithelial cells (reviewed by Hulpiau and van Roy 2009). The following two important heterophilic interactions between cadherin-related molecules have been recognized, but the mechanisms remain unclear. The first interaction occurs between mammalian fat (FAT4) and Dachsous (DCHS1). The other is the *trans* interaction between a cadherin-related-23 (CDH23) homodimer and a cadherin-related-15 (CDHR15/PCDH15) homodimer. Current structural knowledge is limited to the CDHR23 EC1–EC2 domains (Elledge et al. 2010): unexpectedly, there is an extra calcium (Ca0) at the N-terminus. Mutating Asn3 and Arg4 residues nearly abolishes the heterotypic interaction; this means that they are crucial in this novel adhesion mechanism. Finally, protocadherins interact with classical cadherins, but the mechanism is not known. N-cadherin was shown to bind to Pcdh8 (reviewed by Nishimura and Takeichi 2009). In *Xenopus*, paraxial protocadherin (PAPC) is one of the three homologs of mammalian protocadherin-8 (Hulpiau and van Roy 2009), and it can form a functional complex with fibronectin leucine-rich domain transmembrane protein-3 (FLRT3) and with C-cadherin. Many of the structures mentioned above need further structural and experimental validation to elucidate the mechanisms involved. There is not even a single adhesion structure reported for several types of cadherins and cadherin-related molecules, such as the longer type-III cadherins, flamingo (CELSR) cadherins, Fat, Fat-like, and Dachsous cadherins.

Heterotypic adhesion modes (between different cell types) might be fully mediated by cadherins, but they might also involve other types of adhesion molecules. For instance, the localization of intraepithelial lymphocytes in the intestine is based on a heterophilic, heterotypic interaction between E-cadherin on keratinocytes and αEβ7 integrins on lymphocytes (reviewed by van Roy and Berx 2008). The Glu31 residue at the tip of the EC1 structure is essential for this binding as well as, surprisingly, the MPED (or EC5) domain.

Adhesion Characteristics of Cadherins

Type I classical cadherins have been shown to mediate strong and selective cell–cell adhesion that is generally both homophilic (like molecules bind each other on apposed cell surfaces; Figs. 3 and 4) and homotypic



Cadherins, Fig. 4 Schematic overview of representative cadherin superfamily members making intercellular contacts. The scheme represents a "universal" cell type. Natural cell types, such as epithelial cells or neurons, generally express only some of the molecules depicted, while other cadherin superfamily members and associated molecules not shown here might also be expressed. *On top*: homophilic interaction between δ-protocadherins having six to seven extracellular cadherin repeats (EC1 to EC6 or -7). Their cytoplasmic domains may contain conserved motifs CM1–CM3, and they may interact with the intracellular proteins listed on the *left*. In the *middle*: the classical cadherin–catenin complex (CCC), with five ECs in their ectodomain, binding to each other in both *cis* and *trans* adhesion modes (see text). The cytoplasmic domains of classic E- and N-cadherin share two conserved domains for interaction with armadillo proteins, including p120ctn binding to a juxtamembranous domain (JMD), and β-catenin binding to a more C-terminal catenin-binding domain (CBD). At the *bottom*: composition of typical desmosomes; various desmosomal cadherins (DSG and DSC isoforms) contribute to this junction. Their cytoplasmic domains associate with a variety of armadillo proteins, including plakoglobin and plakophilins (PKP), and possibly also with the aminoterminal ends of desmoplakin (DP) dimers. Alternatively, the main role of plakoglobin and PKP may be to link DSG and DSC to DP. The drawing also summarizes several other molecular interactions, either in the extracellular space (indicated by *double open arrows*), or in the cytoplasm. Briefly, monomeric α-catenin binds to the CCC via β-catenin. It can occur as three isoforms: αE-, αN-, and αT-catenin. Dimeric αE-catenin cannot bind β-catenin but instead binds and cross-links filamentous actin (F-actin). The *broken double arrow* indicates a possible dynamic conversion between the monomeric and dimeric states. A selection of additional cytoplasmic interaction partners of p120ctn, β-catenin and α-catenin is listed on the *left* and described in the text. *Single arrows* indicate molecular interactions or activating effects; *double bent arrows* indicate additional systems of intercellular junctions. *SVs*: synaptic vesicles (Modified after Brigidi and Bamji (2011); van Roy and Berx (2008))

(like cells bind each other). A good example of homophilic, heterotypic interaction mediated by E-cadherin is the binding between keratinocytes and melanocytes. Historically, the founding member E-cadherin, a type-I epithelial cadherin, was discovered as a mammalian transmembrane protein of about 120 kDa that was protected by Ca^{2+} against iodination and trypsinization, and mediates Ca^{2+}-dependent cell–cell adhesion (reviewed by van Roy and Berx 2008). Antibodies reactive with its ectodomain revealed that different tissues express related but not identical cadherin types. Distinct spatiotemporal expression patterns have been consistently observed for the large cadherin superfamily. Further, use of neutralizing antibodies confirmed the essential contribution of classic cadherins to cell–cell adhesion. Once the corresponding cDNAs were cloned and used in dual transfection experiments, individual cells in mixed aggregation cultures were found to sort out from each other on the basis of homophilic cadherin-mediated adhesion activity (reviewed by van Roy and Berx 2008). The protein motif that is mainly responsible for this homophilic recognition is localized in the N-terminal EC1 repeat. A stretched and stable structure of the whole ectodomain is essential and possible only upon Ca^{2+} binding.

The cadherin-dependent cell adhesion strength is much enforced by clustering due to interactions with a cortically organized actin cytoskeleton. In the case of type-II classic cadherins, evidence for strong and homophilic cell–cell adhesion is often lacking, and the binding pattern might be rather promiscuous. For protocadherins, the evidence regarding cell–cell adhesion is still sparse but points to weak interactions, but nevertheless, these proteins might have important functions in sorting out different cell types (see below).

The GPI anchor of cadherin-13 forms the basis for its unusual location at apical instead of basolateral membranes in polarized epithelial cells (reviewed by Berx and van Roy in Nelson and Fuchs 2010). The cadherin-13 adhesion mode is homophilic but relatively weak, possibly due to its structural peculiarities summarized above. This weakness, in combination with the absence of direct coupling to intracellular structures, implies that cadherin-13 functions mainly in cell recognition and signaling rather than in adhesion (see also below). Phylogenetically, cadherin-16 and cadherin-17 also branch separately from the typical cadherins (Hulpiau and van Roy 2009). They show a duplication of the first two N-terminal ECs generating a seven-EC ectodomain, in combination with a short cytoplasmic domain lacking both conserved motifs for interaction with armadillo proteins. These two elongated cadherins were found to interact homophilically but with lower adhesion strength than classical cadherins. Evidence was recently provided for a heterophilic interaction between cadherin-17 and E-cadherin.

Expression Patterns of Cadherin Family Members

E-cadherin is widely expressed in most epithelial tissues and cell lines. In simple monolayered epithelia with well-organized intercellular contacts, the junctions are concentrated in the lateral cell–cell contacts. E-cadherin is expressed along the whole lateral plasma membrane but can be enriched in more compact adherens junctions (AJ), also named zonulae adherentes (ZA). These junctions are associated with a subcortical concentration of actin filaments, and are generally localized near the apical surface but below the tight junctions (zonulae occludentes). Tight junctions serve as a selective barrier against the "outside world" by controlling the paracellular transport of molecules and small particles. In the lateral membranes, there are also gap junctions for chemical and direct electrical intercellular communication, and the spot-like desmosomes (maculae adherentes), which form shear-resistant intercellular junctions distributed rather randomly on the lateral surfaces of simple epithelia (reviewed in Nelson and Fuchs 2010). Due to their multimolecular cytoplasmic plaque structure, desmosomes are rigidly connected by the linker protein desmoplakin to intermediate filaments, which are cytokeratins in epithelial cells. Interestingly, in both desmosomes and AJ, the cells are connected by members of the cadherin superfamily, but the packing density of desmosomal cadherins is much higher (Harris and Tepass 2010). Desmosomal cadherins occur as several isoforms of either desmogleins (DSG) or desmocollins (DSC), all of which have a single ectodomain with four typical calcium-binding ECs and a membrane-proximal anchor region (reviewed by Delva et al. in Nelson and Fuchs 2010). Both DSG and DSC seem to be required for strong cell–cell interactions, although it is unclear whether this occurs in a homophilic way (for instance, DSG1 binding to DSG1) or a heterophilic way (for instance, DSG1 binding to DSG2 or DSC1). The cytoplasmic

domains of these desmosomal cadherins are longer than those of classical cadherins because they contain more motifs. Interaction occurs with plakoglobin, plakophilins, and desmoplakin (Fig. 4).

In multilayered stratified epithelia, such as the epidermis, only the basal cells contacting the basal lamina show a polarity comparable to that of simple epithelia. The suprabasal layers express E-cadherin and form desmosomes all over their perimeter, and in that way the layers are bound together tightly in the tissue. The expression of particular DSG, DSC, and PKP isoforms is influenced by the differentiation status of the suprabasal cells (reviewed by Delva et al. in Nelson and Fuchs 2010). In other tissues, the situation is varied. For instance, N-cadherin in neurons is localized at tiny synaptic contacts (puncta adhaerentia) and contributes to synaptogenesis by circumscribing the central neurotransmitter release zone (reviewed by Giagtzoglou et al. in Nelson and Fuchs 2010). In the heart, N-cadherin, a type-I classic cadherin, is localized at so-called intermediate junctions (fasciae adherentes) in the intercalated discs connecting individual cardiomyocytes (reviewed by Franke in Nelson and Fuchs 2010). These junctions also contain peculiar molecular complexes that comprise both classical desmosomal proteins (plakophilin-2, desmoplakin) and adherens junctional (AJ) proteins (beta-catenin, alpha-E-, and alpha-T-catenin). In endothelial cell junctions, N-cadherin is strongly expressed but not at homotypic junctions (between endothelial cells). Indeed, the main cell–cell adhesion function is taken over by a class-II classic cadherin, VE-cadherin or cadherin-5. In muscle cells, cadherin-15 (M-cadherin) is the major class-II cadherin. In mesenchymal cells, including osteoblasts, cadherin-11 (OB-cadherin) is an important classic cadherin. Cadherin-16 and -17 are expressed predominantly in renal and intestinal epithelia, respectively. GPI-anchored cadherin-13 is expressed by endothelial cells, mostly at the leading edge of migrating cells, and this has a pro-survival and pro-angiogenic effect (reviewed by Berx and van Roy in Nelson and Fuchs 2010).

Much less is known about the expression patterns of other cadherin superfamily members. Vertebrate CELSR2 and CELSR3 are expressed by several types of neurons. FAT1, the vertebrate homolog of *Drosophila* fat-like, is expressed at lateral cell junctions of epithelial cells but it is more abundant in basal regions than in AJs. Nonetheless, loss of FAT1 indirectly affects AJ integrity by influencing F-actin organization (Nishimura and Takeichi 2009). Mammalian FAT4, the ortholog of *Drosophila* fat, is expressed in various cell types, where it interacts heterophilically with Dachsous-1 (DCHS1) in neighboring cells of identical or different types. Protocadherins are differentially expressed at high levels in various neural tissues, but the delta-protocadherins are also widely expressed by other cell types. As mentioned above, the cadherin-related proteins CDHR15 (PCDH15) and CDHR23 interact with each other in auditory hair cells of the inner ear, both as transient links between adjacent stereocilia in developing hair cells and as tip links in mature hair cells (reviewed by El-Amraoui and Petit in Nelson and Fuchs 2010).

Molecular Interaction Partners and Functions of Cadherin Superfamily Members

Agreement on the biological relevance of the cadherin superfamily members is evidenced by numerous functional studies. Cadherins play key roles during early embryonic development and in morphogenesis (reviewed by Stepniak et al. in Nelson and Fuchs 2010; reviewed by Nishimura and Takeichi 2009). Not surprisingly, they are affected in many genetic diseases and other pathologies, and particularly in cancer (see below). Mechanistically, one can divide the functional parts of cadherins into two domains: the extracellular one and the cytoplasmic one. First, the number of EC repeats in the N-terminal extracellular domain is variable, and there are additional EGF-like and LamG repeats in several family members (Fig. 1). This extracellular domain is mainly involved in *cis* and *trans* binding with other cadherins, but it can also associate with other transmembrane proteins, as pointed out below. Second, the cytoplasmic domains exhibit more structural variability among family members but often have conserved domains within subfamilies. These domains are either known to bind specific cytoplasmic interaction partners for structural or signaling purposes or are expected to do so. In the case of classic cadherins, these interaction partners are armadillo proteins, which have been studied extensively. More recently, cytoplasmic interaction partners for protocadherins and cadherin-related proteins have also been identified, but other binding proteins will surely be discovered.

Cytoplasmic interaction partners of classical cadherins. The cytoplasmic domains of classic

cadherins (types I to IV) bind two types of armadillo proteins: p120ctn and related protein family members, and beta-catenin and the homologous plakoglobin (gamma-catenin). More specifically, p120ctn binds to a conserved juxtamembrane domain (JMD), whereas β-catenin binds to a conserved C-terminal domain (Fig. 4). Association of p120ctn protects cadherins from premature endocytosis and hence stabilizes the junctions (reviewed by van Roy and Berx 2008). On the other hand, β-catenin forms a molecular bridge between the cadherins and α-catenins, which are F-actin-binding vinculin-related proteins. In a classical cadherin–catenin complex, also referred to as CCC, classic cadherins are linked to the F-actin cytoskeleton via a β-catenin/α-catenin molecular bridge, which is sensitive to regulation, for instance by reversible phosphorylation or irreversible ubiquitination (reviewed by van Roy and Berx 2008). However, recent data reported by the Nelson and Weis groups have cast doubt on this model: other actin-binding linker molecules, such as α-actinin and Eplin, might be involved in the cytoskeletal anchoring of cadherin-dependent junctions (Fig. 4). Interestingly, both p120ctn and β-catenin have important signaling functions as cytoplasmic or nuclear proteins outside the CCC, but these functions fall beyond the scope of this essay. Consequently, sequestering these armadillo proteins by cadherins at the junctions inhibits their alternative functions. This generates a more quiescent phenotype that is less proliferative and less migratory. Even more molecular complexity is reached by the binding of the protein afadin (AF-6) to either p120ctn or α-catenin in the CCC (reviewed by Nishimura and Takeichi 2009; van Roy and Berx 2008) (Fig. 4). Indeed, the central PDZ domain of afadin can bind at the same time to the C-termini of nectins. The latter are immunoglobulin-like transmembrane adhesion molecules binding either homo- or heterophilically. In this way, nectin–nectin interactions facilitate, via cytoplasmic bridging, cadherin-mediated AJ formation.

It is important to realize that the catenins in the classic CCC serve not only in mechanistic assembly but also in extensive focal signaling. This concept has become progressively clear in recent years and has been studied most extensively at excitatory synapses (reviewed by Brigidi and Bamji 2011; Harris and Tepass 2010). On one end, the C-terminus of β-catenin has a PDZ-binding motif through which it acts as a scaffold for recruitment of various proteins to the CCC, including the presynaptic scaffolding protein Scribble and the postsynaptic scaffolding protein S-SCAM (Magi2) (Fig. 4). Synaptic vesicles (SVs) are recruited via Scribble to the presynaptic membrane. Moreover, cadherin-associated p120ctn recruits the cytoplasmic tyrosine kinase Fer to the CCC. Fer phosphorylates and activates the tyrosine phosphatase SHP2, which in turn dephosphorylates β-catenin and thereby promotes the stability of the CCC and the local clustering of SVs. At the postsynaptic side, CCC-associated S-SCAM recruits the cell adhesion protein neuroligin-1 (NL1) to the synapse, where it engages in a *trans*-synaptic binding with neurexin. This has a cooperative effect on the clustering of SVs in the presynaptic compartment. Likewise, δ-catenin binds several PDZ-domain-containing proteins, including postsynaptic receptor scaffolding proteins. δ-catenin is a p120ctn homolog exclusively expressed in the brain. By modulating small GTPases, both CCC-associated and cytoplasmic p120ctn and δ-catenin contribute to the regulation of postsynaptic spine morphology (spine head width, length, and density) (reviewed by Brigidi and Bamji 2011). Moreover, spine head width is increased by the clustering of postsynaptic N-cadherin. The associated α-catenin recruits the adaptor molecule afadin (AF-6), which in turn recruits the Rac-GEF Kalirin-7, promoting Rac1-dependent spine maturation. Functional interaction of catenins, be it β-catenin, p120ctn, or α-catenin, with small GTPases and actin remodeling proteins is a recurrent theme that has evident implications for correct tissue morphogenesis (reviewed by Harris and Tepass 2010).

More recently, it has been demonstrated that AJs also interact with microtubules, either the plus ends of microtubules via β-catenin, or the minus ends of microtubules via p120ctn (reviewed by Harris and Tepass 2010) (Fig. 4). Microtubular minus ends are associated with the centrosomes in single cells, but in polarized epithelial cells lateral microtubules are typically oriented with their minus ends directed toward the AJ in the apical part of the lateral membranes. Association of the AJ with microtubules facilitates its assembly, and in addition it allows the AJ to influence intracellular structuring. For instance, the orientation of both symmetric and asymmetric cell divisions turned out to be influenced by AJs (reviewed by Harris and Tepass 2010).

Cytoplasmic interaction partners of non-classic cadherins. Knowledge about molecular interaction partners of non-classic cadherin types is sparser. The cytoplasmic sequences of non-clustered δ-protocadherins are rather diverse and so are their interaction partners (reviewed by Redies et al. 2005) (Fig. 4): the phosphatase PP1α binds to the conserved motif CM3 (sequence RRVTF), which is present in a subclass of long isoforms; the transcriptional regulator TAF1/Set binds to the cytoplasmic domain of protocadherin-7; the adaptor protein Dab-1 binds to the cytoplasmic domain of protocadherin 18. For the clustered protocadherins, which have within each cluster a largely shared cytoplasmic domain (see above), the tyrosine kinase Fyn has been shown to associate with α-protocadherins, whereas the microtubule-destabilizing protein SCG10 associates with at least one member of the γ-protocadherins.

The functional consequences of these specific interactions are generally poorly understood. A recent report describes a specific complex between the actin-organizing complex Nap1/WAVE and the cytoplasmic domain of protocadherin-10 (OL-protocadherin) (reviewed by Nishimura and Takeichi 2009). Evidence shows that this complex stimulates migration: at sites of cell–cell contacts, protocadherin-10 becomes enriched and it recruits Nap1/WAVE, which in turn leads to weakening of the classic CCC at the junctions. These molecular interactions might explain the aberrant migration of particular neurons in mice in which protocadherin-10 is knocked out. Also the cytoplasmic tail of the cadherin-related protein FAT1 interacts with an actin organizer, Ena/VASP, and this regulates actin dynamics such as polymerization of stress fibers (reviewed by Nishimura and Takeichi 2009). It is noteworthy that the cytoplasmic domain of FAT4 deviates completely from those of FAT1 to FAT3 (Hulpiau and van Roy 2009). Upon binding of FAT4 to DCHS1, FAT4 signals to the Hippo-YAP pathway, which has tumor suppressor activity in humans, but the underlying mechanism is unresolved (reviewed by Berx and van Roy in Nelson and Fuchs 2010). Both CDHR23 and CDHR15 (PCDH15) occur as alternative splice forms differing in sequence only in their cytoplasmic domains (reviewed by El-Amraoui and Petit in Nelson and Fuchs 2010). Particular isoforms interact with the PDZ domain protein harmonin. The cytoplasmic domain of one CDHR15/PCDH15 isoform interacts also with myosin VIIa.

Transmembrane interaction partners. On the other hand, also the ectodomains of classic cadherins are involved in interactions with other protein types. For instance, the E-cadherin ectodomain interacts physically with the ectodomains of receptor tyrosine kinases, such as EGFR and the HGF-receptor c-Met. These interactions have either an inhibitory effect on the growth stimulating effects of the ligand, or a stimulatory effect ascribed to co-endocytosis of E-cadherin with the receptor (reviewed by van Roy and Berx 2008). It has been demonstrated that the ectodomain of N-cadherin interacts molecularly and functionally with the FGF-receptor ectodomain to prevent FGFR internalization and allow sustained receptor activation and downstream signaling (reviewed by Berx and van Roy in Nelson and Fuchs 2010). In neural cells, the ectodomain of N-cadherin also associates with the AMPA receptor GluR2, and this interaction appears to be essential for GluR2-mediated spine maturation (reviewed by Brigidi and Bamji 2011). Interestingly, the ectodomain of the *Xenopus* δ-protocadherin PAPC (Hulpiau and van Roy 2009) interacts with the ectodomain of Frizzled-7, and both of these transmembrane proteins turned out to be essential for planar cell polarity (PCP) phenomena, such as convergent extension movement of mesoderm during gastrulation (reviewed by Nishimura and Takeichi 2009; Redies et al. 2005). GPI-anchored cadherin-13 shows a peculiar type of binding (reviewed by Berx and van Roy in Nelson and Fuchs 2010). Upon homophilic ligation on endothelial cell surfaces, this atypical cadherin becomes linked to Grp78/BiP. The latter is normally ER-retained but can be secreted under particular conditions. The formation of the complex of Grp78 with cadherin-13 triggers the anti-apoptotic Akt kinase pathway.

In view of these findings on extracellular interactions, it is somewhat surprising that several transmembrane proteins seem to interact with the cytoplasmic domains of classic cadherins. For instance, in endothelial cells, VEGFR2 associates with the cytoplasmic domain of VE-cadherin (the type-II cadherin-5). This interaction also leads to prevention of receptor internalization and signaling, which ultimately inhibits cell growth. Another interesting case is the cytoplasmic interaction in synaptic junctions of N-cadherin with arcadlin, which corresponds to the rat protocadherin-8, a non-clustered δ-protocadherin (reviewed by Nishimura and Takeichi 2009). Excitation of hippocampal neurons upregulates arcadlin, and this

promotes N-cadherin internalization, a process accelerated by the homophilic interaction of arcadlin ectodomains and involving an associated MAPKKK. A similar observation of cross-inhibition involves the induction by activin of PAPC expression in *Xenopus*, which is linked to decreased adhesion activity of C-cadherin, a class-I cadherin in frog.

Cadherin-Associated Pathologies in Mouse Models and Human Patients

Several zygotic (total) and conditional knockout mice have been generated for members of the cadherin superfamily and for the cytoplasmic catenins associated with them (reviewed by Stepniak et al. in Nelson and Fuchs 2010). The cadherins analyzed in this way are mainly from the type-I and type-II families. A zyogotic knockout of E-cadherin is early lethal (at E4) due to defects in trophectoderm. Interestingly, these defects could not be rescued by expressing an N-cadherin cDNA from the E-cadherin locus in a gene replacement approach. Zygotic N-cadherin ablation leads to death at E10 due to heart defects. Various mice with tissue-specific knockout of E-cadherin, N-cadherin, or both of them often develop lethal defects associated with impaired differentiation and induced apoptosis. The zygotic knockout of cadherin-5 (VE-cadherin) is lethal at E9.5 due to severe vascular defects. The zygotic knockout of protocadherin-10 (OL-protocadherin), which interacts with the actin-regulating complex Nap1-WAVE, results in abnormal migration of the growth cones of striatal neurons (reviewed by Nishimura and Takeichi 2009). The importance of a few other δ-protocadherins has been studied by gene silencing in *Xenopus* (reviewed by Redies et al. 2005). Zygotic deletion of the entire cluster of γ-protocadherins revealed a role for these proteins in spinal synaptic development and activity (reviewed by Morishita and Yagi 2007). Further, it is noteworthy that the zygotic knockout of cadherin-related protein 23 (CDHR23) leads to degeneration of inner ear structures, vestibular defects, and deafness. Also other mutants of mouse and zebrafish demonstrate the importance of CDHR23–CDHR15 interactions for correct auditory hair organization and associated mechano-electrical transduction. Most importantly, Usher syndrome 1 (USH1), which is the most severe form of hereditary deaf-blindness in humans, is a monogenic disorder caused by mutations in any one of five USH1 genes; four of these genes encode the above-mentioned proteins: CDHR23, CDHR15 (PCDH15), harmonin, and myosin VIIa (reviewed by El-Amraoui and Petit in Nelson and Fuchs 2010).

Human mutations in P-cadherin (class-I cadherin-3) have been linked to the HJMD and EEM syndromes, which have common features such as hair loss and progressive blindness. Also mutations in the human desmoglein-4 (DSG4) gene are associated with an inherited hair disorder. The importance of appropriate desmosome formation is also demonstrated by the following findings (reviewed by Stepniak et al. in Nelson and Fuchs 2010). Autoantibodies against either DSG1 or DSG3 cause, respectively, the blistering diseases pemphigus foliaceus and pemphigus vulgaris. Heterozygous mutations in the human genes encoding the desmosomal components DSG2, DSC2, plakoglobin, plakophilin-1 and -2, and desmoplakin are at the basis of about 50% of arrhythmogenic right ventricular cardiomyopathy (ARVC). One more example of a cadherin superfamily member associated with disease in humans is protocadherin-19, a δ-protocadherin encoded by the X-chromosome. Mutations in PCDH19 have been identified in a female-restricted epilepsy and cognitive impairment syndrome and also in the Dravet syndrome, which is featured by epileptic encephalopathy mainly in females. It has been proposed that protocadherin-11Y (PCDH11Y), encoded by the human Y-chromosome, might compensate for the PCDH19 defects in males. Finally, the small CLSTN1, which has only 2 ECs, has been related to Alzheimer's disease.

Importantly, several cadherin family members are involved in the major human pathology of cancer (reviewed by Berx and van Roy in Nelson and Fuchs 2010). The inactivation of E-cadherin in malignant epithelial cancers has been a paradigm for a cell–cell adhesion molecule functioning as both tumor suppressor and invasion suppressor. E-cadherin can become inactivated in cancer by different events: inactivation mutations in combination with allelic loss, as frequently observed in invasive lobular breast cancers, germline mutations in families with hereditary diffuse gastric cancer (HDGC), promoter methylation, and transcriptional silencing by members of the Snail/Slug or ZEB families. Also posttranslational modifications, such as specific phosphorylation of cadherins or catenins, and increased endocytosis of the CCC might play a role in increasing the

malignancy of tumor cells. Regularly seen in tumor cells at the invasive front is the process of epithelial-mesenchymal transition (EMT), which is concomitant with cadherin switching: epithelial E-cadherin is downregulated and replaced by so-called mesenchymal cadherins, such as N-cadherin, cadherin-6, or cadherin-11. It is most interesting that similar cadherin switches do occur during dynamic morphogenetic processes. Impressive examples are the processes of neurulation, somitogenesis, and neural crest morphogenesis and directed migration (reviewed by Stepniak et al. in Nelson and Fuchs 2010).

There is mounting evidence that other cadherin superfamily members can serve as tumor suppressors, including several δ-protocadherins, such as protocadherin-8, -10, and -20. In contrast, it has been proposed that cytoplasmic expression of a protocadherin-11Y isoform truncated at its N-terminus contributes to the androgen resistance of advanced prostate cancers. Overexpression of cadherin-5 (VE-cadherin) in melanomas causes vascular mimicry and promotes malignancy. Also, constitutive activation of the atypical RET protein, with EC motifs in the short ectodomain and a cytoplasmic tyrosine kinase domain, causes thyroid cancer and multiple endocrine neoplasias. A special case is the GPI-anchored cadherin-13. Its expression by cancer cells inhibits their growth but the underlying mechanism is unclear. On the other hand, its expression by the microvasculature in the tumor environment promotes angiogenesis and cancer metastasis. Further analysis of the cadherin superfamily members in various advanced culture systems and in different organs in informative model organisms and in human pathologies will doubtlessly unveil even more about the important role of cadherins in metazoan life.

Cadmium Absorption

Samuel Ogheneovo Asagba
Department of Biochemistry, Delta State University, Abraka, Delta State, Nigeria

Synonyms

Assimilation of cadmium; Uptake of cadmium

Definition

Cadmium (Cd) is a soft, ductile, silver-white electropositive metal, which is widely distributed in the environment. Environmental contamination by Cd is due to human and natural activities. Food and drinking water are the main routes of exposure to Cd for nonsmoking

general population. The absorption of Cd after dietary exposure ranges from 0.5% to 3.0% in majority of animal species, while in man a range of 3.0–8.0% has been reported. The metal accumulates mainly in the liver and kidney where it has multiple cytotoxic and metabolic effects. Cd bioavailability, retention, and consequent toxicity are influenced by several factors such as diet composition, chemical forms of Cd, nutritional status, among others.

Introduction

Contamination of the environment by Cd may occur through anthropogenic and natural sources (WHO 1992). The main routes of Cd exposure from the environment are inhalation and ingestion. Although the efficiency of Cd absorption through inhalation (25–50%) is much higher than that through ingestion (1–10%) (Zalups and Ahmad 2003; WHO 1992), concerns about airborne exposure are limited to special populations, including smokers, people living near smelters, and metal-processing workers. In contrast, dietary Cd intake is an important public health issue for the general world population despite the lower bioavailability of Cd through the gastrointestinal tract (GIT). This is because the element is readily distributed to tissues after oral exposure, where it inhibits antioxidant enzymes (Asagba and Eriyamremu 2007). This inhibition can lead to increased oxidative stress which may result in membrane damage and loss of membrane-bound enzymes such as the ATPases (Asagba et al. 2004; Asagba and Obi 2005). Tissues in which these effects have been reported are the liver and kidney which are considered the main target organs in acute and chronic cadmium exposure (Zalups and Ahmad 2003; Asagba and Obi 2000). Other tissues involved in Cd toxicity include the testis, heart, bone, eye, and brain (WHO 1992; Asagba et al. 2002; Eriyamremu et al. 2005; Asagba 2007).

Since the major route of human contamination is oral, understanding the mechanisms by which Cd crosses the intestinal barrier, and what regulates its absorption is of prime interest. Following oral exposure, Cd is absorbed in mammals preferentially in the duodenum and proximal jejunum (Zalups and Ahmad 2003). After uptake into the organism, Cd is transported via the blood to various tissues, particularly to the liver where it induces the synthesis of metallothionein (MT), an ubiquitous metal-binding protein of low molecular mass and high cysteine content (Zalups and Ahmad 2003). This protein may be required in the gastrointestinal absorption of Cd (WHO 1992).

Although knowledge of the absorption of Cd from experiments with human subjects is very limited, a considerable body of animal experiments is available in literature (WHO 1992; Andersen et al. 1992). These experiments indicate that different factors seem to affect the degree of absorption and toxicity of cadmium. Besides age, intestinal absorption of cadmium is influenced by a variety of factors including its chemical form, dose and route of exposure, intestinal content, diet composition, nutritional status, and interactions of cadmium with other nutrients (WHO 1996; Zalups and Ahmad 2003).

According to Andersen et al. (1992), the two aspects of intestinal cadmium uptake that have been studied mainly in experimental animals are (1) the effects of dietary components on the intestinal uptake of ionic cadmium administered after mixing with the diet, in drinking water, or given as a single oral dose and (2) the bioavailability for intestinal uptake of cadmium incorporated into various foodstuffs. Besides these two aspects, this entry will also be focused on the findings, assertions, and hypothesis pertaining to the molecular mechanisms involved in absorption of oral cadmium.

Absorption of Cadmium

This entry is focused mainly on gastrointestinal absorption of cadmium because the body burden of Cd is derived primarily from ingestion of food and drinking water contaminated with Cd. Besides, a significant fraction of inhaled Cd ends up in the gastrointestinal tract as a result of mucociliary clearance and subsequent ingestion. In fact, studies have demonstrated that as much as 60% of the inhaled dose of Cd ended up being translocated to the gastrointestinal tract in rats exposed acutely to aerosols containing Cd carbonate (Zalups and Ahmad 2003). It has been shown that the efficiency of gastrointestinal absorption of Cd is only about 1–2% in mice and rats, 0.5–3% in monkeys, 2% in goats, and 5% in pigs and lambs.

In humans, the efficiency of gastrointestinal absorption of Cd has been reported to be approximately 3–8% of the ingested load (Zalups and Ahmad 2003).

The major site of cadmium uptake in the intestine is not certain; however, a low pH of the gastric content emptied into the duodenum is thought to contribute to improve uptake (Andersen et al. 1992). Beyond the duodenum, the pH increases, and cadmium will rapidly be chelated by various dietary components, and therefore, its bioavailability will be reduced.

The chemical form of Cd is an important factor on its gastrointestinal absorption. It has been reported that Cd in foods such as meat, seafoods, and vegetable exists mainly as Cd–MT or MT-like Cd-binding proteins (Ohta et al. 1993). As is already well known, MT is induced in the intestinal tissue by oral Cd administration, and discussion on the mechanism of gastrointestinal absorption of Cd has been based on Cd ion mainly (Kikuchi et al. 2003). However, the chemical form of Cd such as Cd–MT in foods or Cd bound by MT induced in the intestinal tissue has also been considered in literature (Zalups and Ahmad 2003; Groten et al. 1991; Groten et al. 1994).

It has been shown that during dietary Cd exposure, Cd may be absorbed as complexes with MT or other dietary constituents which may be soluble or insoluble. However, there is conflicting information in literature on the availability of Cd–MT for intestinal uptake in relation to that of ionic Cd. Some reports indicate lower Cd absorption in rats fed Cd–MT than in that fed with ionic Cd (Andersen et al. 1992; Zalups and Ahmad 2003). These reports also indicate that the ratio of the concentration of Cd in the kidney to the concentration of Cd in the liver was higher after oral administration of Cd–MT than after oral administration of $CdCl_2$. On the other hand, similar uptake of cadmium acetate and Cd–MT has been reported when these different forms of Cd^{2+} were exposed to rats by gavage (Andersen et al. 1992). Other animal studies also indicate no difference in the bioavailability of Cd incorporated into dietary components such as wheat during growth or oysters in relation to inorganic Cd (Andersen et al. 1992). Similarly, the feeding of cadmium incorporated in pigs' livers resulted in about half the accumulation of cadmium in the rats' livers that took place after intake of a diet containing cadmium chloride (Groten et al. 1990). Conversely, a similar comparative study (Asagba 2010) revealed that more Cd was accumulated in the tissues of rats fed with fish-incorporated Cd in diet relative to those exposed to the metal in drinking water after 3 months of exposure. This disparity in the bioavailability of Cd from these foods may be due to differences in the solubility of proteins or ligands associated with Cd, as postulated by Lind et al. (1995).

Diet and Absorption of Oral Cadmium

There are several studies in literature which indicate that the absorption of Cd is influenced by the type or composition of the diet of a population. Numerous studies have shown that diets rich in fibers such as unrefined whole diets (Andersen et al. 1992) and a Nigerian-like diet (Asagba et al. 2004; Asagba and Eriyamremu 2007) decreased accumulation of Cd in rats.

Little is known about the influence of dietary fibers on metal absorption in human subjects. However, studies have revealed that absorption of cadmium in nonsmoking women 20–50 years of age depends on intake of dietary fibers (Zalups and Ahmad 2003). The findings indicate a tendency toward higher blood Cd (BCd) and urinary Cd (UCd) concentrations with increasing fiber intake; however, the concentrations were not statistically significant at the 5% level, indicating an inhibitory effect of fiber on the gastrointestinal absorption of cadmium.

The role of proteins in the absorption of cadmium has also received attention in biological literature. Studies on the effect of glycinin, ovalbumin, and gelatin on the absorption of cadmium indicate that all three proteins reduced intestinal Cd uptake which suggests that these proteins can protect against Cd toxicity (Andersen et al. 1992). Low protein diets generally enhance Cd toxicity, while high protein diets reduce the toxicity. This is not surprising since low protein diets generally enhance the uptake of Cd, while the reverse effect is observed with a high protein diet (Andersen et al. 1992).

It is well known that many toxic effects of Cd arise from interactions with essential elements, such as zinc (Zn). These interactions can take place at different stages of absorption, distribution in the

organism, and excretion of both metals and at the stage of Zn biological functions. Numerous studies show that enhanced Zn consumption may reduce Cd absorption and accumulation and prevent or reduce the adverse actions of Cd, whereas Zn deficiency can intensify Cd accumulation and toxicity (Brzóska et al. 2008; Roqalska et al. 2009). Studies have shown that the nutritional status of animals or humans with regard to zinc (Zn), iron (Fe), and/or calcium (Ca) can have a profound effect on the rate of Cd absorption from the gut. If the long-term intake of one or more of these minerals is low, the nutritional status is reduced, and Cd absorption increases; by contrast, if long-term intake is high, nutritional status is enhanced, and Cd absorption is decreased (Reeves and Chaney 2001; Brzóska and Moniuszko-Jakoniuk 1998).

A study on the effect of marginal nutritional status of Zn, Fe, and Ca on the bioavailability of Cd in sunflower kernels (SFK) demonstrated a much higher rate of absorption and organ retention of Cd in rats given a marginal supply of these mineral nutrients than in those receiving an adequate supply (Reeves and Chaney 2001). In addition, it was shown that the intrinsic, natural concentration of Zn, but not Ca and Fe, was enough to reduce the absorption and organ retention of dietary Cd supplied by the SFK. Foods such as rice, on the other hand, contain a very low intrinsic amount of Zn, Fe, or Ca (Reeves and Chaney 2001). Previous studies conducted to assess the risk of food-chain Cd indicated that rice, because of its poor supply of Zn, Fe, and Ca, could have caused populations of subsisting rice consumers to suffer a high incidence of Cd-induced renal tubular dysfunction. These individuals consumed rice raised in soils that were contaminated by a mixture of ore wastes of Cd and Zn in a ratio of 0.5–1:100 μg. These populations seem to be more susceptible to Cd poisoning than those who consume more nutritious diets but with similar intakes of Cd (Reeves and Chaney 2002 and Reeves et al. 2005). It has therefore been hypothesized that the low nutritional status of rice consumers, which results from an inadequate supply of these minerals from rice, could contribute significantly to a higher apparent susceptibility to soil Cd contamination from rice than the higher nutritional status of those who consume other grains with higher mineral content.

To test this hypothesis, a study was conducted in which rats were fed diets with adequate or marginal amounts of dietary Zn, Fe, or Ca (Reeves and Chaney 2002 and Reeves et al. 2005). The results obtained from this study support the hypothesis that populations exposed to dietary sources of Cd and subsisting on marginal mineral intakes could be at greater risk than well-nourished populations exposed to similar amounts of dietary Cd. The studies by Reeves et al. (2005) also indicate that MT induction is not involved in duodenal Cd accumulation in animals with marginal dietary status of Fe, Zn, and Ca. In addition, these studies support the hypothesis that marginal deficiencies of Fe, Zn, and Ca, commonly found in certain human populations subsisting on rice-based diets, play an important role in increasing the risk of dietary Cd exposure.

The effect of calcium supplementation on absorption and retention of cadmium in the suckling period was evaluated in Wistar rat pups of both sexes by Sarić et al. (2002). Results showed that after oral exposure, cadmium concentrations in all calcium-supplemented groups were significantly decreased in the organs and carcass and that the effect was dose related. No such effect of calcium was found after parenteral cadmium exposure. The authors concluded that calcium supplementation during the suckling period could be an efficient way of reducing oral cadmium absorption and retention without affecting tissue essential trace element concentrations.

Studies by Grosicki (2004) indicate that vitamin C supplement decreased the carcass Cd burden and the Cd content in the liver, kidneys, testicles, and muscles; the highest decreases were found in the testicles, the lowest ones in the muscles. Similarly, Sauer et al. (1997) observed a significant less cadmium accumulation in the lung, kidney, and testis in retinol-pretreated rats. Another study by Prasad et al. (1982) indicates that vitamin B_6 and B_1 deficiencies in rats resulted in a nonspecific increase in Cd ions.

Mechanisms of Oral Cadmium Absorption

Although food intake is among the most important routes of Cd exposure, not many details are known about the intestinal absorption mechanisms of Cd.

Available research evidence (Foulkes et al. 1981; Foulkes 1989) indicates that the mechanism of cellular Cd uptake in the rat jejunum consists of nonspecific binding to anionic sites on the membrane, followed by a temperature-dependent and rate-limiting internalization step which is probably related to membrane fluidity. Completion of the absorptive process is by transport across the basolateral membrane into serosal fluid. This step proceeds at only 1–2% of the rate of uptake from the lumen. Transport of cadmium from the small intestine is also thought to be facilitated by other possible mechanisms, including metal transport proteins such as divalent metal transporter 1 (DMT1), calcium ion channels, amino acid transporters (as cysteine–cadmium conjugates), and by endocytosis of cadmium–metallothionein (Cd–MT) complexes (Reeves and Chaney 2005).

The gastrointestinal tract produces metallothionein (MT) which can sequester cadmium. MTs are a family of low-molecular-weight heavy-metal-binding proteins, unique in their high cysteine content (Chang et al. 2009). The role of MT in the absorption of Cd has not been fully elucidated. Earlier studies have shown that the ability of the intestine to produce MT is limited but increase from the proximal to the distal small intestine (Elsenhans et al. 1994, 1999). This would improve the ability of the distal small intestine to handle Cd and thus make the metal less bioavailable in this region (Eriyamremu et al. 2005). Similarly, the findings of Min et al. (1992) suggest that mucosal MT in the small intestine might trap Cd absorbed from the intestinal lumen. However, the report by Lind and Wicklund (1997) does not support the hypothesis that intestinal Cd absorption is increased when the Cd-binding capacity of intestinal MT is saturated. It is also noteworthy to point out that the findings of Liu et al. (2001) support the hypothesis that endogenous MT does not function as a protective barrier against Cd absorption or alter its tissue distribution.

Summary and Conclusion

Humans are generally exposed to Cd by two main routes, inhalation and ingestion. The body burden of Cd is derived primarily from ingestion of food and drinking water contaminated with Cd. Most of the absorption of Cd appears to occur primarily in the duodenum, and this process is aided by the low pH in this region.

Intestinal Cd absorption is influenced by diet, nutritional status, the chemical form of Cd, among other factors. The mechanism of Cd absorption consists of nonspecific binding to anionic sites on the membrane, followed by a rate-limiting internalization which is temperature dependent. Absorption of cadmium from the small intestine is also facilitated by metal transport proteins such as divalent metal transporter 1 (DMT1), calcium ion channels, amino acid transporters (as cysteine–cadmium conjugates), and by endocytosis of cadmium–metallothionein (Cd–MT) complexes. However, it is noteworthy that the role of intestinal MT in Cd absorption and subsequent tissue distribution is not fully agreed upon.

The lack of conclusive information on the availability Cd in Cd–MT for intestinal uptake in relation to that of ionic Cd is noticeable, and there is a great need for further studies in this area. Also, since humans are usually exposed to Cd–MT in foods and rarely to inorganic Cd, the toxicity of food-incorporated Cd deserve further investigation, in view of the observed difference in tissue accumulation from these forms of Cd.

Definition

Cadmium (Cd) is a natural element in the Earth's crust. All rocks, soils, and waters contain some Cd. It is a global environmental pollutant potentially with multiple health consequences.

Introduction

Populations worldwide are exposed to a low-level intake of this toxic element through their food, causing an age-related cumulative increase in the body burden (Järup et al. 1998).

People living in the vicinity of industrial emissions and other point sources of Cd release can be exposed to an increased level of Cd other than food (► Cadmium Absorption). Prevention strategies have been proposed and discussed: (1) reduction of the transfer of Cd from soil to plants (passage of Cd into the human food chain) by maintaining the pH of agricultural and garden soils close to neutral and (2) reduction of the intestinal Cd absorption by preserving a balanced iron status (Nawrot et al. 2010a). Here an overview of the recently gained evidence that contributed to our understanding about the effects of Cd on human health is given.

Cadmium-Related Morbidity

Keynote:

- The bone and kidney are the critical target organs for Cd toxicity in humans.
- Both direct and indirect effects on bone.
- Cadmium is a human carcinogen.

Kidney

Microproteins in urine are sensitive biomarkers of Cd-induced renal damage reflecting a tubulotoxic effect. Among them is β_2 microglobulin, a small plasma protein, which passes the glomerular filter and subsequently almost completely reabsorbed in the absence of Cd-induced tubular dysfunction. Depending on the biomarker of nephrotoxicity, thresholds of urinary Cd can range from about 2 μg/g creatinine for the onset of early biochemical alterations (e.g., hypercalciuria) to 10 μg/g creatinine for the development of the classic tubular microproteinuria (Buchet et al. 1990; Roels 2003). A cross-sectional analysis of 14,778 subjects (NHANES) showed that subjects in the highest quartile of blood Cd (>0.6 μg/L) were almost two times more likely to exhibit albuminuria (≥30 mg/g creatinine) and 32% more likely to have reduced glomerular filtration rate (<60 mL/min per 1.73 m^2) (Navas-Acien et al. 2009).

Epidemiological evidence shows higher susceptibility for persons with diabetes to develop Cd-induced renal dysfunction (Nawrot et al. 2010a). Although there is strong evidence that elevated levels of tubular biomarkers of renal dysfunction are associated with urinary Cd, a surrogate of the Cd body burden, there is less agreement about the clinical significance and predictability of these changes. Prospective epidemiological evidence from Belgium (Nawrot et al. 2008) and the USA (Menke et al. 2009) suggests that the increased Cd-related mortality was directly related to the toxic effects of Cd, rather than being mediated by renal dysfunction.

Osteoporosis

Osteoporosis is usually an age-related bone disorder. Evidence accumulates that besides the kidney the bone is a primary target organ of Cd toxicity as well. Clinical features associated with osteoporosis include increased risk of new fractures and increased mortality. Studies among populations from Belgium, China, Japan, and Sweden showed associations between

osteoporosis and low-level environmental Cd exposure. The commonly accepted explanation is that Cd-induced renal tubular damage reduces the calcium reabsorption in the nephron, resulting in hypercalciuria and decreased bone mineral density, and hence increased fracture risk (Järup et al. 1998; Staessen et al. 1994), particularly in postmenopausal women and older men. However, a recent study also discovered a dose-response association between the odds of osteoporosis in young men (mean age 45) and urinary Cd (Nawrot et al. 2010b).

Hypercalciuria (a urinary concentration of more than 200 mg of calcium per liter) should be considered an early tubulotoxic effect of Cd, because it may exacerbate the development of osteoporosis, especially in the elderly. In the studies performed in northeast Belgium, bone mineral density was negatively associated with urinary Cd in postmenopausal women. A twofold increase in urinary Cd excretion at baseline was associated with a 73% increased risk of fractures in women (95% confidence interval [95%CI], 1.16–2.57). The corresponding results for men were 1.20 (0.75–1.93) (Staessen et al. 1999). Swedish investigations showed a doubling of the risk for osteoporosis for urinary Cd levels of 0.5–3 μg Cd/g creatinine (middle tertile) compared with the lowest tertile (<0.5 μg Cd/g creatinine) (Alfven et al. 2000).

Recent data (as reviewed in Nawrot et al. 2010a) provide more insight into the mechanisms supporting a direct osteotoxic effect of Cd independent of the status of kidney function, in that urinary excretion of pyridinium cross-links from bone collagen is increased. The shape of this association was linear with effects observed at low levels. The Cd-induced effect on bone is not mediated via impaired activation of vitamin D.

Cancer

Keynote: Four lines of evidence explain why Cd is classified as a human carcinogen:

1. First, as reviewed by Verougstraete and colleagues (2003), several studies in workers revealed a positive association between the risk of lung cancer and occupational exposure to Cd. The combined estimate showed an increased risk of 20% in workers exposed to Cd compared with those not exposed (Verougstraete et al. 2003).
2. Second, data obtained from rat studies showed that the pulmonary system is a target site for carcinogenesis after Cd inhalation. However, exposure to toxic metals in animal studies has usually been much higher than that reported in humans environmentally exposed to toxic metals (Nawrot et al. 2010a).
3. Third, several in vitro studies have indicated plausible toxicodynamic pathways, such as increased oxidative stress, modified activity of transcription factors, and inhibition of DNA repair (Jin et al. 2003). Most errors that arise during DNA replication can be corrected by DNA polymerase proof reading or by post-replication mismatch repair. Inactivation of the DNA repair machinery is an important primary effect of Cd toxicity, because repair systems are required to deal with the constant DNA damage associated with normal cell function. The latter mechanism might indeed be relevant for environmental exposure because it has been shown that chronic exposure of yeast to environmentally relevant concentrations of Cd can result in extreme hypermutability (Jin et al. 2003). In this study, the DNA-mismatch repair system was already inhibited by 28% at Cd concentrations as low as 5 μM. For example, the prostate of healthy unexposed humans contained Cd concentrations of 12–28 μM and human lungs of nonsmokers contained Cd concentrations of 0.9–6 μM (Jin et al. 2003).
4. Further, in vitro studies provide evidence that Cd may act like an estrogen, forming high-affinity complexes with estrogen receptors, suggesting a positive role in breast cancer carcinogenesis.

Along with this experimental evidence, recent epidemiological studies (reviewed in: Nawrot et al. 2010a), summarized in Table 1, provided new insights on the role of exposure to Cd in the development of cancer in humans. First, the results of a population-based case-control study noticed a significant twofold increased risk of breast cancer in women in the highest quartile of Cd exposure compared with those in the lowest quartile (McElroy et al. 2006). In a population-based prospective cohort study with a median follow-up of 17.2 years in an area close to three zinc smelters, the association between incident lung cancer and urinary Cd was assessed (Nawrot et al. 2006). Cd concentration in soil ranged from 0.8 to 17.0 mg/kg. At baseline, geometric mean urinary Cd excretion was 12.3 nmol/day (1.78 μg/day) for people in the high-exposure area, compared

Cadmium and Health Risks, Table 1 Studies on cancer in association with environmental cadmium exposure

Site	Reference	Population	Effect size	Shape of the association
Breast	McElroy et al. (2006)	Case-control study $n = 254$ cases $n = 246$ controls USA, based on NHANES sample	Odds ratio: 2.29 (95% CI: 1.3–4.2) comparing the highest quartile of urinary Cd (≥0.58 μg/g crt) to the lowest (<0.26 μg/g crt)	Continuous linear increase in risk
Endometrium	Åkesson et al. (2008)	Cohort study $n = 30{,}210$ postmenopausal women 16 years follow-up, Sweden	Relative risk: 1.39 (95% CI: 1.04–1.86) for highest tertile of intake of cadmium ≥16 μg Cd/day versus <13.7 μg Cd/day (lowest tertile)	Third tertile significantly different from first. Shape linear
Lung caner	Nawrot et al. (2006)	Cohort study $n = 994$ 15 years follow-up Belgium	Relative risk 1.31 (95% CI: 1.03–1.65) for doubling in urinary cadmium	Continuous linear increase in risk
Pancreas	Kriegel et al. (2006)	Case-control study $n = 31$ cases $n = 52$ controls Egypt	Odds ratio 1.12 (95% CI: 1.04–1.23) per μg/L serum Cd	Continuous increase risk
Prostate	Vinceti et al. (2007)	Case-control study $n = 45$ cases $n = 58$ controls Italy	Odds ratio: 4.7 (95% CI: 1.3–17.5) for highest quintile toenail Cd (≥0.031 μg/g) versus <0.007	Threshold observed ~0.015 μg/g toenail Cd
	Van Wijngaarden et al. (2008)	Cross-sectional 1,320 men NHANES population sample, United States	Significant cadmium–zinc interaction Men with zinc intake <12.7 mg/day a urinary cadmium increase of 1 μg/g crt is associated with a 35% increase in serum PSA	Effect size depends on zinc intake
Urinary bladder	Kellen et al. (2007)	Case-control study $n = 172$ bladder cases $n = 359$ controls Belgium	Odds ratio: 5.7 (95% CI: 5.0–13.8) comparing the highest (≥1 μg/L) to the lowest tertile (<0.2 μg/L) of blood cadmium	Continuous linear increase in risk

with 7.7 nmol day^{-1} (0.87 μg/day) for those in the reference (low exposure) area. The risk of lung cancer was 3.58 higher in the high-exposure area compared to the area with low exposure. The 24-h urinary excretion is a biomarker of lifetime exposure to Cd. The risk for lung cancer was increased by 70% for a doubling of 24-h urinary Cd excretion. Confounding by co-exposure to arsenic was unlikely.

Epidemiological studies did not convincingly imply Cd as a cause of prostate cancer. Of 11 cohort studies, only 3 found a positive association (Verougstraete et al. 2003). However, a recent case-control study (Vinceti et al. 2007) with 40 cases, and 58 controls showed an excess cancer risk in subjects in the third and fourth (highest) quartiles (above 0.0145 μg Cd/g) of toenail Cd concentration [OR = 1.3 (95% CI, 0.3–4.9)] and 4.7 μg/g [(95% CI, 1.3–17.5), respectively, p-trend = 0.004] compared with subjects in the bottom quartile. In the NHANES population, which included a sample of 1,320 men (Van Wijngaarden et al. 2008),

an effect modification by zinc on the blood prostate-specific antigen levels (PSA) and urinary Cd has been reported (Table 1). An increase in urinary Cd by 1 μg/g creatinine was associated with a 35% increase in PSA levels, in subjects with a zinc intake below the median (12.7 mg/day). In a case-control study, pancreatic cancer was associated with serum Cd levels (Table 1) (Kriegel et al. 2006). For each 1 μg Cd/L serum increase, the odds for pancreatic cancer increased with 12%. In a study of bladder cancer Kellen et al. (2007) showed a 5.7-fold increase in risk between subjects with blood Cd at the lowest tertile (<0.2 μg/L) versus the highest tertile (≥1 μg/L) (Table 1).

Prospective Mortality Studies

- *Keynote*: Environmental exposure to Cd increases total mortality continuously without evidence of a threshold, independently of kidney function and other classical factors associated with mortality including sex, age, smoking, and socioeconomic status.

Recently, two population-based cohort studies showed an increased risk for premature death in association with Cd exposure. The average urinary Cd concentration at baseline was about three times higher in the Belgian cohort (~1 μg/g creatinine) (Nawrot et al. 2008) compared with the US cohort (Menke et al. 2009). The hazard ratios for all-cause mortality, associated with a twofold higher urinary Cd were 1.28 (95% CI, 1.15–1.43) in men and 1.06 (95% CI: 0.96–1.16) for women in the US cohort (NHANES III), and 1.20 (95% CI, 1.04–1.39) in the Belgian cohort men and women combined. In the Belgian cohort, the hazard rates were not different between men and women (no urinary Cd by gender interaction in relation to mortality observed). The cause-related mortality pattern differed between the two cohorts. In the Belgian cohort, deaths from non-cardiovascular but not cardiovascular causes increased with higher 24-h urinary Cd excretion (Nawrot et al. 2008). In the NHANES study, both non-cardiovascular and cardiovascular disease increased with higher urinary Cd concentrations in men whereas in women non-cardiovascular diseases were borderline significantly associated but not cardiovascular mortality.

Conclusion

There has been substantial progress in the evaluation of the health effects of Cd and the exploration of the shape of the concentration-response function at different organ systems. These results have important scientific, medical, and public health implications. Indeed, the mean exposure for adults across Europe is close to the tolerable weekly intake of 2.5 μg/kg body weight. Subgroups such as vegetarians, children, smokers, and people living in highly contaminated areas may exceed the tolerable weekly intake about twofold.

To reduce the transfer of Cd from soil to plants, the vegetable bioavailability of Cd in soils should be diminished by maintaining pH of agricultural and garden soils close to neutral. A balanced iron intake is effective in reducing the bioavailability of Cd present in the intestine, by reducing its absorption. Along with the recent knowledge concerning low-dose Cd exposure, the current exposure to Cd at the population level should be kept as low as possible so that the urinary Cd concentration is kept below 0.66 μg/g creatinine (margin of safety = 3) as proposed by the EU (European Community report, EUR 23424 EN).

Definition

Cadmium (Cd) is a nonessential metal which is an important environmental pollutant, heavily toxic to the living world. In mammals, the major target organs of Cd are liver and kidneys, in which the toxicity is closely connected with the expression of metallothioneins (MTs), a family of small, cysteine-rich metal-binding proteins with Cd detoxification, antioxidative, and antiapoptotic functions. In the liver, Cd binds to the endogenous and/or de novo synthesized MTs and accumulates as an inert CdMT complex. This complex is released into circulation from the intoxicated cells and reaches the kidney, where it is filtered, endocytosed by the proximal tubule epithelium, and degraded. The liberated Cd binds to the endogenous and newly synthesized MTs and becomes sequestered as CdMT in the cell cytoplasm. When the binding capacity of MTs is surpassed, free Cd ions become cytotoxic, damaging the structure and function of proximal tubule cells. MTs in the urine can be used as an indicator of kidney damage in the general population exposed to environmental Cd.

Cadmium

Cadmium (Cd) is a chemical element from the group of transition elements/metals. Some of these metals (Fe, Co, Cu, Zn) represent essential elements that

play important roles in cell biology and physiology, whereas some others, like Cd, Pb, and Hg, are highly toxic for humans, animals, and plants. Cd occurs widely in nature, and in the Earth's crust and oceans it is closely associated with Zn. According to physicochemical properties, Cd is in many respects similar to Zn, and numerous Cd-induced toxic effects in the mammalian cells reflect the interactions of Cd with Zn-related functions.

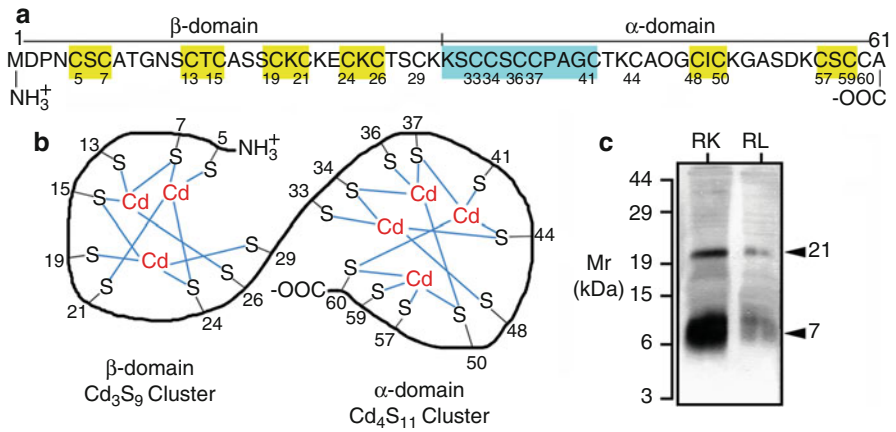
In the environment, volcanic activity is the major natural source of Cd, whereas various anthropogenic activities (combustion of fossil fuels, mining, metal smelting and refinery, production of steel, cement, batteries, paints, plastics and phosphate fertilizers, waste disposal, tobacco smoking) contaminate soil, water, air, and food with this environmental health hazard. In the general population, tobacco smoking represents the most important single source of chronic Cd exposure. Absorption of Cd from the lungs is much more effective than that from the intestine; up to 50% of the Cd inhaled via cigarette smoke may be absorbed, whereas the intestinal absorption of Cd accounts for 5–8% of the load (Foulkes 1986; Järup et al. 1998). In humans, an acute intoxication with Cd is also possible; it occurs as a result of occupational exposure to high Cd concentrations via inhalation of fumes or dust or via ingestion of contaminated food and/or water, causing severe injuries in lungs and gastrointestinal tract. However, the Cd-polluted living environment represents the base for continuous, long-term, and wide-scale exposure of humans and animals to small doses of this toxic metal. With time, Cd accumulates in various mammalian organs and (a) causes damage to the liver, kidneys, and gastrointestinal and reproductive tract, (b) interferes with embryonal development, (c) affects functions of neuronal and immune system, (d) causes high blood pressure, (e) inhibits bone mineralization, (f) potentiates diabetes, (g) contributes to mutagenicity and metaplastic transformation of cells, and (h) acts as an endocrine disruptor. Various aspects of Cd biology and toxicology in plants, humans, and experimental animals were described in a book edited by Foulkes 1986, a detailed status of Cd as an environmental and health problem relevant to humans was reviewed by Järup et al. 1998, and two excellent up-to-date collections of reviews and original articles dedicated to various epidemiological, clinical, and molecular aspects of Cd toxicity in mammalian cells appeared recently as special issues of relevant scientific journals (Prozialeck 2009; Moulis and Thevenod 2010).

Metallothioneins

Various aspects of biology of metallothioneins (MTs) and their roles in mammalian and nonmammalian cells were reviewed and collected in a recent book by Sigel et al. (2009), and a few extensive reviews describing the proposed roles of MTs in the mammalian cells were published recently in scientific journals (Davis and Cousins 2000; Miles et al. 2000; Prozialeck 2009; Moulis and Thevenod 2010).

Numerous studies have shown that actions of Cd in the mammalian cells are closely connected with the expression and function of MTs, a family of small (6–7 kilodaltons (kDa)) metal-binding proteins. MTs represent evolutionary conserved, heat-stable single-chain polypeptides, with 61–68 amino acids, among them are 20 cysteines. In the metal-free form of proteins (thioneins, apo-MTs), cysteines are assembled in a characteristic pattern, and the tertiary-structured protein is arranged in two domains (α- and β-clusters) with different metal-binding capacity. These structural and Cd-binding characteristics are schematically shown in Fig. 1 for MT1, an MT isoform common to most mammalian cells. In Western blot of the rat kidney and liver cytoplasm, this protein usually exhibits several bands, a strong one at ~7 kDa, reflecting the monomeric forms, and one or more weaker bands of higher molecular mass that reflect the presence of oligomers, such as dimers and/or trimers (Fig. 1c).

The thiol groups in apo-MTs are highly reactive, and the proteins exhibit high-affinity/high-capacity binding properties with various transition metal ions. One molecule of apo-MT can bind seven or more Zn, Cd (shown in Fig. 1b), Cu, or Hg ions. Although in physiological conditions, Zn is the usual content of the metal-MT complex, the common apo-MTs in the mammalian cells have higher affinity for Cd, Hg, Pb, or Cu than for Zn, and the stability constant of the CdMT complex is up to 1,000-fold higher than that of ZnMT. These phenomena have two important consequences for the onset and development of toxicity induced by Cd or other toxic metals: (a) higher-affinity metals can displace Zn from ZnMT, and (b) higher-affinity metal-MT complexes exhibit higher resistance to degradation by proteases. However, some studies



Cadmium and Metallothionein, Fig. 1 (**a**) Amino acid sequence of the rabbit MT1 contains 61 residues, 20 of them being cysteines (C; the numbers under the Cs denote their place within the sequence). Six C-X-C repeats (C is cysteine and X can be any other amino acid) are labeled yellow, whereas the blue-labeled sequence K-X-X-C-C-X-C-C-P-X-X-C denotes a characteristic pattern common to all mammalian MTs. (**b**) Schematic representation of the MT1 tertiary structure. The protein exhibits two functionally independent Cd-binding domains (clusters); the α-domain binds four Cd ions (Cd_4S_{11} cluster), whereas the β-domain binds three Cd ions (Cd_3S_9 cluster). Blue lines represent interactions of Cd ions with the thiol (S) groups of specific cysteines indicated by numbers. The scheme was generated using the information in Klaassen et al. (1999) and Sigel et al. (2009). In physiological conditions, the molecule can bind an equal number of Zn ions. Recent studies have shown that in various tumor cells, established cell lines, and in fresh tissues from various rat organs, only a part of MTs is complexed with Zn; a large proportion of the total MT (up to 90% in some cell lines and tumor cells and up to 54% in the rat tissues) exists as the metal-free form (apo-MT) (Petering et al. 2006; Sigel et al. 2009). (**c**) Western blot of MT in cytosolic fractions from the rat kidney cortex (RK) and liver (RL) homogenates. In these samples, a monoclonal antibody, which recognizes a highly conserved domain common to MT1 and MT2, labeled a strong ~7 kDa and a weak ~21 kDa protein band related to monomeric and oligomeric (trimeric) forms of the proteins, respectively. *Mr* relative molecular mass

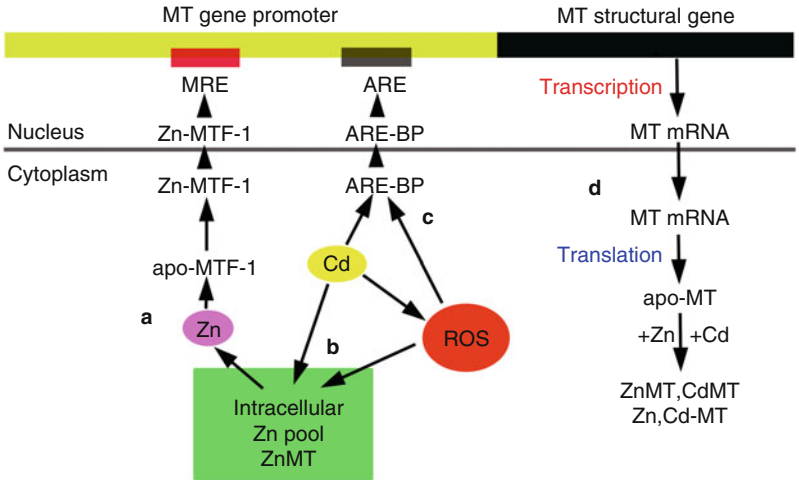
have shown that the metal-MT complex is less sensitive to proteolysis than the apo-MT in the acidic lysosomes (pH ~ 5.5), but in the neutral cytoplasmic conditions (pH ~ 7), apo-MT is more stable than the metal-saturated MT (Foulkes 1986; Miles et al. 2000; Sigel et al. 2009).

Regulation of Metallothionein Expression: Effect of Cadmium

Various effectors of MT gene activity and MTs expression at the level of mRNA and protein have been reviewed in more detail elsewhere (Andrews 2000; Davis and Cousins 2000; Miles et al. 2000; Sigel et al. 2009; Sabolic et al. 2010). MTs in rats and mice are controlled by four genes which code for apoproteins MT1, MT2, MT3, and MT4, whereas human MTs are controlled by 17 genes, 10 of which are functional. The common four MTs (MT1–MT4), present in most mammalian organs/tissues and studied most extensively, exhibit significant polymorphism in their amino acid sequences, and their expression in some organs shows species and sex differences.

MT3 is predominantly expressed in the brain, while MT4 is expressed exclusively in stratified squamous epithelia, where they may function as intracellular regulators of Zn and Cu and cell protectors by scavenging reactive oxygen species (ROS). MT3 and MT4 are poorly responsive to the usual inducers of MT expression, such as Zn and Cd. On the other hand, MT1 and MT2 represent the most prevalent thioneins expressed in most mammalian tissues, and their roles in homeostasis of essential metals (Zn, Cu) and Cd toxicity have been extensively documented in various experimental models in vivo and in vitro. A number of important information regarding the possible roles of MTs in the cell physiology and Cd-induced toxicology has been collected from the experiments in genetically modified mice with inactivated MT1 or MT2 (or both) genes and nominal absence of the respective proteins (knockout (KO) mice) and in mice with multiple identical MT genes and overproduction of the respective proteins (transgenic (MT-TG) mice).

A variety of factors are known to activate the MT1 and MT2 genes and upregulate the production



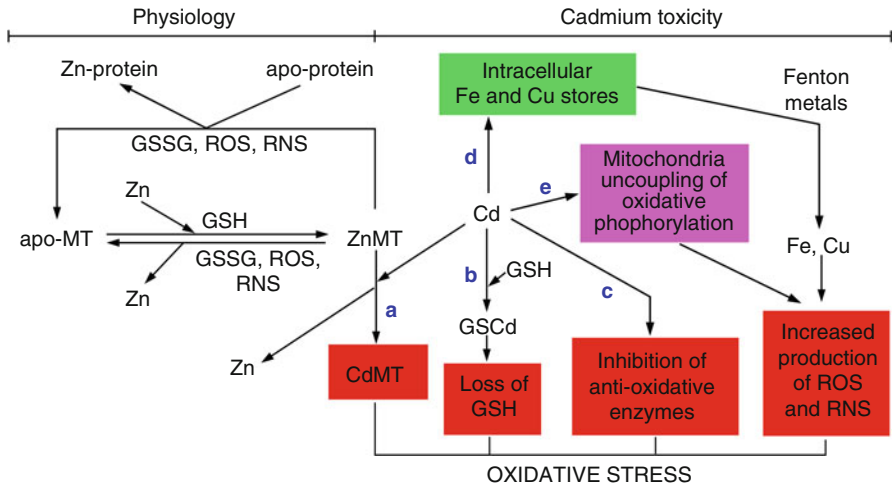
Cadmium and Metallothionein, Fig. 2 A simplified scheme showing regulation of the mouse *MT1* gene activity with Zn or Cd. More complicated interactions, with other activators and inhibitors of the gene activity, were elaborated in detail previously (Davis and Cousins 2000; Miles et al. 2000; Sigel et al. 2009; Sabolic et al. 2010). MRE (metal response element) and ARE (antioxidant response element) are specific locations in the gene promoter. ARE-BP, ARE-binding protein; MTF-1, metal-regulated transcription factor 1; ROS, reactive oxygen species (free radicals, such as H_2O_2). (**a**) The apo-MTF-1 is an inactive cytoplasmic protein, which can be activated by Zn-induced phosphorylation and then migrates as Zn-MTF-1 into the nucleus to associate with MRE, a step which activates the MT transcription. In case of Cd intoxication, (**b**) Cd ions and ROS can activate MTF-1 indirectly, by mobilizing Zn from the intracellular pool (including from ZnMT) and, (**c**) independently on Zn, by activating the ARE-BP, which translocates into the nucleus, binds to ARE, and activates the *MT* gene. (**d**) The final product of the *MT* gene activation is apo-MT, which can bind Zn (ZnMT) or Cd (CdMT) or both ions (Zn, CdMT) in any stoichiometric combination. A synergistic activation of the MT gene via MRE and ARE may be important in Cd-induced hepatotoxicity and nephrotoxicity, when a high intracellular concentration of Cd is associated with an increased production of free radicals (Modified from Sabolic et al. 2010, with kind permission from Springer Science+Business Media B.V.)

of apo-MTs. Cd and various stress-related conditions are particularly strong inducers, largely via generating free radicals, e.g., ROS and reactive nitrogen species (RNS) in the affected cells. Zn and ROS/RNS, generated during normal metabolism, may be the major players in regulating MT gene expression in physiological conditions. As shown schematically in Fig. 2, the induction of mouse liver MT1 gene results in an enhanced transcription following interaction of inducers with specific response elements in the gene promoter.

Roles of Metallothioneins in Physiology and Cadmium-Induced Toxicity

MTs are predominantly intracellular proteins detected largely in the cell cytoplasm but also in lysosomes, mitochondria, and nuclei. The presence of MTs in a variety of mammalian cells and their organelles suggests possible important intracellular functions of these metalloproteins. However, the MT-null (KO for MT1 and MT2) and MT-TG mice have no significant phenotypic or reproductive problems, indicating that these functions are not vital for animal survival and reproduction. The following roles for MTs in the mammalian cells have been proposed: (a) intracellular storage, transport, and homeostasis of the essential metals Zn and Cu; (b) provision of Zn and Cu for metalloproteins, enzymes, and transcription factors in various intracellular compartments during prenatal, perinatal, and postnatal periods; (c) binding and neutralizing the highly reactive ionic forms of toxic metals, such as Cd, thus providing protection against their cytotoxicity, genotoxicity, and carcinogenicity; (d) scavenging free radicals (ROS/RNS) generated in normal metabolism and in oxidative stress induced by toxic metals and other factors; and (e) protection of cell vitality in neurodegenerative and other diseases (Foulkes 1986; Klaassen et al. 1999; Miles et al. 2000; Kang 2006; Sabolic 2006; Prozialeck 2009; Sigel et al. 2009; Moulis and Thevenod 2010).

The scheme of intracellular MT roles in the absence and presence of Cd is shown in Fig. 3. The redox status in the cell seems to be the major regulator of interaction of Zn, apo-MT, and other apo-proteins.



Cadmium and Metallothionein, Fig. 3 Schematic presentation of the role of intracellular MTs in Zn homeostasis in physiological conditions and in the presence of toxic concentrations of Cd. In physiological conditions, a relative abundance of apo-MT and ZnMT depends on the intracellular redox state; the reduced conditions, with higher GSH/GSSG ratio, favor formation of ZnMT, whereas the oxidized conditions, with lower GSH/GSSG ratio and a limited abundance of reactive species (ROS/RNS), favor the release of Zn and its transfer to various Zn-dependent metalloproteins. (**a**) In Cd-induced toxicity, due to higher affinity of SH groups for Cd, Zn is released and replaced by Cd, thus forming the nontoxic CdMT complex. When the Cd-binding capacity of MTs is surpassed, (**b**) the free Cd ions bind to and deplete GSH and other intracellular antioxidants, thus decreasing the GSH/GSSG ratio, (**c**) inhibit the activity of antioxidative enzymes, (**d**) displace and release the Fenton metals Fe and Cu from intracellular stores, which then promote generation of free radicals, and (**e**) uncouple the oxidative phosphorylation in mitochondria, causing a massive production of free radicals. An overall manifestation of this toxic condition represents oxidative stress. As discussed in Fig. 2, the liberated Zn and ROS enhance the activity of MT gene and production of apo-MT. Being itself redox active, the newly synthesized apo-MT can fight oxidative stress by binding and neutralizing free radicals (ROS/RNS scavenger). However, ROS and RNS can also act as signaling molecules and activate a cascade of reactions that can lead to cell death in form of apoptosis or necrosis. All these processes have been elaborated previously (Andrews 2000; Miles et al. 2000; Kang 2006; Sabolic 2006; Prozialeck 2009; Sigel et al. 2009; Moulis and Thevenod 2010)

In physiological conditions, when the metabolic production of ROS/RNS is limited, and the ratio of reduced (GSH) versus oxidized (GSSG) glutathione is high, the reactive thiol groups of apo-MT exhibit high affinity for Zn, forming the ZnMT complex. The prooxidative molecules (GSSG, ROS, RNS) interact with ZnMT, oxidize cysteines into cystines, and enable release of Zn and its transfer to various intracellular apo-proteins. The presence of Cd ions shifts these reactions into prooxidative direction. At low Cd concentration, due to higher affinity of MT thiol groups for Cd, Zn becomes released and replaced, and the toxic metal becomes entrapped and inactivated/detoxicated as the CdMT complex. In case of overloading with Cd, when the capacity of MTs to buffer toxic metals is lost, free Cd ions directly target various intracellular structures and functions, and the redox status becomes heavily compromised due to loss of antioxidants, inhibition of antioxidative enzymes, and enhanced production of prooxidants, resulting in the state named "oxidative stress" (Fig. 3).

Role of Metallothioneins in Cadmium Entry into the Organism

Various aspects of Cd handling in epithelia, as well as the role of MTs and other proteins in Cd transport, have been reviewed by Zalups and Ahmad 2003 and Bridges and Zalups 2005. The major routes of Cd entry into the mammalian body are lungs and intestine; absorption via the skin and/or eyes plays only a minor role in this respect. In the lung cells, MTs may protect from oxidative injury induced by Cd or other factors. Following inhalation of Cd-contaminated aerosols, the lungs react with inflammation, edema, and hemorrhage. These symptoms are strongly diminished in experimental animals with higher content of MTs in their lung tissue and intensify in the MT-null animals. A possible role of MTs in Cd transport across the

alveolar epithelium into the blood has not been documented. In the gastrointestinal tract, Cd in the contaminated drink and food is absorbed largely by enterocytes in the proximal small intestine. The endogenous MTs are expressed in the intestinal epithelium, but their primary function may be storage and regulation of the intracellular Zn concentration and neutralization of the locally generated free radicals. Cd stimulates the expression of MTs in the intestinal cells and is sequestered as CdMT, but a possible role of MTs in the intestinal Cd absorption is unclear.

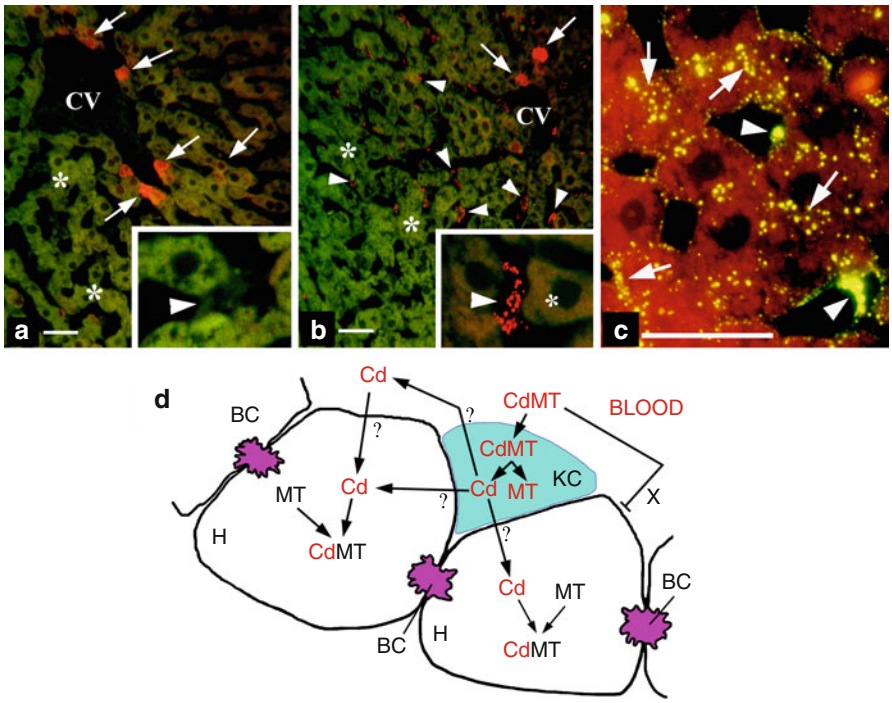
Following absorption in the lungs or intestine, Cd is distributed by systemic circulation to various organs largely bound to albumin and other thiol-containing reactive biomolecules in the plasma, and less as CdMT. In humans, a small concentration of MTs is always present in the plasma, which in a healthy organism may distribute Zn and Cu among organs. Much higher (>tenfold) concentration of plasma MTs was measured in workers occupationally exposed to Cd and in experimental animals treated with $CdCl_2$ (Foulkes 1986; Prozialeck 2009; Sigel et al. 2009).

Role of Metallothioneins in Cd-Induced Hepatotoxicity

Although Cd is heavily toxic for all mammalian organs, liver and kidneys represent the major targets where interactions of Cd and MTs in acute and chronic Cd intoxication have been studied most extensively. In these organs, MTs are important for prevention and protection against Cd-induced toxic effects, but in the kidneys, MTs can also be mediators of Cd toxicity.

Cd circulating in the blood enters the liver cells by poorly defined mechanisms; while free Cd ions may cross the hepatocyte plasma membrane by various transporters, Cd-albumin and similar protein complexes may be internalized by endocytosis (Zalups and Ahmad 2003; Bridges and Zalups 2005). However, this may not be valid for the CdMT complex. As found in our immunocytochemical studies in cryosections of the liver tissue from control rats (Fig. 4), individual hepatocytes exhibited a variable expression of endogenous MTs in their cytoplasm, whereas reticuloendothelial (Kupffer) cells showed no significant staining for MTs (Fig. 4a and inset). However, 15 min following intravenous (i.v.) injection of CdMT, a massive, endocytosis-mediated accumulation of this complex was observed in intracellular vesicles of Kupffer cells (Fig. 4b and inset), whereas hepatocytes exhibited no visible internalization of this complex. On the other hand, the process of endocytosis in the same liver cells was highly active, as shown in Fig. 4c, already 5 min after i.v. injection of the fluorescent marker FITC-dextran in rats both Kupffer cells and hepatocytes exhibited a vigorous, endocytosis-mediated accumulation of this marker in numerous intracellular vesicles. This indicates that the CdMT complex is probably not a substrate for endocytosis in the rat hepatocytes in vivo, possibly because megalin, a scavenger receptor for MTs, is missing in the hepatocyte plasma membrane (Sabolic et al. 2010). Rather, the complex may be endocytosed by macrophages, e.g., the Kupffer cells, and degraded in their lysosomes, and the liberated Cd ions may be released into the pericellular space and/or blood (Fig. 4d) and taken up by hepatocytes via the poorly defined ionic transports (Zalups and Ahmad 2003). This further means that in chronic Cd intoxication, when hepatocytes produce and release into circulation an increased amount of CdMT (see later), an amount of Cd from the complex could continuously recycle between the Kupffer cells and hepatocytes and cause toxicity for a long time, while the bulk of CdMT in circulation ends in the kidneys.

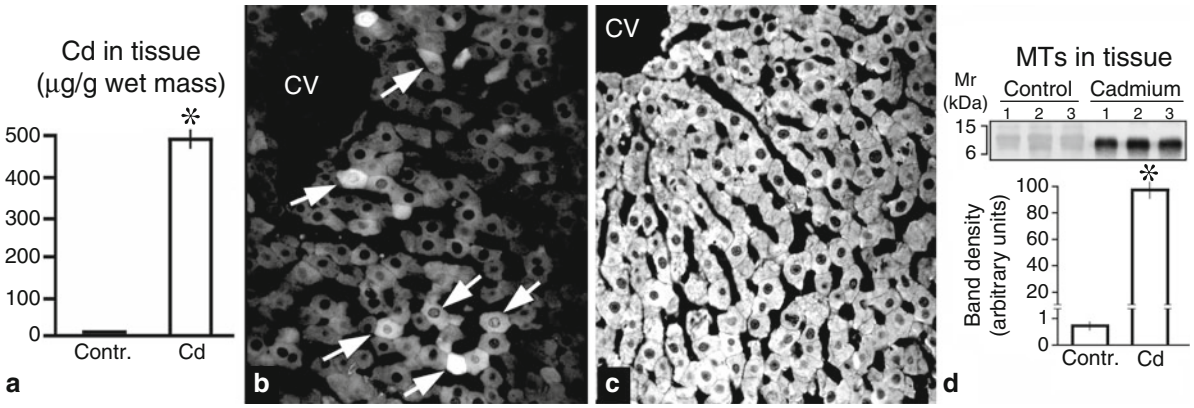
In various experimental animals, Cd acts as a potent hepatotoxin after acute or chronic exposure. Inside the hepatocytes, Cd binds to cytoplasmic proteins, largely to the existing (endogenous) MTs, and becomes trapped inside the cytoplasm, inactivated, and detoxicated. During a short-term poisoning with high Cd doses, it is assumed that Cd ions initially bind to the existing MTs until saturation, and thereafter, they become toxic, causing an extensive oxidative stress and ROS/RNS-mediated damage of the cell structure and function, manifested by inflammation, apoptosis, and/or necrosis of hepatocytes (Foulkes 1986). Various studies have shown that in acute Cd-induced hepatotoxicity, MTs have strong protective and antioxidative functions. Acute hepatotoxicity is (a) weak or absent in immature rats, which in the liver exhibit much higher concentrations of MTs than the adult animals; (b) prevented by pretreating animals with small doses of Cd or Zn, which in the liver and other organs induce synthesis of new apo-MTs; (c) absent in TG mice, which in the liver have elevated levels of MT1; and (d) increased in MT-null mice (Miles et al. 2000; Prozialeck 2009; Sigel et al. 2009; Moulis and Thevenod 2010).



Cadmium and Metallothionein, Fig. 4 Fate of CdMT in the rat liver. (**a**) Immunolocalization of MTs in the liver of rats that had been injected i.v. with saline 15 min before sacrifice. Individual hepatocytes, largely those around the central vein (CV), exhibited a variable cytoplasmic staining of endogenous MT (*red* fluorescence, *arrows*), whereas most hepatocytes (*asterisks*) and the Kupffer cells (*inset*, *arrowhead*) did not show a significant MT staining. (**b**) In rats injected i.v. with CdMT (0.4 mg Cd/kg body mass) 15 min after the injection, intracellular organelles with the red-stained material indicated the presence of endocytosed CdMT in the Kupffer cells (*arrowheads* and *inset*). Some hepatocytes exhibited a variable content of endogenous MT (*arrows*), but most of them were negative for endogenous MT (*asterisks*), and none of them showed any endocytosis-mediated internalization of CdMT. However, (**c**) both the Kupffer cells (*arrowheads*) and hepatocytes (*arrows*) exhibited a vigorous endocytosis of the fluorescent marker FITC-dextran; already 5 min following the i.v. injection of this marker, the fluorescence accumulated in numerous yellow-stained intracellular vesicles randomly scattered in the cell cytoplasm (*arrows*). Bars, 20 μm. (**d**) Scheme of the fate of CdMT in the rat liver. CdMT is internalized by endocytosis in the Kupffer cells (KC) and degraded in lysosomes. The liberated Cd ions are released into the pericellular space and/or blood and taken up by the surrounding hepatocytes (H) via the poorly defined transport mechanisms (?). The endocytosis-mediated internalization of CdMT in hepatocytes seems to be very low, if present at all (X). In hepatocytes, the CdMT complex is reformed by binding of Cd ions to endogenous MTs. *BC* bile canaliculi

Chronic Cd hepatotoxicity in humans can result from a long-term exposure to small Cd concentrations, whereas in experimental animals, this condition can be mimicked with repeated small doses of $CdCl_2$ from a few weeks to a few months injected intraperitoneally or subcutaneously (s.c.) or by oral exposure for several months to years. Such treatments result in a time- and dose-dependent accumulation of Cd and increase in MT content in the liver due to continuous stimulation of MT synthesis. With time, the cytoplasmic CdMT accumulates and can reach a very high concentration. A time-dependent upregulation of MTs, GSH, and antioxidative enzymes and amelioration of the toxicity by various antioxidants indicate oxidative stress as the underlying mechanism in this condition (Moulis and Thevenod 2010). An example of Cd and MT accumulation in a subchronic model of Cd hepatotoxicity in rats is demonstrated in Fig. 5.

The final result of either acute or chronic Cd-induced hepatotoxicity is a release of CdMT from the damaged (apoptotic and/or necrotic) hepatocytes into the blood circulation, by which this complex reaches the kidneys.



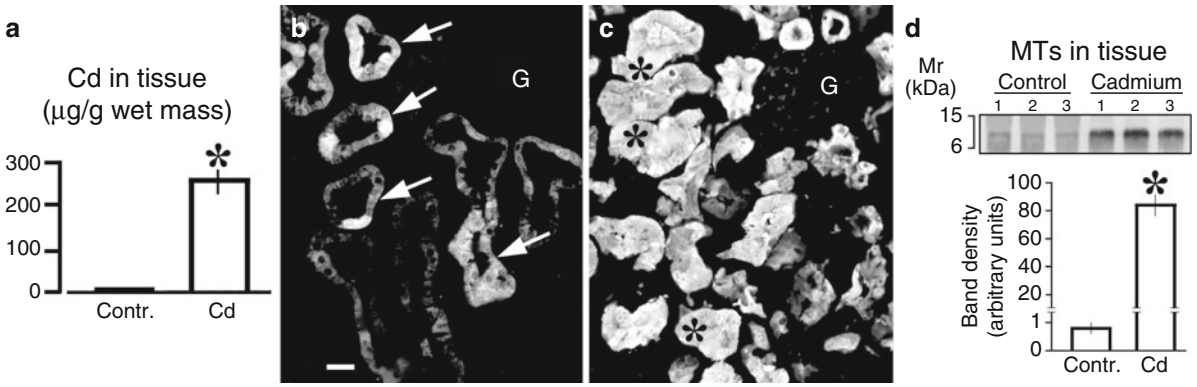
Cadmium and Metallothionein, Fig. 5 Cd and MTs in the liver of rats ($n = 3$) treated s.c. with saline (0.5 mL/kg body mass/day; control) or $CdCl_2$ (2 mg Cd/kg body mass/day) for 14 days. (**a**) After 14 days of treatment, the tissue content of Cd increased from nearly zero in controls to ~500 µg/g wet mass in Cd-treated rats. (**b**) Immunocytochemical localization of MTs in the liver of control rats; the individual hepatocytes expressed a variable staining intensity, reflecting a variable content of endogenous MTs in their cytoplasm (*arrows*). (**c**) In $CdCl_2$-treated rats, all hepatocytes exhibited a very strong staining for MTs. (**d**) Western blot of proteins in the liver tissue extract revealed a weak MT band (~7 kDa) in control rats and a strongly upregulated band in $CdCl_2$-treated rats. By densitometry, the band density in Cd-treated rats was ~135-fold stronger than in control animals. *CV* central vein. *Mr* relative molecular mass; *, Vs. control, $P < 0.05$ (Modified from Sabolic et al. 2010, with kind permission from Springer Science+Business Media B.V.)

Role of Metallothioneins in Cd-Induced Nephrotoxicity

In humans and experimental animals, kidneys represent the major target in the long-term environmental and/or occupational exposure to Cd. Cd primarily targets the structure and function of proximal tubule (PT) cells, resulting in reabsorptive and secretory malfunctions with urinary symptoms resembling the acquired Fanconi syndrome (Foulkes 1986; Järup et al. 1998; Prozialeck 2009). The interaction of Cd and MTs in Cd-induced nephrotoxicity has been extensively studied in various animal models and mammalian cell cultures treated with $CdCl_2$ or CdMT. To induce Cd-induced nephrotoxicity in rodents, the animals can be treated in different ways with $CdCl_2$ from a few days to a few years, and such treatments result in kidney damage, which is always associated with the accumulation of Cd and upregulation of MTs in the tissue (Foulkes 1986; Järup et al. 1998; Sabolic et al. 2010; Prozialeck 2009; Sigel et al. 2009). An example of these phenomena is shown in Fig. 6, which contains the data obtained in the rat model of subchronic Cd-induced nephrotoxicity, where the accumulation of Cd in the kidney cortex was correlated with the expression of MTs by immunocytochemistry in tissue cryosections and by Western blotting of the tissue extract.

Although Cd may enter renal cells by different mechanisms (Zalups and Ahmad 2003; Bridges and Zalups 2005), there is a general opinion that chronic Cd-induced nephrotoxicity is primarily induced by the CdMT complex that arrives by circulation from the Cd-injured organs, largely from the liver. Such a pattern was proven (a) in rats following transplantation of the Cd-intoxicated rat liver into a healthy animal, where CdMT from the donor liver was released into circulation and caused toxic injury in the acceptor's kidneys, and (b) in rodents following s.c. or i.v. application of CdMT (Foulkes 1986; Sabolic 2006; Sabolic et al. 2010). Indeed, as shown in Fig. 7, in rats that had been injected i.v. with CdMT, the complex was filtered in the glomeruli and endocytosed by the PT cells; 15 min following i.v. injection, CdMT was localized in numerous intracellular organelles (endocytic vesicles and/or lysosomes) randomly scattered in the PT cell cytoplasm (Fig. 7b). This finding fits the current model of chronic Cd-induced nephrotoxicity, as depicted in Fig. 7c.

The existent and the newly synthesized apo-MTs in the cell cytoplasm during chronic Cd-induced nephrotoxicity are important for sequestration and accumulation of the ionic Cd, and in this way, they protect from and ameliorate the toxic actions of Cd ions as the ROS/RNS scavengers. This is supported by the

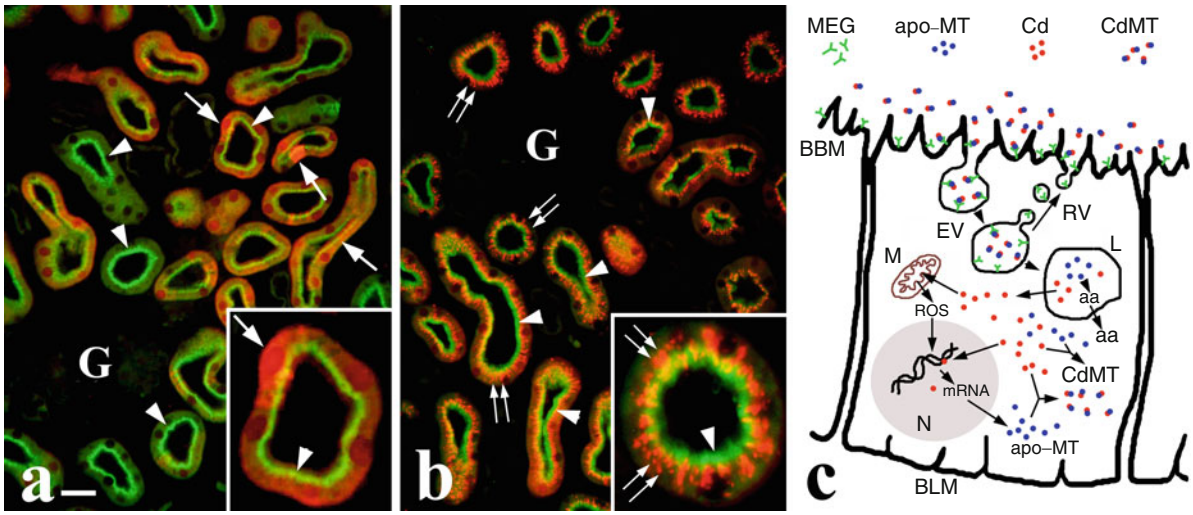


Cadmium and Metallothionein, Fig. 6 Cd and MTs in the kidney cortex of rats ($n = 3$) treated s.c. with saline (0.5 mL/kg body mass/day; control) or $CdCl_2$ (2 mg Cd/kg body mass/day) for 14 days. (**a**) After 14 days of treatment, the tissue content of Cd increased from nearly zero in controls to ~280 µg/g wet mass in Cd-treated rats. (**b**) Immunocytochemical localization of MTs in the cortical tubules of control rats; the cells in PT expressed a variable staining intensity, reflecting a variable content of endogenous MTs in their cytoplasm (*arrows*). (**c**) In $CdCl_2$-treated rats, the cells in all types of cortical tubules were strongly positive for MTs. In PT, the cells were edematous, and the tubule lumen was largely clogged with the debris from the injured epithelium (*asterisks*). (**d**) Western blot of proteins in the kidney cortex tissue extract revealed a weak MT band (~7 kDa) in control rats and a strongly upregulated band in $CdCl_2$-treated rats. By densitometry, the band density in Cd-treated rats was ~95-fold stronger than in control animals. *G* glomerulus; Bar, 20 µm, *Mr* relative molecular mass. *, Vs. control, $P < 0.05$ (Modified from Sabolic et al. 2010, with kind permission from Springer Science+Business Media B.V.)

following observations: (a) in MT-null mice treated with $CdCl_2$, the initial accumulation of Cd is not affected, but the rate of Cd elimination is faster, indicating that the cytosolic MTs are necessary for binding and sequestering Cd ions; (b) MT-null mice are more sensitive to chronic $CdCl_2$-induced nephrotoxicity than the normal (wild-type) mice; and (c) pretreatment of rodents with small doses of $ZnCl_2$ and $CdCl_2$ upregulates MTs and protects from acute nephrotoxicity induced by CdMT. However, in case of overloading conditions with Cd ions, it is assumed that the binding capacity of cytoplasmic MTs eventually becomes insufficient and that Cd ions attack other molecules and induce a full-scale oxidative stress and toxic condition that can end in apoptosis or necrosis of the tubular epithelium (Miles et al. 2000; Thevenod 2003; Sabolic 2006; Prozialeck 2009; Sigel et al. 2009; Moulis and Thevenod 2010).

Cadmium-Related Expression of Metallothioneins in Other Mammalian Organs

In rodents, acute or chronic treatment with $CdCl_2$ induced various toxic effects in reproductive organs, such as vascular damage, testicular necrosis, degenerative changes in ovaries, and loss of reproductive potency. These effects were not associated with significant changes in the expression of MTs at the level of mRNA and/or protein so that the role of MTs in these organs remains unknown (Foulkes 1986; Järup et al. 1998; Prozialeck 2009; Moulis and Thevenod 2010). However, MTs may play a protective role in Cd-induced osteotoxicity; a long-term exposure to Cd in humans and experimental animals is associated with a loss of calcium from the bones and its excretion in the urine, thus increasing the risk of kidney stones, osteomalacia, and osteoporosis. Following Cd treatment in rats, MT1 and MT2 proteins and their mRNA in bone cells are upregulated, playing a protective and antiosteoporotic role (Järup et al. 1998; Prozialeck 2009). Furthermore, a chronic environmental or experimental exposure to Cd in humans and animals can induce anemia and impaired immunity. Platelets and various blood cells contain a limited amount of Cd-inducible MTs, which seem to protect from Cd-related oxidative stress (Järup et al. 1998; Prozialeck 2009). MTs were also found to be protective against the ROS/RNS-mediated cell damage in ischemia-reperfusion injury of the heart. Finally, recent epidemiological and experimental data have indicated that chronic exposure to Cd in humans and animals can be associated with cancerogenesis in various organs. The animals with higher content of MTs in the specific organs (lungs, liver) had a lower incidence of Cd-induced carcinoma, thus suggesting that



Cadmium and Metallothionein, Fig. 7 Fate of the i.v. injected CdMT and localization of megalin in the rat kidney, as shown by immunofluorescence staining with specific antibodies. (**a** and *inset*) In control rats injected i.v. with saline (0.5 mL/kg body mass) 15 min before sacrifice, many cells of the cortical PT exhibited a variable content of endogenous MTs in their cytoplasm (red fluorescence; arrows), whereas megalin was localized largely in the cell subapical domain (*green* fluorescence; *arrowheads*). (**b** and *inset*) In rats injected i.v. with CdMT (0.4 mg Cd/kg body mass), 15 min later, the injected complex was detected in numerous intracellular organelles (endosomes and lysosomes) randomly scattered in the cell cytoplasm (*red*-stained organelles; *thin double arrows*), indicating that the complex had been filtered in the glomeruli and endocytosed by the epithelial cells. Megalin was labeled with green fluorescence (*arrowheads*). *G* glomerulus. Bar, 20 μm. (**c**) Schematic presentation of the current model of nephrotoxicity induced by CdMT in chronic Cd exposure. Being a small molecule, the circulating CdMT is freely filtered in the glomeruli, it binds to the receptor protein megalin at the bottom of the epithelial cell BBM, and this complex (CdMT-megalin) is internalized by endocytosis and delivered to the endolysosomal compartment for degradation. Following dissociation of this complex in the acidic medium, megalin recycles back to the BBM via recycling vesicles, whereas CdMT is further dissociated into ionic Cd and apo-MT. The latter is degraded, whereas the ionic Cd is transported into the cell cytoplasm, where it primarily binds to endogenous cytoplasmic MTs, thus becoming detoxicated, but it also indirectly induces production of free radicals (ROS/RNS) and stimulates the machinery for synthesis of apo-MTs. All these phenomena have been described elsewhere in more detail (Christensen et al. 2009; Prozialeck 2009; Sigel et al. 2009; Moulis and Thevenod 2010). sequestering Cd and scavenging ROS/RNS during the oxidative stress may protect from activation of oncogenes and uncontrolled cell proliferation (Miles et al. 2000; Prozialeck 2009; Moulis and Thevenod 2010).

Cadmium-Related Expression of Metallothioneins as a Diagnostic Tool

As reviewed in more detail previously (Prozialeck 2009; Moulis and Thevenod 2010), MTs in blood and urine can be used in the human population for diagnostic purposes in conditions related to Cd-induced toxicity. Thus, the expression of MT1/MT2 mRNA in blood and peripheral lymphocytes can be used as a sensitive biomarker of environmental and occupational exposure to Cd, whereas recent epidemiological studies revealed that Cd-exposed humans exhibit anti-MT antibodies in their blood plasma and that these antibodies could be used as a biomarker for severity of this toxic condition. In the urine, MTs were found to be closely linked to urine Cd and may represent a perspective indicator of environmental and/or occupational Cd exposure and associated kidney damage.

Cellular redox balance; Oxidative challenge

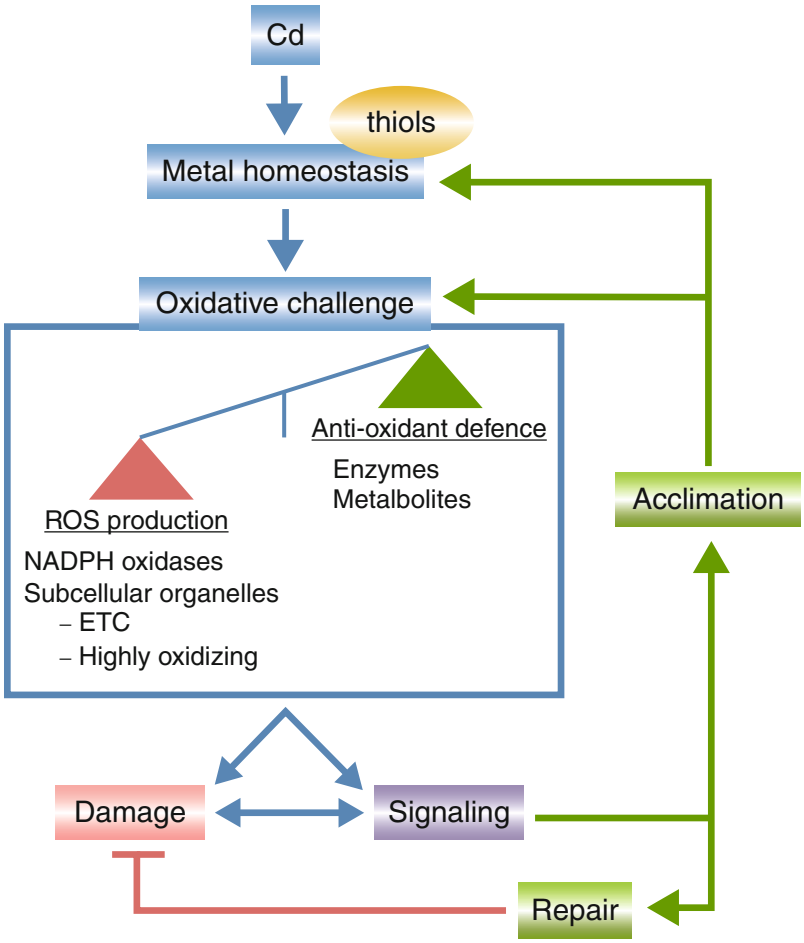
Definition

Oxidative stress is a process in which the cellular redox balance between pro- and antioxidants is disturbed in favor of the former.

Introduction

Cadmium (Cd) contamination is a widespread complication of industrial's reliance on metals and the intensive use of agrochemicals containing Cd. Cadmium is not biodegradable, and therefore, the global environmental risk is constantly increasing due to its accumulation via the food chain. Furthermore, as Cd is classified as a type I carcinogenic element, it poses a serious threat to humans and animals but also other organisms, such as plants, fungi, and bacteria, present in all compartments of different ecosystems, are negatively affected by Cd.

Cadmium has a very high affinity for sulfhydryl (thiol) groups, and through binding with these functional groups of, for example, enzymes or structural proteins, it causes metabolic disruptions (Sharma and Dietz 2009; Cuypers et al. 2010). Many micronutrients are cations and are essential components of metalloproteins, as cofactor in the enzymatic catalysis and manifold of other cellular processes (Cuypers et al. 2009). Under physiological conditions, Cd is present as a bivalent cation that can either replace essential elements from their complexes or interfere with their uptake and, in this way, exert its toxic action. Another important underlying mechanism of Cd-induced morphological and physiological damage is oxidative stress, a process in which the cellular redox balance between pro- and antioxidants is disturbed in favor of the former. Although Cd is not redox active and therefore unable to directly induce reactive oxygen species (ROS) production, multiple studies report elevated ROS levels when organisms are exposed to Cd (Cuypers et al. 2009, 2010). The resulting Cd-induced oxidative challenge is important for downstream induction of both damage and signaling processes (Fig. 1). The interest in this apparent paradox is rapidly increasing in current research and is focused on in this entry. When comparing the results of different studies, one should bear in mind to discuss them in relation to the experimental setup used,



Cadmium and Oxidative Stress, Fig. 1 Generalized model for the Cd-induced cellular oxidative challenge

that is, (1) exposure time (acute or chronic), (2) the Cd concentration used, (3) the chemical form in which the metal is applied (e.g., $CdCl_2$ or $CdSO_4$), (4) the way of administration (e.g., food, drinking water, intraperitoneal in case of animals; growth media in case of plants), (5) in vitro or in vivo experiments, and (6) organism specific characteristics such as species, age, and developmental stage. The mechanisms of Cd-induced responses clearly depend on all these variables.

A disturbed redox homeostasis is one of the main reported outcomes of all Cd-based studies, and fluctuations in the oxidative challenge, determined by pro- and antioxidants leading to damage or signaling, are outlined in the next sections.

Cadmium and Thiols: Toxicity and Detoxification

In general, almost all metals strongly bind to thiol groups and thus to cysteine-rich proteins. As mentioned earlier, this is an important toxicity mechanism of Cd, but it also makes up one of the most important detoxification systems. Metabolites and peptides containing thiol groups are of primary importance in Cd detoxification through chelation, that is, formation of cellular Cd–thiol complexes. In human and animal systems, cysteine-rich metallothioneins bind and detoxify Cd, while phytochelatins form important Cd-chelating agents in plants (Valko et al. 2006; Sharma and Dietz 2009; Cuypers et al. 2010).

Metallothioneins are gene-encoded cysteine-rich polypeptides, while phytochelatins are short cysteine-rich metal-chelating peptides in plants that are enzymatically formed. Glutathione (GSH; γ-Glu-Cys-Gly) is a highly abundant tripeptide, containing one cysteine molecule that forms the core of its properties as a chelating agent, but also as an antioxidant metabolite. As such, diverse detoxification pathways are combined in GSH.

Cadmium-Induced ROS Production

All aerobic organisms need oxygen for energy production in mitochondria. As a consequence, electrons can leak from the electron transport chain to oxygen (O_2), and during this monovalent reduction, ROS can be formed such as superoxide ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($^{\bullet}OH$) (Halliwell 2006).

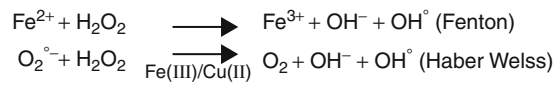
Redox-active metals such as iron (Fe) can directly induce ROS production via Fenton-like reactions (Fig. 2), whereas Cd, as a bivalent cation, is unable to perform these reactions. It can merely alter the cellular redox status via targeting thiol, carboxyl, and other functional groups present in the electron transport chain or antioxidative defense enzymes. Also, it activates prooxidative enzymatic mechanisms such as NADPH oxidases, which results in a disturbed redox balance in favor of the prooxidants. This status is currently known as oxidative stress, but the term "stress" has a negative connotation as ROS also exert beneficial functions within a cell, alternatively the term "oxidative challenge" is used.

Replacement of Redox-Active Elements

When freely available in the cytoplasm, redox-active elements directly enhance the production of $^{\bullet}OH$ through the Fenton reaction (Fig. 2). By replacing metals in various proteins, Cd increases the amount of free redox-active metals in the cell. Reduction of the oxidized metal ion can be achieved by the Haber–Weiss reaction with $O_2^{\bullet -}$ as a substrate (Fig. 2) (Cuypers et al. 2010).

Mitochondrial ROS Production

Due to the presence of the electron transport chain and its associated ROS production, mitochondria are a major target for different environmental stressors including Cd (Cannino et al. 2009). Different studies point toward the generation of ROS and mitochondrial dysfunction during Cd stress caused by morphological alterations and physiological disturbances. The thiol groups of respiratory complexes I to V are critical targets for Cd, and activities of complexes II and III appear the most inhibited in liver, brain, and heart of Cd-exposed guinea pigs. Production of ROS is maximal at the level of complex III and is related to the opening of the mitochondrial permeability transition (MPT) pore. A disrupted mitochondrial electron transport and corresponding mitochondrial permeability lead to an increased ROS production and/or leakage as compared to healthy tissues (Cannino et al. 2009; Cuypers et al. 2010).



Cadmium and Oxidative Stress, Fig. 2 Fenton and Haber–Weiss reaction

Mitochondrial ROS production might lead to the oxidation of membrane phospholipids, mitochondrial DNA cleavage, and impaired ATP generation with resulting mitochondrial damage and induction of apoptosis, effects that resemble aging-related processes. It is noteworthy to mention that Cd also affects the regulation of mitochondrial gene expression and is involved in mitochondrial retrograde signaling to the nucleus (Cannino et al. 2009). In this way, not only apoptosis but also cell survival and/or (malignant) cell proliferation could be linked to mitochondrial ROS production with Cd as a transcriptional regulator of cell proliferation processes (Liu et al. 2009).

Induction of NADPH Oxidases

NADPH oxidases (NOX) are multicomponent enzymes that use electrons derived from intracellular NADPH sources, to reduce molecular O_2 generating $O_2^{\bullet -}$ in the extracellular space. Their role as key components in human innate host defense is clearly demonstrated in multiple studies. As they also generate ROS in their metabolic reaction without external stress factors, the NOX family contributes to cellular signaling, regulation of gene expression, posttranslational protein processing that can lead to cell differentiation, and apoptosis (Thévenod 2009).

The gene expression of *NOX4* was upregulated in mice kidneys following chronic exposure to low levels of Cd. Unlike other NOX proteins, NOX4 does not depend on cytoplasmic cofactors and is regulated only at the level of transcription. Increased *NOX4* gene expression, thus could have led to the observed increase in NOX activity in these kidneys. The exact role NOX4 plays in Cd toxicity is not yet described but may be to produce ROS as a signal to activate the antioxidative defense system leading to acclimation (Fig. 1). In Cd-exposed hepatocytes, NADPH-dependent ROS production is also described and triggers signal transduction leading to protection mechanisms. Alternatively, excess ROS production may also cause Cd-induced damage in, for example, mouse neuronal cells. These authors describe a cyclooxygenase-2 upregulation induced by NADPH oxidase–dependent ROS, culminating in cell death after Cd exposure (Cuypers et al. 2010 and references therein).

In summary, cellular NOX activity can be affected by Cd, resulting in either signaling leading to the onset of cellular protection mechanisms or, alternatively, in cellular toxicity via the induction of cell death or (malignant) cell proliferation. Therefore, controlled levels of ROS production are crucial to ensure correct levels for signaling or defense responses. A large network of antioxidative mechanisms is described and will be discussed in the next paragraphs.

Cadmium-Induced Antioxidative Defense

During evolution, cells have developed protection mechanisms to minimize oxidative damage. Oxidants such as ROS are balanced against a well-developed antioxidative defense system consisting of both enzymes and metabolites present in all subcellular compartments and aiming at maximal protection (Halliwell 2006). In stress conditions, an increased ROS production triggers cells to activate and expand their antioxidative network. As such, Cd exerts a dual role on antioxidative capacity: it inhibits antioxidants (cfr. *supra*) but also activates several antioxidative components by disturbing the redox balance and, consequently, inducing a signal transduction cascade (Fig. 1).

Antioxidative Enzymes

Superoxide dismutases (SOD) are metalloenzymes catalyzing the dismutation of $O_2^{\bullet -}$ to the less reactive H_2O_2 with remarkably high efficiency. Multiple SOD isoforms exist, each containing a redox-active metal in their catalytic site to perform the reaction: CuZnSOD and MnSOD are expressed in different subcellular locations (Halliwell 2006). Activation of SOD during Cd stress is studied at transcriptional and metabolic levels. It is, however, difficult to generalize the SOD response due to the different exposure conditions and organs studied. In rats exposed to 50 mg Cd per liter of drinking water, during 12 weeks, an increased versus decreased total SOD activity in kidney and liver, respectively, was noticed. Acute exposure (24 h), however, resulted in a decrease of both kidney and liver SOD activities after an intraperitoneal administration of a single dose of 5 mg/kg. An in vitro study where neuronal cortical cells were exposed for 24 h to different Cd concentrations showed an increase in total SOD activity (Cuypers et al. 2010 and references therein).

Different SOD isoforms, according to their metallic cofactor, show specific subcellular distribution as well as response rates. Their involvement also has to be taken into account when comparing oxidative signatures described in different studies. Fluctuations in specific SOD isoforms can result in different subcellular ROS levels and species, but do they eventually lead to different physiological outcomes? Although there are clear indications for this, further research is needed to elucidate whether and how subcellular ROS levels are involved in downstream signaling (Valko et al. 2006; Thévenod 2009).

Both catalases (CAT) and peroxidases (Px) are involved in H_2O_2 quenching, and different roles during Cd exposure are suggested depending on the intensity of the stressor. Whereas CATs are active in severe stress situations, peroxidases (Px) are suggested to protect the cell against low levels of oxidative stress, possibly indicating a role for these enzymes in the fine-tuning of ROS levels important in signal transduction. In most organisms, CAT activity is mainly located in the peroxisomes and, to a lesser extent, in the cytoplasm of erythrocytes, the nucleus, and mitochondria, and it converts H_2O_2 to O_2 and H_2O. In contrast to CAT, Px-mediated H_2O_2 detoxification occurs via the oxidation of other organic substrates.

Glutathione peroxidase (GSH–Px), with GSH as a substrate, appears in five isoforms in most mammals and has a selenocysteine in its active site. Also in this case, as mentioned for SOD, the activation of CAT and Px is probably differentially regulated and dependent on tissue and organism studied, exposure conditions, etc. (Valko et al. 2006; Cuypers et al. 2010).

In mice, an increased CAT activity in liver was detected after 6 days of intraperitoneal Cd exposure that was similar to outcomes of experiments using rats exposed for 5 days to Cd via gastric gavage, where an increased blood CAT activity was observed. On the other hand, reduced CAT activities were observed in both kidney and liver of rats after acute intraperitoneal administration (24 h) as well as via Cd exposure through drinking water (10–30 days). Several possible underlying mechanisms for decreased CAT activities are hypothesized, for example, an interaction between Cd and the catalytic subunit of CAT; an observed Fe deficiency in kidney and liver of rats chronically exposed to Cd possibly decreased the CAT activity, since Fe is an essential element in the active center of CAT (Cuypers et al. 2010 and references therein). As for CAT, both increases and decreases in GSH–Px were observed in different studies. In rats, GSH–Px activity was found in blood cells after acute (24 h) intraperitoneal exposure to Cd, whereas decreased GSH–Px activities were reported after chronic Cd exposure in liver and kidney of mice and rats. As selenium (Se) forms the core of the active site of the GSH–Px, a possible underlying mechanism for a decreased activity is via Se depletion through Cd–Se–Cys complex formation. Furthermore, competition between GSH–Px and metallothioneins for S–amino acids could be a potential cause for a reduction in GSH–Px activity during Cd stress (Cuypers et al. 2010 and references therein).

Antioxidative Metabolites

Whereas antioxidative enzymes are specifically involved in ROS scavenging, several metabolites are – next to their antioxidative properties – also essential in diverse metabolic processes. These metabolites can be classified into two groups: (1) water-soluble or hydrophilic metabolites such as glutathione (GSH) and ascorbic acid (AsA) reacting with Cd-induced prooxidants in cells and blood plasma and (2) lipid-soluble or hydrophobic metabolites such as vitamin E that protect cell membranes from Cd-induced lipid peroxidation (Valko et al. 2006; Cuypers et al. 2010).

The widely distributed tripeptide GSH (cfr. *supra*) is one of the most important metabolites involved in defense against Cd-induced oxidative stress. Its antioxidant properties are attributed to the thiol (SH) group on the cysteine residue (Halliwell 2006), which enables GSH to transfer its reducing equivalents to GSH–Px, glutathione S-transferases, glutaredoxins, and AsA. In the cell, GSH is maintained in its reduced form by glutathione reductase (GR), and it has a dual role during Cd stress as it neutralizes ROS but also detoxifies Cd directly through chelation (cfr. *supra*). The latter lowers the cellular amount of damaging free Cd and can therefore reduce Cd-induced oxidative stress.

Ascorbic acid (AsA) also directly neutralizes Cd-induced ROS production. However, humans, primates, and some other species require dietary AsA uptake since they lost the ability for the complete AsA biosynthesis during evolution. Reduced AsA is diminished under Cd stress in mouse testes, although no effects on renal AsA content were detected. Several animal studies indicate that AsA supplementation reverses the adverse effects of Cd due to its antioxidative properties, although it also influences Cd absorption and distribution. Vitamin E (tocotrienol) is part of the tocochromanol family and is only synthesized by photosynthetic cells, again requiring dietary uptake in animals. α-Tocopherol is the most abundant and active isoform in human and animal tissues, where it incorporates into lipophilic environments. Vitamin E significantly decreases Cd-induced lipid peroxidation in different organs and body fluids of rats, but the exact mechanisms of uptake, distribution, and cellular effects have to be elucidated (Valko et al. 2006; Cuypers et al. 2010).

Cadmium Stress: A Real Challenge for Plants

Plants, crop plants in particular, form a link between the Cd contamination in the soil and the accumulation of this nondegradable contaminant in the food chain. As they are sessile organisms, plants cannot escape stress situations; consequently, uptake of the nonessential element Cd on contaminated soil is unavoidable as it enters the plant via uptake systems for essential

elements like Zn, Fe, Mg, Cu, and Ca. This is due to the chemical similarity of Cd^{2+} ions with the ions of these essential elements, which also causes deregulation of their homeostasis (DalCorso et al. 2008; Kucera et al. 2008; Sharma and Dietz 2009). Once taken up by the plant, Cd causes phytotoxic reactions, mainly through (a) displacement of essential cations from their functional site in biomolecules – again due to chemical similarity; (b) direct interaction with thiol, histidyl, and carboxyl groups of proteins, leading to loss of protein function; and (c) excessive generation of ROS (Sharma and Dietz 2009; Cuypers et al. 2009).

Cadmium-Induced ROS Production in Plants

Similar to animals, ROS generation can be due to the induction of enzymatic ROS production, for example, through plant NADPH oxidases (RBOHs; respiratory burst oxidase homologues) or lipoxygenases. In contrast to animals, plant NADPH oxidases are integral plasma membrane enzymes, but they also produce extracellular $O_2^{\bullet -}$. Lipoxygenase activity causes the formation of lipid peroxides, which in controlled levels are precursors for oxylipin signaling molecules, but Cd exposure can also lead to excessive lipid peroxidation, causing membrane damage and loss of membrane functionality (DalCorso et al. 2008; Kucera et al. 2008; Cuypers et al. 2009; Sharma and Dietz 2009). Cadmium also stimulates peroxisome biogenesis that contributes to excessive ROS production: xanthine oxidase and NADPH-dependent oxidase generate $O_2^{\bullet -}$, and glycolate oxidase, flavin oxidase, and β-oxidation of fatty acids yield H_2O_2, which is metabolized by CAT activity (Sharma and Dietz 2009).

Like in animals, Cd influences the electron transport chain in mitochondria, but this is only under recent investigation because a lot of attention has been given to an extra major source of excessive ROS in plants, more specifically the chloroplast. Cadmium hampers the photosynthetic activities of the chloroplast by damaging the light harvesting complex II and photosystem (PS) II. Cadmium (Cd^{2+}) is a competitive inhibitor of the Ca^{2+} site in the catalytic center of PSII in *Chlamydomonas reinhardtii*, inhibiting PSII photoactivation. Blockage of the electron flow in PSII leads to the formation of excited triplet chlorophyll that reacts with molecular oxygen ($^3O_2$) to form the highly reactive singlet oxygen ($^1O_2$) (Kucera et al. 2008; Sharma and Dietz 2009).

The electron transport is also impaired under Cd stress because of the peroxidation and loss of thylakoid membrane integrity. Furthermore, Cd inhibits chlorophyll synthesis leading to decreased total chlorophyll content, and Cd can replace Mg in chlorophyll, together resulting in decreased photosynthesis capacity. Cadmium negatively influences the carbon fixation, since Cd exposure induces stomatal closure and inhibits enzymes involved in CO_2 fixation (Kucera et al. 2008; DalCorso et al. 2008).

Antioxidative Defense in Plants Under Cd Stress

As plants are sessile organisms, they cannot escape from adverse mineral conditions, and in order to cope with sublethal stress conditions, they have mechanisms to adjust their metabolism. Comparison of redox-related components between tolerant/hyperaccumulator phenotypes and nontolerant relatives that were exposed to Cd revealed a relationship between metal sensitivity and redox imbalance: it was apparent that oxidative stress is a major component of Cd phytotoxicity as all tolerant/hyperaccumulator plants showed elevated antioxidative capacities, especially constitutive high levels of H_2O_2 and $O_2^{\bullet -}$ decomposing enzymes like ascorbate peroxidase (APx), CAT, and SOD (Sharma and Dietz 2009).

The antioxidative defense system of plants consists of enzymes and metabolites, similar to animals. Superoxide is scavenged by superoxide dismutases (SODs) and H_2O_2 by peroxidases and catalases (CATs). As is demonstrated for CAT and GSH–Px in animals, also APx has a strong affinity for H_2O_2 and therefore can result in a tight regulation of H_2O_2 levels for signaling purposes (Sharma and Dietz 2009). Antioxidative enzyme activities can be increased or inhibited by Cd, depending on several factors, such as exposure concentration, exposure time, and plant species. For example, SOD activity in plants exposed to Cd was increased in wheat but decreased in pea plants (DalCorso et al. 2008). SOD isoforms in plants exist in the cytoplasm, chloroplast, and mitochondria, and these may be differentially influenced. For example, Cd inhibited gene expression of the chloroplastic isoforms of SOD (Cu/ZnSOD2 and FeSODs), whereas cytoplasmic (Cu/ZnSOD1) and mitochondrial (MnSOD) SODs were not influenced (Cuypers et al. 2009).

Two important antioxidative metabolites that are special to plants are ascorbic acid and tocopherols in

comparison to humans. Ascorbic acid takes part in the ascorbate–glutathione pathway for ROS detoxification. Initially, APx oxidizes ascorbate when it reduces H_2O_2 to H_2O. Consecutively, the ascorbate–glutathione cycle uses the reducing power of NADPH to recycle AsA back to a reduced state, after they have been oxidized in the removal of excess ROS. Enzymes of this cycle are localized in chloroplast, mitochondria, peroxisome, and at the plasma membrane (Kucera et al. 2008). The AsA–GSH cycle is stimulated under Cd stress, and the expression and activities of APX were higher in the metal tolerant *Arabidopsis halleri* than in *Arabidopsis thaliana* (DalCorso et al. 2008; Cuypers et al. 2009).

Also, tocopherols are important plant compounds, which can reduce damage to lipids and protect cell membranes. Tocopherols react with singlet oxygen ($^1O_2$), and they can terminate the chain reactions that are occurring during lipid peroxidation. α-Tocopherol levels increased strongly immediately after Cd exposure along with an increased expression of hydroxypyruvate dioxygenase, an enzyme involved in tocopherol biosynthesis, and the tocopherol deficient *vte1* mutant was hypersensitive to Cd (Sharma and Dietz 2009).

A Disturbed Redox Balance: Two Different Outcomes?

The oxidative changes that arise during Cd exposure are often linked to damaging processes, hence the term oxidative stress. However, fluctuations in redox homeostasis also function as a regulator of diverse signaling processes. Signaling cascades, among which the MAPK (mitogen-activated protein kinase) pathway, efficiently respond to small changes in ROS content or composition, aiming at an acclimation of the cellular state. All of these kinases are described in literature as being influenced under Cd stress. Likewise are Ca-dependent kinases, calmodulins, and redox-related transcription factors (Thévenod 2009). A clear sequence of events, however, is not obvious to describe. Neither is a link between exposure condition and outcome. Most studies associate long-dose chronic exposure with the induction of signaling processes that lead to acclimation and repair mechanisms (Fig. 1). Signal transduction pathways activated under acute exposure to higher levels of Cd, on the other hand, often lead to the induction of programmed/apoptotic cell death (Cuypers et al. 2010; Templeton and Liu 2010 and references herein). Whereas, an increased accumulation of ROS and lipid peroxidation induces programmed cell death or apoptosis; also, necrotic events and uncontrolled cell proliferation are associated with (severe) redox-related damage (Liu et al. 2009).

In conclusion, cross talk and spatiotemporal interactions between signaling pathways depend on the strength and duration of the ROS levels as well as on the influence of the surrounding environment. ROS are produced at different subcellular locations, within different time intervals, and in a different composition and concentration. The main challenge remains how to link a disturbed redox balance with the induction of either damaging or signaling processes.

Cadmium and Stress Response

Masanori Kitamura
Department of Molecular Signaling, Interdisciplinary Graduate School of Medicine and Engineering, University of Yamanashi, Chuo, Yamanashi, Japan

Synonyms

Endoplasmic reticulum stress response; Oxidative stress response; Unfolded protein response

Definition

Exposure to cadmium results in cellular stress and evokes responses that involve injurious signaling and protective reactions. The most typical examples are oxidative stress and endoplasmic reticulum (ER) stress. Oxidative stress represents an imbalance between the production of reactive oxygen species (ROS) and the potential to detoxify ROS. The oxidative stress response comprises (1) generation of ROS and consequent modulation of cellular components including proteins, lipids, and DNA, leading to cellular activation or apoptosis and (2) induction of antioxidant systems that protect cells from ROS-mediated activation and cell injury. ER stress is defined as accumulation of unfolded proteins in the ER. It triggers an adaptive program, namely the unfolded protein response (UPR). The UPR alleviates ER stress by suppression of protein synthesis, facilitation of protein folding, and reinforced degradation of unfolded proteins. The UPR may activate an array of kinases and transcription factors, leading to expression of target genes. However, when stress is beyond the capacity of the cytoprotective machinery, cells undergo apoptosis. Like the pro-survival process, the pro-apoptotic process is also mediated by the UPR.

Introduction

Cadmium is a toxic metal and a potent environmental pollutant. In humans, cadmium intoxication is caused by its intake through contaminated water, food, and air – especially cigarette smoke. Because of its low excretion rate, cadmium accumulates in different organs over time and causes various negative effects on human's health, including renal dysfunction, osteoporosis/bone fractures, and development of cancers. Cadmium accumulates in some target organs, especially in the kidney where its highest concentrations are observed. Human studies indicated that 7% of the general population have renal dysfunction caused by cadmium exposure. Cadmium nephropathy is characterized by proteinuria, aminoaciduria, glucosuria, phosphaturia, and reduction in glomerular filtration rate. In the kidney, accumulation of cadmium occurs mainly in the proximal tubules. Following prolonged and/or high levels of exposure to cadmium, apoptosis is induced in the proximal tubules (Thevenod 2003).

Several underlying mechanisms have been postulated, and currently, ROS are considered as crucial mediators for the cadmium-triggered tissue injuries (Cuypers et al. 2010). However, recent investigation disclosed that, in addition to oxidative stress, cadmium causes ER stress in vitro and in vivo, which also plays a crucial role in the induction of cell injury (Kitamura and Hiramatsu 2010).

Principles

Oxidative Stress Response

Under normal conditions, ROS are generated by the leakage of activated oxygen from mitochondria during oxidative phosphorylation. Under pathological situations, mitochondria are also the major source of ROS that leads to activation of specific signaling pathways and consequent regulation of cell behavior including proliferation, migration, differentiation, and apoptosis. In particular, excessive ROS cause damage of cellular proteins, lipids, and DNA, leading to apoptotic and necrotic cell death. On the other hand, in response to generation of ROS, cells are able to exert defense mechanisms to control cellular homeostasis. Xanthine oxidase, NADPH oxidases, and cytochromes P450 contribute to the production of ROS, and cellular antioxidant enzymes such as superoxide dismutase (SOD), catalase, and glutathione peroxidase are involved in scavenging of ROS.

In biological systems, sequential reduction of oxygen leads to the generation of superoxide anion ($O_2^{\bullet -}$)

and hydrogen peroxide (H_2O_2). SOD scavenges $O_2^{\bullet -}$ by catalyzing conversion of $O_2^{\bullet -}$ to H_2O_2. $O_2^{\bullet -}$ also rapidly reacts with nitric oxide, yielding another reactive species, peroxynitrite ($ONOO^-$). All of these ROS are potential triggers for apoptosis.

ER Stress Response

ER stress is induced under a variety of pathological situations. Regardless of types of triggers, ER stress induces a coordinated adaptive program, the UPR. Three major transducers for sensing ER stress are present at the membrane of the ER, that is, protein kinase-like ER kinase (PERK), activating transcription factor 6 (ATF6), and inositol-requiring enzyme 1 (IRE1). Activation of PERK leads to phosphorylation of eukaryotic translation initiation factor 2α (eIF2α), which causes general inhibition of protein synthesis. In response to ER stress, 90 kDa ATF6 (p90ATF6) transits to the Golgi where it is cleaved by proteases, yielding an active transcription factor, 50 kDa ATF6 (p50ATF6). Similarly, activated IRE1 catalyzes removal of a small intron from the mRNA of X-box binding protein 1 (XBP1). This splicing event creates a translational frameshift in *XBP1* mRNA to produce an active transcription factor. Active p50ATF6 and XBP1 subsequently bind to the ER stress response element (ERSE) and the UPR element (UPRE), leading to expression of target genes including ER chaperone 78 kDa glucose-regulated protein (GRP78) (also called BiP) and ER-associated degradation factors involved in elimination of unfolded proteins. Primarily, these pathways contribute to attenuation of ER stress (Kitamura 2008).

During the UPR, however, death signals may also be transduced from the ER (Kim et al. 2006). For example, activation of the PERK-eIF2α pathway causes selective induction of transcription factor ATF4. Subsequently, ATF4 triggers expression of pro-apoptotic CCAAT/enhancer-binding protein-homologous protein (CHOP) through binding to the amino acid response element. ER stress activates caspase-12 localized at the ER membrane through an interaction with IRE1 and TNF receptor-associated factor 2 (TRAF2), leading cells to undergo apoptosis. The IRE1–TRAF2 interaction also allows for recruitment and activation of apoptosis signal-regulating kinase 1 and downstream c-Jun N-terminal kinase (JNK), both of which are involved in a variety of pro-apoptotic signaling.

Evidence

Induction of Oxidative Stress by Cadmium

Metals such as iron, copper, chromium, vanadium, and cobalt are capable of redox cycling in which a single electron may be accepted or donated by the metal. This action catalyzes reactions that produce reactive radicals and generate ROS. However, cadmium is a bivalent cation and unable to generate free radicals directly, although production of ROS in cadmium-exposed cells has been documented in many studies (Liu et al. 2009). Because cadmium possesses a high affinity for thiols, the major thiol antioxidant glutathione (GSH) that is abundant in cells is considered as a primary target for cadmium. That is, depletion of the reduced GSH pool results in a disturbance of the antioxidant defense mechanism. Cadmium depletes glutathione and protein-bound sulfhydryl groups, resulting in enhanced production of ROS such as $O_2^{\bullet -}$, H_2O_2, and hydroxyl radicals. The spin-trapping technique in conjunction with electron spin resonance also provided direct evidence for cadmium-triggered generation of these ROS in vitro and in vivo (Liu et al. 2009).

Induction of ER Stress by Cadmium

Cadmium has the potential to induce ER stress in various cell types, as reviewed recently (Kitamura and Hiramatsu 2010). Cadmium triggers expression of GRP94 in thymocytes and GRP78 in lung epithelial cells and renal tubular cells. Cadmium causes expression of CHOP and activation of caspase-12 in mesangial cells and hepatoma cells. It also induces splicing of *XBP1* mRNA in fibroblasts. We showed that, in renal tubular cells, cadmium caused phosphorylation of PERK and eIF2α, activation of ATF6, and splicing of *XBP1* mRNA, and it was associated with induction of GRP78, GRP94, and CHOP. Furthermore, administration of cadmium in mice also triggered expression of GRP78 and CHOP in the kidney and liver. Thus, cadmium is able to activate the three major branches of the UPR.

Molecular mechanisms underlying the induction of ER stress by cadmium are not fully understood, but ROS are possible candidates to mediate induction of ER stress. This issue is described in detail in the section "Cross Talk Between Oxidative Stress and ER Stress." In addition to ROS, several recent reports suggested release of calcium from the ER mediates

cadmium-induced apoptosis of several cell types. Depletion of calcium store in the ER is a well-known trigger to induce ER stress, and induction of ER stress by cadmium may, in part, be mediated by mobilization of intracellular calcium.

Role of Oxidative Stress in Cadmium-Induced Cell Death

Several previous studies showed involvement of ROS in cadmium-induced cell injury. As described, exposure of cells to cadmium causes generation of ROS, which is associated with a decrease in glutathione levels and consequent cellular death. Another line of evidence shows that cadmium-triggered apoptosis is inhibited by treatments with antioxidants, suggesting crucial roles of ROS.

Several mechanisms have been postulated to the cytotoxic effect of ROS in cadmium-exposed cells. First and foremost, excessive ROS cause damage of cellular components including proteins, lipids, and DNA, leading to apoptotic and necrotic cell death. When applied in low to moderate concentrations, cadmium mainly causes apoptosis. However, exposure of cells to its high concentrations leads to necrotic cell death. Both apoptosis and necrosis are induced by increased accumulation of ROS and associated with facilitation of lipid peroxidation. Cadmium-induced ROS also interact with the cellular defense machinery via activation of mitogen-activated protein (MAP) kinases and other signaling pathways. For example, cadmium-induced ROS triggers activation of p38 MAP kinase, leading to both pro- and anti-apoptotic events, for example, activation of caspase-3 and induction of 70 kDa heat shock proteins. Cadmium also increases phosphorylation of JNK via changes in cytosolic Ca^{2+} fluxes and/or changes in the cellular redox balance, leading to apoptotic cell death (Cuypers et al. 2010).

Role of ER Stress in Cadmium-Induced Cell Death

Cadmium induces both ER stress and apoptosis in vitro and in vivo. Cells transfected with ER chaperones such as GRP78 and 150 kDa oxygen-regulated protein are resistant to cadmium-induced apoptosis (Yokouchi et al. 2007), suggesting a crucial role of ER stress.

There are three proximal transducers in the ER for sensing of ER stress, and all the transducers are activated by cadmium. The first transducer is ATF6. Cadmium induces activation of the ATF6 pathway, and treatment of cells with an inhibitor of ATF6 attenuates cadmium-induced apoptosis. Similarly, dominant-negative inhibition of ATF6 suppresses cadmium-induced apoptosis. The second proximal transducer for ER stress is IRE1. Activated IRE1 catalyzes the removal of a small intron from *XBP1* mRNA, leading to production of the active transcription factor. Treatment with cadmium rapidly induces splicing of *XBP1* mRNA. Transfection with a dominant-negative mutant of XBP1 leads to cellular resistance against cadmium-induced apoptosis. Similarly to the pro-apoptotic effect of XBP1, JNK, another molecule downstream of IRE1, is also phosphorylated by cadmium, leading to induction of apoptosis. Thus, the ATF6 and IRE1 pathways participate in the induction of apoptosis by cadmium (Yokouchi et al. 2007).

The third transducer for ER stress is PERK, the activation of which leads to phosphorylation of eIF2α and blockade of protein synthesis. Cadmium rapidly induces phosphorylation of PERK and downstream eIF2α. Salubrinal, a selective activator of eIF2α, inhibits cadmium-induced apoptosis. Furthermore, dominant-negative inhibition of eIF2α significantly enhances cadmium-induced apoptotic cell death. In contrast to the ATF6 and IRE1 pathways, the PERK-eIF2α pathway is anti-apoptotic in cadmium-exposed cells (Yokouchi et al. 2007).

Taken together, these results suggest differential, bidirectional regulation of apoptosis by the UPR in cadmium-exposed cells.

Cross Talk Between Oxidative Stress and ER Stress

Oxidative stress and ER stress occur in cells under the exposure to cadmium. The oxidative stress response and the UPR may occur independently, but cross talk is also present between these stress responses under the exposure to cadmium. Accumulating evidence suggests that protein folding and generation of ROS are closely linked with each other (Malhotra and Kaufman 2007; Kitamura and Hiramatsu 2010). Prolonged activation of the UPR may result in oxidative stress and consequent cellular death. Accumulation of ROS by the UPR is caused through two mechanisms; the ER-dependent and the mitochondria-dependent ROS generation. On the other hand, another line of evidence suggests that induction of the UPR occurs under oxidative stress, which is an adaptive mechanism to preserve cell function. We found that cadmium-induced ER stress was attenuated by antioxidants in

renal tubular cells. Exposure of cells to ROS donors caused ER stress, whereas suppression of ER stress did not attenuate cadmium-triggered oxidative stress, suggesting that ER stress is the event downstream of oxidative stress (Yokouchi et al. 2008).

In the induction of ER stress by cadmium, particular ROS may play dominant roles. We found that exposure to $O_2^{\bullet -}$, H_2O_2, or $ONOO^-$ induced apoptosis of renal tubular cells, whereas ER stress was caused only by $O_2^{\bullet -}$ and $ONOO^-$. Scavenging of $O_2^{\bullet -}$ attenuated cadmium-induced ER stress and apoptosis, whereas inhibition of $ONOO^-$ was ineffective. Furthermore, $O_2^{\bullet -}$ was involved in the activation of the ATF6 and IRE1 pro-apoptotic pathways in cadmium-exposed cells (Yokouchi et al. 2008). These results provide evidence that $O_2^{\bullet -}$ is preferentially involved in cadmium-triggered, ER stress-mediated apoptosis.

Oxidative Stress, ER Stress, and Other Stress Signaling

Cadmium triggers an array of signaling pathways. For example, cadmium has the potential to activate stress-related signaling including MAP kinase cascades, the Akt pathway, and NF-κB signaling, all of which are involved in the regulation of cell survival and death (Thévenod 2009). It is well known that ROS trigger activation of MAP kinases, Akt, and NF-κB (Kamata and Hirata 1999). ER stress also has the potential to activate Akt and NF-κB, at least in part, through the ATF6 pathway (Kitamura 2009). Recently, we reported that ER stress induces activation of extracellular signal-regulated kinase, p38 MAP kinase and JNK through activation of the PERK-eIF2α pathway and the IRE1 pathway (Zhao et al. 2011). The activation of Akt, MAP kinases, and NF-κB by cadmium seems to be nonselective and possibly the events downstream of oxidative stress and ER stress. Oxidative stress and ER stress may be at the top of the chain of most signaling pathways activated by cadmium.

Therapeutic Implications

Previous reports suggested that antioxidants are useful for the prevention of cadmium-related tissue injury. Currently, treatments against cadmium toxicity include antioxidant therapy with melatonin and vitamin E. In addition to antioxidants, some reagents that attenuate ER stress may also be useful for this purpose. For example, chemical chaperone 4-phenylbutyric acid (4-PBA) is an agent that stabilizes protein conformation, improves ER folding capacity, and facilitates trafficking of mutant proteins. Oral administration of 4-PBA to a murine model of type 2 diabetes alleviates ER stress, reduces diabetic symptoms, and lowers systemic inflammation. Based on the fact that ER stress is involved in cadmium-induced toxicity, chemical chaperoning may be another possible strategy for the treatment of cadmium intoxication. However, it is worthwhile to note that some reports indicated caution in the use of antioxidants against cadmium toxicity. For example, studies in cancer cells have shown that use of vitamin C (ascorbate) in the presence of some metal (cadmium or nickel) caused damage of double-stranded DNA and apoptotic cell death. Toward therapeutic intervention in cadmium-related pathologies, the complex interactions among metals, antioxidants, and chemical chaperones need further investigation.

Conclusion

Exposure to cadmium causes oxidative stress and ER stress, both of which evoke injurious signaling as well as cytoprotective reactions. The oxidative stress is located upstream (or downstream) of ER stress, and cross talk of these stress responses forms proximal events that regulate activation of downstream signaling. Appropriate control of oxidative stress and ER stress is a potential strategy for therapeutic intervention in cadmium-related disorders.

Cadmium Carbonic Anhydrase

Claudiu T. Supuran
Department of Chemistry, University of Florence, Sesto Fiorentino (Florence), Italy

Synonyms

Cadmium(II); Cd(II); Zinc carbonic anhydrases

Definition

Cadmium: Cadmium is a metallic element with the oxidation state of +2, occurring rarely in metalloproteins, except some carbonic anhydrases. It is currently considered highly toxic, but in Cd-CAs, this metal ion has a catalytic role.

Carbonic anhydrase: Superfamily of metalloenzymes catalyzing CO_2 hydration to bicarbonate and protons. Ubiquitous in all life kingdoms.

Biological implications: Cd-CAs are involved in CO_2 fixations and photosynthesis in many diatoms.

Carbonic Anhydrase Families

The carbonic anhydrases (CAs, EC 4.2.1.1.) are a superfamily of metalloenzyme which evolved independently several times, with five genetically distinct enzyme classes known to date: the α-, β-, γ-, δ-, and ζ-CAs (Supuran 2008). The α-, β-, and δ-CAs use Zn(II) ions at the active site (Supuran 2008, 2010); the γ-CAs are probably Fe(II) enzymes (but they are active also with bound Zn(II) or Co(II) ions) (Ferry 2010), whereas the ζ-class uses Cd(II) or Zn (II) to perform the physiologic reaction catalysis (Xu et al. 2008). All these enzymes, including the Cd-CA catalyze a very simple but essential reaction, hydration of carbon dioxide to bicarbonate and protons (Supuran 2008). The 3D fold of the five enzyme classes are very different from each other, as it is their oligomerization state: α-CAs are normally monomers and rarely dimers; β-CAs are dimers, tetramers, or octamers; γ-CAs are trimers, whereas the δ- and ζ-CAs are probably monomers, but in the case of the last family, three slightly different active sites are present on the same protein backbone which is in fact a pseudotrimer, at least for the best investigated member of the class, the enzyme from the marine diatom *Thalassiosira weissflogii* (Xu et al. 2008). Many representatives of all these enzyme classes have been crystallized and characterized in detail, except the δ-CAs. Cd-CAs were described so far only in diatoms (Xu et al. 2008).

Biological Role of Cd-CAs

CAs are key enzymes involved in the acquisition of inorganic carbon for photosynthesis in phytoplankton (Xu et al. 2008). Most of the phytoplankton operate a carbon-concentrating mechanism (CCM) to increase

the CO_2 concentration at the site of fixation by RuBisCO several folds over its external concentration, allowing the enzyme to function efficiently. Marine diatoms possess both external and internal CAs. It has been hypothesized in the model diatom *T. weissflogii* that the external CA catalyzes the dehydration of HCO_3^- to CO_2 to increase the gradient of the CO_2 diffusion from the external medium to the cytoplasm, and the internal CA in the cytoplasm catalyzes the rehydration of CO_2 to HCO_3^- to prevent the leakage of CO_2 to the external medium again (Xu et al. 2008). One of the most remarkable findings regarding the ζ-CA from *T. weissflogii* was that this is a Cd(II)-containing enzyme, which can also work with Zn(II) bound at the active site, and that there is a rather rapid metal exchange between zinc and cadmium, depending on the availability of metal ions in the marine environment (Xu et al. 2008). It is not known yet where this enzyme is localized in *T. weissflogii* or other diatoms.

Role of Cd(II) in the Catalytic Mechanism

The Cd(II) ion is essential for catalysis being coordinated by two Cys and one His residues, with a water molecule completing the coordination sphere. Cd(II) is thus in a distorted tetrahedral geometry, but a second water molecule is nearby, so that it is not clear whether Cd(II) is indeed tetrahedral or trigonal bipyramidal in this cadmium enzyme (Xu et al. 2008; Viparelli et al. 2010).

It is generally accepted that in Cd-CAs, a cadmium hydroxide moiety acts as nucleophile in the catalytic cycle, similar with the zinc hydroxide one in other classes of CAs (Supuran 2010). The enzyme can be inhibited by inorganic, metal-complexing anions or sulfonamides, similar to the Zn(II)-containing CAs. The *T. weissflogii* Cd-CA is one of the most effective enzymes known in nature, with a turnover number for the hydration of CO_2 to bicarbonate close to the limit of the diffusion-controlled processes (Xu et al. 2008; Viparelli et al. 2010). Their function in diatoms is extremely important for the CO_2 fixation process, and with the climate change in fact, a better study of such enzymes may prove critical for understanding these intricate phenomena. It is also interesting to note that a metal ion, such as cadmium, normally associated with high toxicity for mammals, plays a crucial role in this enzyme found in diatoms, being essential to their life cycle.

Synonyms

Adaptation: Acclimatization; Refitting
Resistance: Insusceptibility; Obstruction; Opposition; Resistivity

Definition

Adaptation: The fact for a living species to become better suited to its environment.

Resistance: The process of opposing the harmful threat of a toxic compound.

Speciation: Describes the associated forms in which elements, e.g., metals, occur in complex systems, such as a biological medium.

Redox: Acronym for oxidation-reduction. Here, refers to the set of reactions in which electrons can be exchanged within a cell.

Reactive oxygen species (ROS): Designates three oxygen-containing compounds, the superoxide radical anion, hydrogen peroxide, and hydroxyl radical, which all derive from dioxygen by successive reduction steps. By extension, ROS may refer to strongly oxidative (i.e., electron withdrawing) oxygen-containing molecules such as the hypochlorous anion or peroxynitrite.

Introduction

Cadmium compounds are overwhelmingly toxic in their interactions with living bodies (Satarug et al. 2010), even though apparently safe and functional replacement of zinc in a carbonic anhydrase isoform from diatoms is documented (Morel 2008). Depending on the means of exposure, on the considered living species, and on speciation, cadmium has different molecular targets: cadmium jeopardizes the exposed organism by inducing cell death or at least malfunction.

A characteristic feature of cadmium toxicity is the range of molecules being able to interact with the ionic form of the metal (Cd^{2+}, the only one of significant biological importance). The affinity of divalent cadmium for thiolates is often put forward, but binding to nitrogen-containing ligands (histidine imidazole, amines, amides, etc.) and carboxylic acids also occurs (Moulis 2010). Regarding this chemical versatility, the major challenge of cadmium toxicity is to identify the most relevant biological pathways that are perturbed by the toxic metal. Changing the cellular environment by introduction of a toxic compound such as cadmium triggers a cellular response that can be described in two phases, a homeostatic one aiming at maintaining the cellular functions as they were prior to the insult and an adaptive one helping cells to cope with the new situation in the long run. Schematically, the first phase is preeminent upon acute exposure, and it may be sufficient to keep viability if the exposure does not last and is not too large. The second phase is expected to gain more importance upon chronic, often low concentration, exposure to the toxic metal. The fundamental molecular mechanisms underlying these two sets of situations are sketched in this essay to provide a general view of cadmium toxicity, with emphasis on the changes allowing cells to sustain long-term cadmium exposure.

Cadmium-Induced Cell Death

As most of the antioxidant systems available to cells rely on thiol-containing molecules, divalent cadmium is expected to displace the cellular balance between oxidants and reducing molecules (i.e., *redox* equilibrium). The intracellular abundant cysteine-containing tripeptide glutathione (GSH) chelates cadmium, and the function of prominent redox-active proteins such as thioredoxins, glutaredoxins, and peroxiredoxins is perturbed by the presence of cadmium ions. The imbalance in the availability and production of antioxidant molecules triggers the upraising of radicals and other reactive molecules, including the now well-known reactive oxygen species (ROS), which modify and inactivate scores of biological components and lead to necrosis and death at high concentrations (Liu et al. 2009; Cuypers et al. 2010).

In a generally less brutal way, the challenge generated by moderate levels of cadmium to the redox balance and the ensuing increase of the concentration of ROS and other oxidizing molecules impact several pathways without immediate damage. The cellular response aims at correcting the changes by inducing various activities known as the antioxidant response. But the drastic changes cadmium induces may not allow cells to cope with the unbalanced situation, and apoptosis may occur.

Although cell death is a likely outcome upon cadmium exposure, some cells may remain viable. They originate from a few, or even a single, clones of the initial population, and they play a prominent role in cadmium-induced carcinogenesis in mammals when they proliferate. This process requires an adaptive response which efficiently handles the cadmium threat and in which many distinct mechanisms may be at play.

Resistance to Cadmium Toxicity

Chronologically, cells have to be able to sustain the insult of toxic compounds before being able to recover or in a position to proliferate. Means enhancing the activities that are immediately challenged by cadmium allow cells to resist, at least transiently.

Resistance by counteraction against oxidants. The molecules involved in the antioxidant response are naturally at the forefront of the resistance mechanisms. Enzymes participating to the synthesis and the turnover of GSH, such as γ-glutamate cysteine ligase (GCL) or GSH synthetase and GSH reductase (GR), respectively, are upregulated in some cadmium resistant cells. In mammalian cells, the enhanced antioxidant response is mainly mediated by the nuclear respiratory (transcription) factor Nrf2. Nrf2 binds to antioxidant response elements found in the promoter sequences of genes triggering the antioxidant response, including the ones encoding heme oxygenase 1, GR, or GCL for instance.

But not all resistance mechanisms against cadmium are directly dependent on Nrf2. Reallocation of cellular resources can help fighting the cadmium challenge. For instance, increase of the cytosolic $NADP^+$-dependent isocitrate dehydrogenase diverts cells from apoptosis, most likely by increasing cytosolic NADPH, one of the few electron donors (i.e., reductant) in this cellular subcompartment.

Resistance by enhancing cadmium-inactivated activities. More generally, any metabolic activity which is inhibited by cadmium has to be reestablished to a sufficient level to allow cells to resist to the toxic metal. Various ways to this aim have been identified, including overproduction of potent antioxidant activities mediated by Nrf2-induced transcription. Transcriptional upregulation of cadmium-inactivated activities is often observed to compensate or substitute jeopardized pathways and targets. An interesting mechanism has been evidenced in yeast: the increased demand for GSH called for by increased cadmium concentrations is partly met by reallocation of the cell sulfur resources to GSH synthesis by switching isozymes production (pyruvate decarboxylase, aldehyde dehydrogenase, enolase) from cysteine-rich to cysteine-poor forms, with the likely additional advantage of decreased sensitivity to cadmium inhibition (Fauchon et al. 2002). In plants, cadmium exposure increases synthesis of participants to major metabolic pathways, such as glycolysis and the pentose phosphate pathway, with the apparent purpose of maintaining energy-rich metabolites (ATP, NADH, NADPH) and of building molecules involved in cadmium binding (Villiers et al. 2011).

Resistance by cadmium trapping. Among them, phytochelatins (PC) are strongly produced as a response to cadmium. GSH is the precursor of these sulfur-rich molecules which participate in cadmium traffic and vacuolar sequestration (see "► Accumulation"). This upregulation occurs at different levels, and phytochelatin synthase activity is strongly stimulated by cadmium bound to GSH. In a similar tone, metallothioneins (MT) increased synthesis is a common observation resulting from cadmium exposure in other cells. These cysteine-rich proteins display a strong affinity for cadmium, and they also participate in cadmium traffic (Klaassen et al. 2009; Maret 2011). For instance, ingested cadmium in mammals rapidly reaches the liver where induced MT synthesis protects the organ from cadmium damage. The chelated form of the metal is excreted from the initial target organs (duodenum, liver, etc.), and it ends up in the renal glomerulus via the circulation. The Cd-MT complex enters proximal tubule cells via endocytosis, and the metal accumulates in kidneys as the result of Cd-MT processing. This series of events illustrates that different cell types handle cadmium in different ways, and that the physiological metal speciation in multicellular organisms has a major influence on the toxicological consequences of cellular cadmium exposure. MT induction is mainly a transcriptional mechanism involving a specialized transcription factor, MTF-1, which binds metals such as zinc and cadmium and interacts with metal-responsive elements in the promoter regions of dependent genes, including MT ones. Despite the importance of MT in the first line of defense against cadmium, the very long half-life of the metal (several decades in humans) once absorbed implies that MTs and PCs cannot be considered as single mediators of long-term cadmium detoxification, and additional mechanisms have to be implemented to allow cells to overcome the cadmium insult.

Resistance by competition from other metals. Many processes involved in cadmium distribution within the body correspond to situations in which the toxic metal hijacks the molecular devices devoted to the traffic of essential metals (Clemens 2006; Moulis 2010;

Thévenod 2010). Competition between (some of) these metals and cadmium may occur for transporters, chelators (e.g., GSH, MT, or PC), and other molecules. Hence, increased availability of selected essential (nontoxic) metals may oppose cadmium toxicity. The most obvious example is zinc, an abundant and hardly toxic biological metal, which strongly resembles cadmium. Zinc supplementation contributes to the antioxidant response, by increasing the Nrf2-triggered transcription of the catalytic subunit (heavy chain) of glutamate-cysteine ligase for instance, and it often protects from cadmium-induced cell death. Other indirect mechanisms may mediate the cellular protection afforded by essential metals against cadmium. The viability of a human epithelial cell line that was developed in high zinc concentrations was far larger upon exposure to high cadmium concentrations as compared to naïve cells. But instead of reflecting a mere competition between zinc and cadmium, adaptation to zinc inhibited cadmium entry into the cells via a transporter which was responsible for manganese and cadmium uptake but not directly involved in zinc traffic.

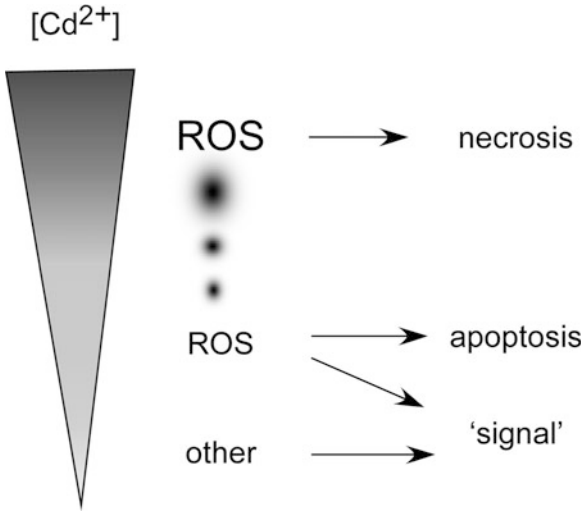
This single example shows that the permeation of the plasma membrane to cadmium is a major player in the sensitivity/resistance to the toxic effects of the metal. Many molecular components of this membrane (transporters of various kinds and ionic channels) can potentially move cadmium in and out in different cell types. In a given case, one specific molecule often supersedes other possible contributors. Consequently, inhibiting, in the case of inward movement, or inducing, in that of extrusion, this transporter protects cells from toxicity. This often occurs upon sustained exposure to cadmium and cellular selection for viability. For instance, mouse testicular cadmium toxicity is associated with SLC39A8 (Zip8) activity, and resistance to necrosis results from inactivation of the gene (He et al. 2009).

Resistance via signaling. As a stressful agent for cells, cadmium impacts a range of signaling cascades, and resistance mechanisms have been associated with changes in the efficiency of signal transduction or escape of targets from the regulation. In the presence of cadmium, resistance mechanisms associated with alterations of signaling pathways must enhance proliferative signals or dampen apoptotic ones (Thévenod 2009). Biochemically, most of these effects can be traced back to the interaction of cadmium ions with reactive sites in signal sensing molecules or the modifications of these sites induced by cadmium-triggered redox imbalance. Examples include extracellular cadmium interaction with E-cadherin with subsequent effects on the epithelial-mesenchymal transition favoring metastasis spreading and decreased activation of MAPK (mitogen-activated protein kinases) lowering the efficiency of cadmium-triggered apoptosis in resistant cells.

The above variety of mechanisms which have been evidenced in different cells under different conditions does not imply that conditions circumventing cell death may last for long periods of time. In most reports, the information about the length of the resistance effect is lacking, as is that of its reversibility (both aspects are generally connected). But in the cases in which viability is maintained with or without the continuous presence of cadmium, the selected cells have turned the resistance process into an adaptive, most often malignant, change. Many of the resistance mechanisms described above are relevant to acute exposure of naïve cells to cadmium, and they aim to maintain viability upon a sudden chemical threat (Fig. 1). Yet, sustained exposure to the poison requires other or adjusted mechanisms. For instance, it is not always clear that low cadmium doses need to be counteracted by a massive antioxidant response. The continuous exposure of the cells is accompanied by a shift of the homeostatic status, and adaptation aims at affording the necessary corrections in a permanent way.

Adaptation and DNA Lesions

A well-established mechanism to permanently affect any cell behavior is through genetic imprint. Solid evidence for cadmium as a mutagenic chemical is virtually nonexistent, but it is a likely comutagen with other genotoxic compounds or upon physicochemical stress, e.g., irradiation. Direct DNA oxidative damage induced by cadmium is probably a feature to be associated with acute poisoning. But cadmium does not need to enhance the formation of DNA lesions to be toxic. Various DNA modifications are continuously produced at low levels through side reactions of metabolism, and they need to be repaired to maintain genetic integrity. Accumulated evidence shows that all DNA repair systems (nucleotide excision, base excision, and mismatch repair) are particularly



Cadmium Exposure, Cellular and Molecular Adaptations, Fig. 1 Cellular fate as a function of the cadmium concentration. Cells may be exposed to a range of cadmium concentrations (*left*) which mainly leads to a proportional oxidative stress (*ROS* reactive oxygen species) and to additional effects ("signal" discussed in the text) at low concentrations. The outcome for the cells (*right*) ranges from death, mainly by necrosis at high concentrations, to resistance and adaptation, when the cadmium threat can be overcome

sensitive to cadmium. Several components and steps (damage recognition, removal, and efficiency of the repairing activities) involved in these correcting processes may be impaired by cadmium (Hartwig 2010). The defects in repairing DNA damage have a significant influence on the balance between cellular proliferation and death, and they most probably should take the blame for cadmium-induced transformation, hence adaptation and carcinogenesis (Waalkes 2003; Hartwig 2010).

Furthermore, modifications of the chromosomal integrity and of the fidelity of the genetic information may not be the only way through which cadmium impacts the cellular fate. Epigenetic changes, e.g., the methylation status of DNA, have been evidenced upon cadmium exposure, with particular consequences on the expression of tumor suppressors such as *RASSF1A* or *CDKN2A* and induced regulatory defects of the cell cycle and of DNA repair. It is likely that the impact of cadmium on epigenetics will be more significantly documented in the near future.

Beyond methylation and histone modifications, noncoding DNA is also susceptible to the presence of cadmium. MicroRNA molecules (miRNA) regulate different steps of the turnover of specific genes, such as those carried out by transcription factors and degradation labeling activities (E3 ubiquitin ligases). Examples include miR393 and miR171 in legumes and miR146a in leukocytes, which regulate plant development and cancer (pancreas and glial) cells invasion and metastasis, respectively.

Despite accumulated data, it is usually difficult to discriminate between permanent epigenetic changes that can be transmitted to daughter cells and alterations of signal transduction pathways adjusting to the continuous presence of cadmium.

Adaptation by Transcription/Signaling

A range of signaling events accompanies the exposure of mammalian cells to cadmium with consequences on apoptosis and differentiation, not to mention development. Cell survival and proliferation, decreased DNA repair capacity, and genomic instability all contribute to adaptation to permanent cadmium resistance in transformed cells (Beyersmann and Hechtenberg 1997; Thévenod 2009).

Proliferation occurs via enhancing growth-promoting factors or by inhibiting apoptosis, by enhancing proapoptotic or decreasing antiapoptotic signals. All detailed situations cannot be recapitulated here, but a variety of signaling pathways is generally involved. Kinases and phosphatases, such as mitogen-activated protein kinases, protein kinases C and A, Wnt (wingless-type mammary tumor virus integration site family), nuclear factor-kappa B, and protein phosphatases 2A and 5 to name but a few, appear to be mediators of these effects. For instance, the proapoptotic activation of c-Jun N-terminal kinases (JNK), a member of the MAPK family, by cadmium may be impaired under chronic exposure. Subsequent failure to direct cells to apoptosis provides a strong selective advantage to subpopulations in which the inactivation of this pathway overrides proapoptotic activities. Efficiency of Nrf2-driven transcription is among the multifarious consequences of MAPK enhanced activity.

The presence of cadmium in the cellular environment can also activate several surface receptors without entering cells. Such mechanisms are expected to lead to transient variations of second messengers

(e.g., Ca^{2+}), and chronic exposure to cadmium may permanently change the steady-state concentrations of these messengers, or it may blunt the dynamics of the cellular response via the involved receptors. Candidate molecules which are sensitive to cadmium include Ca^{2+}-sensing G protein–coupled receptors, receptor tyrosine kinases, and steroid receptors, all targeting many downstream events. For instance, cadmium interacts with the ligand-binding domain of estrogen receptor α, and it may interfere with the conformational change of the receptor needed for activation. Although not surface receptors per se, intercellular junction molecules, such as E-cadherin and connexins, can interact with cadmium with both changes of the adhesion properties and activation of signaling pathways by translocation of β-catenin or secretion of messengers (e.g., prostaglandins, insulin, or glutamate) for instance.

The molecular adaptations to cadmium via signaling pathways seem almost countless when data obtained in many experimental systems are cumulated, but some of the practical consequences can be organized into the following few.

Adaptation by Impaired Import

In many examples of persistent resistance to cadmium, cells are protected by the strongly diminished ability of the toxic metal to enter into cells. The physiological function of the membrane components responsible for cadmium uptake may be the transport of metal ions. Instances include calcium channels of different types (voltage or ligand dependent, store operated), metal cotransporters for iron or zinc, and receptors triggering the input of cadmium complexes by endocytosis, such as with megalin and cubilin or the neutrophil gelatinase–associated lipocalin-2 receptor. Adaptation mechanisms via modifications of these different transporters remain ill-documented with the exception of ZIP 8 (Zrt-/Irt-like protein 8, SLC39A8). This divalent cation-bicarbonate cotransporter is probably responsible for high-affinity manganese influx in many cells, and it can transport other cations including cadmium. The molecular changes inactivating it are not completely elucidated, but they may involve epigenetic silencing of expression or inactivation by (protein kinase C) phosphorylation.

Adaptation by Accumulation

A constant feature displayed by cadmium is the strong induction of metallothioneins occurring upon exposure to the metal. In mammals, transcriptional upregulation of MT provides a higher cadmium-binding capacity to targeted cells, yet the cadmium-metallothionein complexes are subjected to distribution and turnover among different cell types, with limited excretion of the noxious metal from the body. Thus, MT upregulation cannot be considered as an efficient and lasting adaptation mechanism in mammalian cells, and there is no evidence that accumulation occurs safely in mammals.

The situation is different in microorganisms and plants. The cells can be protected by extracellular binding to the cell wall, intracellular safe binding (e.g., to polyphosphates) and sequestration into vacuoles, and active export. These different processes can be coupled with, for instance, cadmium binding to strong chelators such as PCs, transport to suitable locations (e.g., plant shoots), and loading into specific organelles such as vacuoles. The movements of cadmium-containing species through membranes are carried out by an extensive range of transporters, including many ATP-binding cassette (ABC) transporters and (P1)-ATPase pumps.

The ability of these proteins to handle toxic compounds such as cadmium is enhanced by the possible adjustment of their regulation in exposed organisms. For example, cadmium accumulator plants, such as *Arabidopsis halleri*, *Thlaspi caerulescens*, or rice to a smaller degree, appear to display a distinct transcriptional response when exposed to cadmium as compared to sensitive plants such as *Arabidopsis thaliana*. The range of contributing genes is large including many encoding transporters, stress (i.e., heat-shock) proteins, and other activities supporting basic metabolic and structural functions. In a similar way, it appears that different yeast strains may adjust the sulfur use of some of their enzymatic isoforms according to their natural habitat, including with respect to its potential cadmium content.

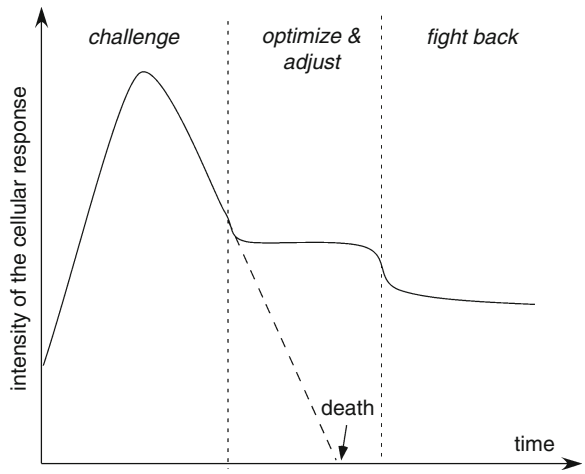
Adaptation by Efficient Export

A last possibility to escape cadmium toxicity is to get rid of the poisonous metal once present inside cells.

As internal ligands such as GSH or PCs are readily mobilized upon cellular cadmium uptake, transporters of these complexes contribute to the resistance to the metal. Cadmium can thus be displaced either to safer places, such as in the vacuole of plants and in the model fission yeast *S. pombe* via ABC transporters, or back to the outside as through the cystic fibrosis transmembrane conductance regulator (CFTR) or the multidrug resistance-associated protein 1 (MRP1) in mammalian epithelial cells. Other transporters, such as those involved in the removal of zinc (the Znt family) or iron (ferroportin, which has been recently shown to be regulated by MTF-1), may participate in cadmium efflux, but the only well-established example of adaptation by sustained enhancement of export in mammalian cells is that of MRP1 upregulation. This adaptive mechanism is mediated, at least in part, by phosphorylation by MAPK (p38) which may shift to a basal higher activity promoting the transport of GSH adducts, including with cadmium. Yet, p38 activation has parallel effects such as counteracting cadmium-driven endoplasmic reticulum stress and activating autophagy, aiming at preserving cells from the poison. As already mentioned above, decreased apoptotic signals can promote cell survival, and cellular efflux proteins can also contribute to remove them (e.g., ceramide metabolites) instead of directly transporting cadmium.

Conclusion

The above description of the cellular response to cadmium exposure draws a complex picture with elusive features depending on the cell type, the cadmium dose, and many other parameters. Yet, a tentative general description of the successive events allowing cells to get through cadmium threat and maintain viability may be proposed (Fig. 2). It should be noticed that the following scenario is likely to apply to many situations in which cells are exposed to toxic compounds; only the specific molecular adjustments may change depending on the properties of the poison. First, the sudden change in the cellular environment must be overcome by cells with means that are quite similar between acute and the initial stages of chronic exposure. Counterbalancing the cadmium-induced oxidative stress and expending various resistance



Cadmium Exposure, Cellular and Molecular Adaptations, Fig. 2 Schematic view of the different phases leading to cellular adaptation in the presence of cadmium. Naïve cells initially mobilize various means to respond in proportion to the cadmium insult (the "challenge" phase, *left*). They then optimize their resources to adjust to the continuous threat (the "optimize and adjust" phase, *middle*). These two phases may be considered as reversible for the most part. If the cadmium insult exceeds the homeostatic potential of the cells, death occurs (*dashed line*). Last, adaptation mechanisms described in the text are set in place (the "fight back" phase, *right*) to allow cells to permanently and irreversibly thrive in the presence of cadmium

mechanisms contribute to maintain viability. The efficiency of the cellular response depends on many parameters. For instance, challenging by a mixture of toxic compounds is a deleterious situation in most cases, whereas successive low-level doses of cadmium usually trigger hormosis and help cells to survive, by a mechanism resembling actual adaptation (see below). But this phase is unlikely to last for long as it puts a strong pressure on the cell resources which cannot be exclusively summoned for the single purpose of canceling out the noxious cadmium effects. Therefore, a second step is needed to optimize ways of adjusting to the new situation. This homeostatic response can be considered as a preparation phase to handle the permanently altered conditions in the case of chronic exposure. Most, if not all, processes implemented up to this point, such as those keeping the redox balance or activating specific signaling cascades, are probably reversible. But, if the presence of cadmium persists, a last phase should come, which is the "adaptation" phase discussed herein. At this stage, cells are irreversibly modified to thrive.

This permanent adjustment may involve epigenetic modifications and definitive metabolic and regulatory changes. Consequently, the cellular status may also be permanently affected with possible drastic changes in the cellular fate: for instance, exposed quiescent cells may be tuned to proliferate, hence developing as neoplasms. In such terminal phases of adaptation, presently available evidence indicates that a complex interaction between genetic, metabolic, and regulatory networks occurs, rather than the up- or downregulation of a single pathway. Henceforth, the present scientific challenge is to decipher the interplay between the involved networks to better understand cadmium toxicology and to relieve the deleterious effects of this lingering pollutant.

Summary

The divalent form of cadmium is a persistent pollutant in the environment to which cells of all kinds may be exposed. The toxicity of this metal is largely mediated by disequilibrium between the pro- and antioxidant cellular components with many molecular consequences ending with cell death. However, cells can cope with the cadmium threat in many ways, and some may even thrive in the continuous presence of moderate concentrations of the metal. This adaptive process optimizes the resistance mechanisms by anchoring them into the genetic, metabolic, and regulatory properties of cells. Cadmium handling can thus result into impeded uptake, safe accumulation, or efficient removal, all maintaining viability. Once naïve cells resist to the initial cadmium exposure, adaptation is a succession of events, the main principles of which are outlined in this essay.

Definition

Transport of cadmium ion across cellular membranes of eukaryotic cells through receptors, channels, solute carriers, or ATPases.

Introduction

Cadmium is a toxic transition metal and has no biological function in eukaryotic organisms (with the exception of certain forms of marine phytoplankton). The toxicologically relevant chemical form of cadmium is the divalent cadmium ion (Cd^{2+}). Cd^{2+} taken up by cells and organisms accumulates because it is eliminated very slowly (e.g., in the human kidney Cd^{2+} has a half-time of 10–30 years). Cd^{2+} binds to many cellular and/or extracellular proteins which store the metal and also partly contribute to its detoxification. Binding may be nonspecific and is characterized by a low affinity between Cd^{2+} and the protein, like serum albumin with an equilibrium dissociation constant (K_D) of $\sim 10^{-4}$ M, or the interaction may be more specific by binding to certain amino acid residues, in particular cysteine sulfurs. Examples of the latter are the antioxidative tripeptide glutathione ($K_D \sim 10^{-10}$ M) or the metal-binding proteins metallothioneins ($K_D \sim 10^{-17}$ M) where Cd^{2+} may displace essential metals, such as Zn^{2+}. Metal exchange evoked by Cd^{2+} binding, as well as disruption of the biological function of these proteins, is just an example of the manifold toxic effects elicited by Cd^{2+} in cells (Waisberg et al. 2003; Thévenod 2009; Moulis 2010).

To accumulate in cells and interfere with cellular functions, hydrophilic Cd^{2+} that is present in extracellular fluids as a free ion or complexed to proteins or peptides must permeate lipophilic cellular membranes. Cd^{2+} can only cross membranes through intrinsic proteinous pathways, and this requires either passive (facilitated diffusion) or active (energy dependence) transport mechanisms. Passive transport of Cd^{2+} may involve channels or solute carriers, whereas active mechanisms comprise primary active pumping of Cd^{2+} out of cells and receptor-mediated endocytosis of Cd^{2+} complexes. The similar chemical properties of Cd^{2+} and essential metals ("ionic mimicry") as well as of Cd^{2+} complexes and endogenous substrates ("molecular mimicry") determine the ability of eukaryotic cells to transport Cd^{2+} (Clarkson 1993; Bridges and Zalups 2005). Transport (and toxicity) can only occur if cells possess transport pathways for essential metals or biological molecules which interact with Cd^{2+} or Cd^{2+} complexes in a specific manner. After entering the intracellular compartment, higher-affinity complex formation of Cd^{2+} to other proteins may take place by ligand exchange, thereby also preventing back diffusion and forming a kinetic trap for Cd^{2+}.

Candidates for Cadmium Transport Pathways

This entry summarizes evidence solely for eukaryotic Cd^{2+} transport pathways that has been obtained using stringent experimental approaches, such as radiotracer, fluorescent dye, and/or electrophysiological transport assays combined with molecular biology techniques, because proof of Cd^{2+} fluxes can only be given by direct demonstration of Cd^{2+} transport across biological membranes. Using this "conservative" approach, several likely candidates have been identified.

SLC39 Transporters

The SLC39 transporters are members of the ZIP family of metal-ion transporters (Eide 2004). This designation stands for Zrt-, Irt-like proteins and reflects the first members of this transporter family to be identified. The products of some of these genes, for example, SLC39A1, SLC39A2, and SLC39A4, are involved in Zn^{2+} uptake across the plasma membrane. Other members may function in the uptake of other metal ions (e.g., Fe^{2+} and Mn^{2+}) or may transport metal ion substrates across membranes of intracellular organelles. Various levels of experimental evidence have been obtained for SLC39A8 (ZIP8) and SLC39A14 (ZIP14) involvement in Cd^{2+} transport in tissues such as kidney, intestine, and testis (He et al. 2009). These two transporters function physiologically as Zn^{2+}/HCO_3^- or Mn^{2+}/HCO_3^- symporters. In mice, ZIP8 expression is highest in lung, testis, and kidney. In ZIP8 cRNA–injected *Xenopus* oocyte cultures, it was shown that ZIP8-mediated $^{109}Cd^{2+}$ and $^{65}Zn^{2+}$ uptake exhibits very low Michaelis constant (K_m) values of ~0.48 and ~0.26 μM, respectively, and studies of electrogenicity to determine whether ZIP8 moves an electrical charge (i.e., carries current) showed an influx of two HCO_3^- anions per one Cd^{2+} (or one Zn^{2+}) cation, that is, electroneutral complexes. SLC39A14 has two exon 4s giving rise to ZIP14A and ZIP14B alternatively spliced products. Mouse ZIP14A expression is highest in liver, duodenum, kidney, and testis; ZIP14B expression is highest in liver, duodenum, brain, and testis. ZIP14B has a higher affinity than ZIP14A toward Cd^{2+} (K_m values of 0.14 vs. 1.1 μM). Given the high affinity for ZIP14, Cd^{2+} is likely to displace Zn^{2+} or Mn^{2+} and enter the body to cause toxicity. Hence, both ZIP8 and ZIP14 are candidates for high-affinity Cd^{2+} transporters mediating toxicity in cells and tissues expressing these solute transporters (He et al. 2009).

SLCA11A2 Transporter

The solute carrier SLCA11A2 or divalent metal-ion transporter-1 (DMT1 also abbreviated to DCT1 for divalent cation transporter-1 or NRAMP2 for natural-resistance-associated macrophage protein-2) is the second member of the *SLC11* gene family of metal-ion transporters that are energized by the H^+ electrochemical gradient (Mackenzie and Hediger 2004). DMT1 transports ferrous ions (Fe^{2+}) but not ferric ions (Fe^{3+}) as a symport/cotransport with H^+ and displays optimal transport activity at acidic pH. DMT1 plays a crucial role in Fe^{2+} homeostasis. DMT1 is ubiquitously expressed, but most notably in the proximal duodenum (where it is the major transporter for iron entry), in red blood cell precursors (where it is essential for full hemoglobinization), in macrophages, but also in the kidney and brain. DMT1 expression is strongest on the brush border of mature villous enterocytes where the expression of DMT1 is tightly regulated by body iron status and is consistent with a role for DMT1 in luminal Fe^{2+} uptake. In macrophages, DMT1 is restricted at the membrane of phagosomes where red cells are engulfed. In the kidney, the majority of DMT1 resides in late endosomal and lysosomal membranes of proximal tubule (PT) cells in the renal cortex, suggesting that DMT1 is involved in movement of Fe^{2+} across late endosomal and lysosomal membranes. DMT1 is not very selective for Fe^{2+}. In fact, a broad range of transition metals (Cd^{2+}, Zn^{2+}, Mn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, and Pb^{2+}) can also evoke inward currents in *Xenopus* oocytes expressing DMT1. Furthermore, radiotracer assays in *Xenopus* oocytes and transfected HEK293 cells have established that DMT1 is capable of transporting Cd^{2+}, Mn^{2+}, and Zn^{2+}. The K_m for Cd^{2+} is ~1.04 μM, and Cd^{2+} appears to be transported even more effectively by DMT1 than Fe^{2+} (K_m ~2 μM). A link between Cd^{2+} uptake (and toxicity) and *DMT1* expression has been proposed under conditions where body iron homeostasis is disrupted, resulting in increased DMT1 expression in duodenum, kidneys, and liver. These conditions with increased demand for iron or pathologically elevated intestinal Fe^{2+} absorption appear to be associated with increased Cd^{2+} uptake from the gastrointestinal tract and an increased Cd^{2+} burden of those tissues, but also testes, brain, and blood. These studies indicate that the disruption of iron homeostasis increases the sensitivity to Cd^{2+} because of increased expression of DMT1. Consequently, DMT1 appears to be a key transporter involved in Cd^{2+} toxicity (Thévenod 2010).

Megalin and Cubilin Receptors

Megalin and cubilin are receptors involved in endocytosis which bind multiple ligands and are expressed primarily not only in luminal (apical) plasma membranes of polarized epithelial cells but also in neurons (Christensen et al. 2009). Megalin and cubilin

are highly expressed in the early parts of the endocytotic apparatus of the renal PT where they are largely responsible for the tubular clearance (i.e., reabsorption) of most proteins filtered in the glomeruli. Megalin and cubilin are structurally very different, and each binds distinct ligands with varying affinities. Megalin is a 600-kDa transmembrane protein belonging to the low-density lipoprotein (LDL) receptor family. Cubilin is a 460-kDa peripheral membrane protein identical to the intrinsic factor–vitamin B12 receptor from the small intestine. Cubilin physically associates with megalin, and it seems that megalin is responsible for internalization of cubilin and its ligands, in addition to internalizing its own ligands. Cubilin also binds amnionless, a 50-kDa transmembrane protein that is required for its membrane expression and internalization. In addition to direct receptor-receptor interaction, megalin and cubilin share several ligands, including vitamin D–binding protein, albumin, hemoglobin, myoglobin, immunoglobulin light chains, and receptor-associated protein (RAP). Following binding to these receptors at the apical membrane, ligands are internalized into coated vesicles and delivered to early and late endosomes. Whereas the receptors are recycled to the apical membrane, the ligands are transferred to lysosomes for protein degradation. Though it has been commonly assumed that the iron-binding protein transferrin (Tf) with a molecular weight of 78 kDa is above the filtration cutoff for glomerular sieving, filtration of Tf at the glomerulus and its subsequent reabsorption by megalin-cubilin-mediated endocytosis has been convincingly demonstrated. This observation is of utmost importance for the understanding of uptake of Cd^{2+} complexed to metallothioneins (CdMT), a major form of Cd^{2+} present in the blood circulation and a major source of Cd^{2+} in nephrotoxicity induced by chronic oral or pulmonary exposure to the metal. CdMT is easily filtered by the glomerular sieve because of its molecular weight of ~7 kDa and is reabsorbed by the PT by a mechanism analogous to receptor-mediated endocytosis (RME) of proteins. Indeed, metallothionein binds to megalin with a K_D of ~100 μM, and endocytosis of CdMT by the megalin-cubilin complex significantly contributes to CdMT toxicity in cultured PT cells. Additional experimental evidence indicates that following degradation of metallothionein moiety in late endosomes and lysosomes Cd^{2+} is extruded by DMT1 expressed in the membrane of these acidic compartments (see above) into the cytosol where ionic Cd^{2+} triggers cell death via apoptosis of PT cells (Thévenod 2010).

Lipocalin-2 Receptor

Because metallothionein uptake is only partially antagonized by typical megalin-cubilin ligands, such as RAP, additional receptors have been postulated to mediate CdMT toxicity in epithelia. A cell-surface receptor for lipocalin-2 (24p3, NGAL, K_D ~100 pM), a secreted eukaryotic protein which delivers iron to cells by binding to iron-containing siderophores, high-affinity iron-chelating compounds secreted by microorganisms such as bacteria and fungi, has been recently cloned and is expressed in a variety of tissues, including kidney, intestine, and liver. This receptor (Lip2R) modulates iron uptake and apoptosis in cancer cells. In the kidney, Lip2R is mainly expressed in the distal nephron. In cultured distal tubule cells lipocalin-2 reduces CdMT toxicity, suggesting that Lip2R contributes to RME of CdMT and other protein-metal complexes. Transiently transfected CHO cells (which do not express megalin-cubilin) mainly express Lip2R in their plasma membranes. When transfected cells are exposed to fluorescently labeled metallothionein, Tf, or the plant Cd^{2+}-detoxifying phytochelatin (PC), all three proteins are selectively taken up by Lip2R-overexpressing cells. The K_D of binding of all three ligands to Lip2R is ~1 μM. CdMT induces apoptotic cell death in Lip2R, but not in control vector-transfected cells and saturates at 1.4 μM MT/10 μM Cd^{2+} after 24 h exposure. Hence, MT, Tf, and PC are ligands of the Lip2R which, in addition to megalin-cubilin, mediates RME of CdMT and cell death (Langelueddecke et al. 2012). The Lip2R expressed in the distal nephron could represent a second high-affinity pathway for clearance of CdMT (and other metal-protein complexes) that has not been endocytosed by the low-affinity system of megalin-cubilin in the initial portion of the nephron.

ABC Transporters

ATP-binding cassette transporters (ABC transporters) are members of a large protein superfamily expressed in many living cells from prokaryotes to humans. They are transmembrane proteins that in their majority utilize the energy of adenosine triphosphate (ATP) hydrolysis to pump various large hydrophobic, anionic, or cationic substrates across extra- and intracellular

membranes, including metabolic products, lipids, sterols, and drugs. ABC transporters are involved in tumor resistance, cystic fibrosis, bacterial multidrug resistance, and a range of other inherited human diseases.

ABCB1

Multidrug resistance P-glycoprotein (ABCB1) pumps a broad range of structurally unrelated, hydrophobic, amphiphilic, and cationic xenobiotics out of cells. ABCB1 is expressed in the apical membrane of epithelia, including the kidney proximal tubule (PT). ABCB1 is highly upregulated in cancer cells, resulting in resistance to chemotherapeutic agents. The expression of ABCB1 can be regulated by a number of stress responses, including nuclear factor kappa B (NF-κB), AP-1, and also Wnt signaling. Pertinently, it was discovered almost 20 years ago that Cd^{2+} causes upregulation of ABCB1 which was found to be associated with decreased Cd^{2+} toxicity in renal PT cells. The simplest mechanism to account for ABCB1-mediated abrogation of Cd^{2+} toxicity is direct Cd^{2+} efflux by ABCB1, as has been proposed by several studies. However, recent experiments indicate that ABCB1 protects PT cells from apoptosis independently of Cd^{2+} efflux. The sphingolipid glucosylceramide may be the proapoptotic substrate extruded by ABCB1 in PT cells, leading to cell survival and possibly propagating Cd^{2+} carcinogenesis (Lee et al. 2011).

ABCC1

The multidrug resistance–associated protein 1 (MRP1; ABCC1) is a high-affinity transporter of the physiological substrate cysteinyl leukotriene C(4) and releases this cytokine from leukocytes into the extracellular space during inflammatory processes. But ABCC1 also functions as a multispecific organic anion transporter, for instance, with oxidized glutathione (GSH) and activated aflatoxin B1 as substrates. In addition, ABCC1 transports glucuronides and sulfate conjugates of steroid hormones and bile salts. ABCC1 and other members of this branch of lipophilic anion transporters are expressed in various epithelial tissues, such as liver and kidney, as well as in endothelia of the blood-brain barrier and in neurons. It is likely that ABCC family members are efflux pumps for Cd^{2+} in the form of Cd^{2+}-GSH complexes (similarly to the yeast vacuolar glutathione S-conjugate transporter YCF1, which has a role in detoxifying metals in yeast and resembles ABCC1), but though GSH efflux by ABCC1 has been demonstrated, Cd^{2+}-GSH transport has not been proven so far.

ABCC7

The cystic fibrosis transmembrane conductance regulator (CFTR; ABCC7) is a cAMP-dependent Cl^- channel expressed in the apical membrane of salt-transporting tissues, such as secretory epithelia and exocrine glands, where it controls ion and fluid homeostasis on the epithelial surfaces, and mutations in the ABCC7 gene cause cystic fibrosis. ABCC7 is also expressed in the apical pole of kidney proximal and distal tubule cells. Recent studies indicate that ABCC7 also mediates GSH export from cells. However, evidence for Cd^{2+} transport by ABCC7 is scarce. Only in one recent study with mouse PT cells expressing ABCC7, low micromolar Cd^{2+} concentrations induced ABCC7-like Cl^- channel gating indirectly by activation of the extracellular signal-activated protein kinase (ERK1/2). Moreover, Cd^{2+}-induced activation of Cl^- currents was associated with ABCC7-mediated extrusion of GSH and Cd^{2+}, possibly as a Cd^{2+}-GSH complex (L'hoste et al. 2009).

Ca^{2+} Channels

Ca^{2+} and Cd^{2+} have similar ionic radii suggesting permeation of Ca^{2+} channels by Cd^{2+} as a mechanism of entry into cells. Many reports have postulated Cd^{2+} uptake by L- and N-type voltage-dependent calcium channels (VDCCs), which are opened by changes in the electrical membrane potential difference, or store-operated calcium channels (SOCs), which are activated by intracellular calcium stores depletion (particularly the endoplasmic reticulum) by hormones or neurotransmitters. However, studies supporting Cd^{2+} flux through these channels using electrophysiological and/or radiotracer techniques are rare. Moreover, Cd^{2+} enters VDCCs and SOCs but potently blocks the pore at submicromolar concentrations and can therefore only permeate the channel if strong nonphysiological potentials are applied. In addition, Cd^{2+} influx through VDCCs or SOCs is likely to be insignificant. The open probability of VDCCs is strongly voltage dependent. Most VDCCs are open over a very narrow voltage range and closed at or near resting membrane potential. The same line of reasoning applies to SOCs which open only upon Ca^{2+} store depletion and are closed under nonstimulated conditions. Nevertheless, several

candidate Ca^{2+} permeable ion channels have been described that are likely to be permeated by Cd^{2+} as well.

TRP Channels

Some members of the transient receptor potential (TRP) superfamily of ion channels have been shown to carry Cd^{2+}. TRPs mediate various sensory functions, such as temperature, touch, pain, osmolarity, or taste. Other proposed functions include repletion of intracellular Ca^{2+} stores, receptor-mediated excitation, and cell cycle regulation. A nonselective cation channel that is stimulated by the drug maitotoxin and differs from SOCs has been characterized in renal MDCK cells which carries $^{109}Cd^{2+}$ (K_m ~1.2 μM) and is blocked by Ni^{2+}, Mn^{2+}, and the specific inhibitory drugs SK525a and loperamide (Olivi and Bressler 2000). Though this channel has been postulated to be associated with TRPC1 (transient receptor potential cation channel 1), a member of the subfamily of "canonical" TRPs that is thought to mediate Ca^{2+} store repletion, its molecular identity has remained elusive so far. Transient receptor potential cation channel M7 (TRPM7) is another member of the TRP channel superfamily which belongs to the "melastatin-related" subfamily. It is blocked by the specific blocker 2-aminoethoxydiphenyl borate (2-APB) and was found to be responsible for Cd^{2+} uptake in human and murine osteoblast-like cells where it could play a role in bone damage induced by Cd^{2+} (Levesque et al. 2008). It is ubiquitously expressed and permeable to Ca^{2+} and Mg^{2+}, but also conducts divalent metals such as Zn^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+}, Ba^{2+}, and Sr^{2+}. TRPM7 is currently believed to regulate Ca^{2+} and Mg^{2+} fluxes to affect cell adhesion, cell growth, proliferation, and cell death. As a caveat, the ability of Cd^{2+} to permeate TRPM7 is the lowest of all divalent metal ions tested. Finally, recently TRPV6, a member of the subfamily of "vanilloid-related" TRP channels (also known as CaT1), which is a highly Ca^{2+} selective channel expressed in duodenum, kidney, and placenta and is involved in vitamin D–dependent Ca^{2+} transport in epithelia, has been shown to transport Cd^{2+} at concentrations $\geq$10 μM using the fluorescent indicator for divalent metals Mag-Fura-2 and to be permeable to 2 mM Cd^{2+} using the electrophysiological patch-clamp technique to study single ion channels in cells (Kovacs et al. 2011).

CACNA1G-I Channels

Among the voltage-gated Ca^{2+} channels, $Ca_V3.1$–3 (CACNA1G-I) T-type calcium channels may be the best candidates for Ca^{2+} channels permeated by Cd^{2+} and other divalent metals under physiological conditions (Perez-Reyes 2003). Under physiological conditions, T-type calcium channels have a pacemaker function in the sinoatrial node of the heart and contribute to tonic bursting activation patterns of neurons in the thalamus. The threshold for T-type channel activation in physiological conditions is between −75 and −60 mV. Moreover, based on the characteristics of the voltage dependence of activation and steady-state inactivation curves, these channels are predicted to exhibit considerable "window" currents close to resting membrane potential, so they could mediate significant tonic Cd^{2+} entry. In preliminary experiments, CACNA1G ($Ca_V3.1$, α1G) T-type Ca^{2+} channels have been shown to carry inward Cd^{2+} (2–10 mM) currents at voltages near resting membrane potential. CACNA1G is also permeable to Fe^{2+} and Mn^{2+}, and though transport rates are low by channel standards, calculations have shown that they are similar to those of Fe^{2+} transporters, such as DMT1. CACNA1G is expressed in excitable cells, such as heart and neurons, but it has also been detected in smooth muscle cells of vessels and organs as well as in the distal nephron of the kidney where its function remains unclear.

Mitochondrial Ca^{2+} Uniporter

The mitochondrial Ca^{2+} uniporter (MCU) is located in the inner mitochondrial membrane (MCU) where it is blocked by nanomolar concentrations of ruthenium red or Ru360. Mitochondrial Ca^{2+} uptake via the MCU controls the rate of energy production, shapes the amplitude and spatiotemporal patterns of intracellular Ca^{2+} signals, and is instrumental to cell death. Patch-clamp experiments have convincingly demonstrated that the MCU is a Ca^{2+} channel (Ryu et al. 2010): A highly Ca^{2+} selective (K_D for Ca^{2+} <2 nM) inwardly rectifying current with a single-channel conductance of 2.6–5.2 pS named MiCa has been demonstrated in mitoplasts from COS-7 cells and is also blocked by nanomolar concentrations of the specific inhibitors ruthenium red and Ru360. In addition, two voltage-dependent Ca^{2+} channels in human heart mitoplasts, mCa1 and mCa2, have been characterized and exhibit high Ca^{2+} selectivity. Like MiCa, mCa1 is inhibited by

nanomolar Ru360 but has a higher mean single-channel unitary conductance (13.7 pS). mCa2 shares the same voltage dependence with mCa1, but exhibits a smaller unitary conductance (7.67 pS) and is relatively insensitive to Ru360. The molecular structure of the MCU Ca^{2+} channel has been recently elucidated (De Stefani et al. 2011). With regard to Cd^{2+} transport, kidney cortex mitoplasts have been shown to take up Cd^{2+} using the Cd^{2+}-sensitive fluorescent indicator FluoZin-1, and Cd^{2+} uptake was blocked by MCU inhibitors (such as micromolar concentrations of La^{3+} or nanomolar concentrations of ruthenium red and Ru360) (Lee and Thévenod 2006). Hence, Cd^{2+} may permeate the MCU directly but more direct evidence, for example, by patch-clamp techniques and/or $^{109}Cd^{2+}$ radiotracer experiments, would substantiate these observations.

Outlook and Future Directions

In recent years, several transport proteins have been identified that carry the toxicant Cd^{2+} across biological membranes, and it is likely that more candidate transporters will be discovered in the future. These proteins transport free Cd^{2+} ions respective Cd^{2+}-protein or -peptide complexes at the low concentrations that are found in biological fluids of organisms chronically exposed to Cd^{2+} in the environment (food, cigarette smoke, etc.). Hence, various putative entry pathways are available to mediate Cd^{2+} uptake into cells which could explain the observation that a variety of tissues and organs are affected by Cd^{2+}. Interestingly, so far, only one group of transporters has been found to mediate Cd^{2+} efflux out of cells with the potential to protect against toxicity, namely, the ABC transporters. However, a drawback of transport by ABC transporters is that they consume energy by hydrolyzing ATP. Moreover, Cd^{2+} efflux also occurs at the expense of cellular loss of the radical scavenger GSH which needs to chelate Cd^{2+} to allow efflux of the metal. Hence, Cd^{2+} efflux is costly and potentially damaging to the cell and may also ultimately cause death or mutagenesis and malignant transformation of Cd^{2+} affected cells (Waisberg et al. 2003; Thévenod 2009). Consequently, strategies to prevent and circumvent the harmful effects of Cd^{2+} should aim at targeting the uptake pathways rather than focusing on efflux mechanisms mediated by ABC transporters which promote Cd^{2+} toxicity of cells.

Introduction

Cadmium (Cd^{2+}) is an ever-present and global environmental pollutant. Current industrial Cd^{2+} emission has been drastically reduced, but Cd^{2+} continues to be a health hazard (Nawrot et al. 2010). Historically, accumulated Cd^{2+} cannot be degraded, and its half-life in the body is long (10–30 years). Several organs are affected by this heavy metal. In general, long-term exposure studies show skeletal damage, lung disease, and lung cancer. Since 1993, Cd^{2+} has been classified as a group I carcinogen by the International Agency for Research on Cancer. The main target for chronic, low-level Cd^{2+} exposure, however, is the kidney. Cd^{2+} intoxication leads to proximal tubule dysfunction. The specific mechanisms, however, by which it produces adverse effects on the kidney, have yet to be fully unraveled. Next to reactive oxygen species (ROS) production (Cuypers et al. 2010), interference with gene expression, and repair of DNA (Hartwig 2010), Cd^{2+} also interacts with transport across cell membranes and epithelia. This can lead to a distortion of the cell's homeostasis and function, with serious consequences on general health. In the renal tubules, it has been observed that Cd^{2+} leads to a diminished reabsorption of sodium (Na^+), potassium (K^+), magnesium (Mg^{2+}), calcium (Ca^{2+}), chloride (Cl^-) and phosphate (P_i), low-molecular-weight proteins (LMWP), amino acids (AA), and glucose, resulting in an increased ejection fraction of these molecules. Clinically this can be observed as polyuria, hypercalciuria, glucosuria, and hyperphosphaturia without a change in glomerular filtration rate (GFR). Although a lot of research has been done to elucidate the mechanisms by which Cd^{2+} influences membrane transport in the kidney, it is not always clear whether Cd^{2+} has primary or secondary effects on cell membrane transport. Also, the Cd^{2+} doses applied in vitro do not always correspond to the in vivo situation. A general overview of, and critical comments on, the research concerning the effect of Cd^{2+} on epithelial transport mechanisms can be found in the review of Van Kerkhove et al. (2010).

This entry gives a short overview of the transport mechanisms that are affected by Cd^{2+}. The main focus will be on the transport in renal proximal tubule cells, since these have been more widely investigated.

Transport Mechanisms in Epithelial Cells

Epithelial cells form a barrier between the internal and external milieu. In case of the kidney for instance, urinary fluid in the lumen of the tubule (external) is separated from the rest of the body by the epithelial cells of the nephron. Epithelial cells are closely connected by tight junctions, through which free diffusion of solutes and fluids is possible, depending on the permeability. The tight junctions around the cells also delimit the two parts of the epithelial cell membrane: the apical membrane at the luminal side and the basolateral membrane at the blood side. In most epithelia, the apical membrane faces the external milieu, while the basolateral membrane is in contact with the extracellular body fluid compartment. Transport of solutes over the epithelial layer can occur in two ways. First, solutes can sequentially pass across the basolateral and the apical membrane (or vice versa) in an either passive (through electrochemical driving forces) or active way (against the electrochemical gradient). Second, solutes can diffuse through the tight junctions; this is called paracellular transport. The Na^+K^+ pump, which is situated at the basolateral

membrane, is a key membrane transporter in cell homeostasis and the prime mover in most of the active transepithelial transport. It couples the hydrolysis of ATP to the vectorial transport of Na^+ and K^+ across the plasma membrane, maintaining electrochemical gradients for Na^+ and K^+. Several secondary and tertiary active transport systems of inorganic ions and small organic molecules are driven by this Na^+ electrochemical gradient. Moreover, an extra driving force for electrogenic transport is provided by the intracellular negative membrane potential, created by the K^+ electrochemical gradient.

Effect of Cadmium on the Na^+K^+-ATPase

In several animal models, administration of Cd^{2+} leads to a loss of basolateral invaginations in the cortical proximal tubule and a decrease in Na^+K^+-ATPase. Although a direct effect of Cd^{2+} on the ATPase has been investigated, the group of Thévenod suggests a more indirect causal mechanism (for references see the review by Van Kerkhove et al. (2010)). They state that Cd^{2+} increases the production of ROS intermediates, which decrease the stability of the α1 subunit of the Na^+K^+-ATPase which is subsequently degraded by both endolysosomal proteases and the ubiquitin protease complex.

It seems that after an initial decline in the activity of the ATPase, intoxicated animals show a defensive pattern. The cells try to cope with oxidative stress and upregulate the Na^+K^+-ATPase, while if doses are too high and/or time of exposure becomes too long, the toxic effect overrules.

Besides the effect of Cd^{2+} on Na^+K^+-ATPase in kidney tubules, reduced activity of the Na^+K^+-ATPase by Cd^{2+} was seen in hepatic microsomes and isolated microsomes of the rat brain.

Cadmium and Ion Transport Across Membranes and Epithelia

Next to the inhibitory effect of Cd^{2+} on the Na^+K^+-ATPase, a large range of other channels and pumps are affected by this heavy metal. Since it is impossible to overview all of the ion transport mechanisms that are influenced by Cd^{2+}, a short selection of some important ions is given.

Zinc Transport

Zinc is a trace element that is involved in a wide variety of biological functions, such as gene expression, cellular proliferation and differentiation, growth and development, apoptosis, and immune response. Zinc reabsorption, which occurs in the renal tubules of the kidney, is inhibited by Cd^{2+}. A clear overview of the influence of Cd^{2+} on the homeostasis of other essential metals is given in a review by Moulis (2010).

Chloride Transport

The kidney is of major importance for the salt and water homeostasis of the body. One of the mechanisms responsible for this is the Na^+Cl^- reabsorption. Cd^{2+} intoxication leads to a mobilization of intracellular Ca^{2+} which activates chloride channels, leading to chloride secretion (see Table 7 in Van Kerkhove et al. (2010)). This, together with some other affected Cl^- transport mechanisms results in a decrease in Cl^- reabsorption, which influences the water homeostasis of the body.

Potassium Transport

K^+ channels exist in many forms and have diverse functions. Cd^{2+} has been shown to affect these channels (see Table 7 in Van Kerkhove et al. (2010)). The K^+ conductance is important in stabilizing the membrane potential of excitable cells or in creating a negative cell potential in transporting epithelia. Apical K^+ channels also play a role in K^+ reabsorption or secretion in the kidney. Interference of Cd^{2+} with these channels and with the membrane potential may have an impact on the transepithelial electrogenic transport and deregulate normal transport rates.

The Effect of Cadmium on Membrane Transport of Glucose and Amino Acids

Under normal circumstances, glucose and AAs are completely reabsorbed in the kidney. The Na^+-dependent transport processes take place in the proximal tubule. As mentioned earlier, clinical signs of Cd^{2+} intoxication can be glucosuria and aminoaciduria, suggesting an impairment of these reabsorption mechanisms. In several animal models, Na^+-dependent glucose uptake, as well as several Na^+-dependent amino acid transport systems, is reduced in the proximal tubule in the kidney. In many cases, Cd^{2+} seems to

affect the V_{max} and therefore the amount and/or expression of the transporter, but not the K_m, i.e., the properties of the transporters (Table 9 in Van Kerkhove et al. (2010)).

The Effect of Cadmium on Calcium and Phosphate and its Role in Bone Demineralization

It is known that Cd^{2+} exposure causes loss of bone (Bhattacharyya 2009). Whether this bone loss is a direct effect on bone of Cd^{2+} intoxication or is secondary to the impairment of Ca^{2+} and P_i reabsorption in the kidney remains to be elucidated.

Normally, more than 99% of the filtered Ca^{2+} is reabsorbed by the nephron. The Ca^{2+} transport mechanisms that could be involved are apical Ca^{2+} channels (all segments), solvent drag, the basolateral Ca^{2+} ATPase and the Na/Ca^{2+} exchanger (all segments). In the proximal tubule of the kidney, Cd^{2+} intoxication will cause a decrease in fluid reabsorption that in turn will have a negative influence on solvent drag, and paracellular Ca^{2+} uptake. Moreover, transcellular Ca^{2+} uptake is also affected by Cd^{2+}. It was found that epithelial Ca^{2+} channels (ECAC) were blocked by Cd^{2+}. However, not only the uptake of Ca^{2+} at the luminal site of the epithelial cell will be impaired. Due to a dose-dependent reduction of the Ca^{2+}-ATPase, an even larger inhibition of Ca^{2+} extrusion across the basolateral membrane will occur. The net effect will be a decreased Ca^{2+} reabsorption with an increased Ca^{2+} content in the kidney cortex. The influence of Cd^{2+} on Ca^{2+}-ATPase was confirmed in several other animal models such as the gill of the rainbow trout, in permeabilized red blood cells and in intestinal epithelium of the rat. In *Tilapia* intestine, an inhibition of the Na^+/Ca^{2+} exchange was observed. Finally, Cd^{2+} may use Ca^{2+} channels to enter cells.

As P_i plays a key role in the possible bone loss in Cd^{2+} intoxication, it is of interest to study the influence of Cd^{2+} on the P_i reabsorption in the kidney. Normally, 90% of the filtered P_i is reabsorbed. In the proximal tubule, P_i reabsorption occurs mainly through secondary active transport. Key player in this process is the Na^+-P_i cotransporter which has been identified in the brush border membrane (BBM) of the proximal tubule. A direct dose-dependent inhibitory effect of Cd^{2+} on this cotransporter is observed in several animal models. This inhibition leads to phosphaturia (see Table 8 in Van Kerkhove et al. (2010)).

The Effect of Cadmium on Membrane Transport of Other Organic Substances and Metals

Metal transporters play a role in the uptake of essential metals into cells, the uptake via the intestine or the extrusion via the liver and the kidney. Cd^{2+} may use these transporters to enter cells and/or impair the transport of essential metals (Thevenod 2010; Moulis 2010).

The membranes of kidney and liver cells also contain several proteins involved in the uptake and/or excretion of xenobiotics and endogenous organic compounds, all that is not reclaimed is excreted.

Organic Anions

Kidney tubules transport a variety of organic substances other than glucose and AA.

The proximal tubule cells secrete many organic anions that need to be removed from the body. This process depends at least in part on the activity of the Na^+K^+-ATPase and the K^+ and Na^+ gradients it creates. As discussed before, Cd^{2+} influences the Na^+K^+-ATPase activity, and therefore, it might also have an effect on the transport of organic anions. Indeed, animals intoxicated with Cd^{2+} showed a reduced excretion of para-aminohippuric acid (PAH) in vivo. Similarly, several in vitro models demonstrated a reduction of the PAH uptake in vitro after exposure to Cd^{2+}. Interestingly, incubation of microdissected proximal tubule segments of the rabbit with Cd^{2+} induced a bell-shaped curve with a twofold increase of PAH transport at low Cd^{2+} levels (1 μM Cd^{2+}). Interestingly, these concentrations seemed to stimulate cell growth. It might be that Cd^{2+}, although damaging cellular processes and transport systems in the end at these low concentrations, observed in the general and the exposed population, also has a signaling function and induces cell dedifferentiation, cell growth/proliferation in an attempt of the cells to defend themselves. This aspect of Cd^{2+} has not really been well studied up to now.

Endogenous metabolites such as the monocarboxylates (lactate, pyruvate), di- and tricarboxylates (malate, citrate, succinate), and bile salts are organic anions that need to be recovered.

Experiments suggest that transport of endogenous organic anions was reduced by exposure to Cd^{2+}, thus interfering with the cell's function. Again, the V_{max} was primarily affected and therefore the amount and/or expression of the transporter, but not the K_m, i.e., the properties of the transporters (see Table 10 in Van Kerkhove et al. (2010)).

Not much is known about Cd^{2+} effects on anion transporters in the intestine or in liver cells.

Organic Cations

Many cell membranes possess transporters for metals, i.e., Mn, Zn, Fe, Ca, Ni, and Co. It has been shown that Cd^{2+} may use these transporters to enter the cells and therefore interfere with the uptake of the essential metals, which in turn may interact with the normal functioning of the cell. ZIP8, ZIP14, DMT1, and Ca^{2+} channels and transporters are listed as candidates for Cd^{2+} transport (Moulis 2010). As the expression of these transporters is high in the intestine, it seems likely that dietary intake of Fe, Ca, Zn, and Mn may influence the intestinal absorption of Cd^{2+} and vice versa.

The Effect of Cadmium on Water Channels and Proton Pathways

Voltage sensitive proton channels and epithelial proton and water channels are sensitive to Cd^{2+} and other metals. Cd^{2+} is known to interfere with the renal vacuolar H^+-ATPase, inducing a strong decrease in the activity and amount of V-ATPase in the proximal tubule brush border membrane. In doing so, Cd^{2+} intoxication might interfere with protein reabsorption, as will be discussed in the next section. Further interaction between Cd^{2+}, proton pathways (see Table 12 in Van Kerkhove et al. (2010)), and cell pH and its role in Cd^{2+} toxicity need to be explored.

Cd^{2+} intoxication can cause polyuria, due to either impaired solute uptake or by blockage of antidiuretic hormone–sensitive water channels. Effects on water channels and their role in fluid loss are questions that need further research.

The Effect of Cadmium on Endocytosis

Endocytosis is a process used by many cells to absorb large molecules by engulfing them with their cell membrane. Cd^{2+} has been shown to interfere with this process in a wide range of organisms (see Table 13 in Van Kerkhove et al. (2010)).

In unicellular and invertebrate organisms, phagocytosis and endocytosis are used in acquisition of food, immune responses, and are crucial for the survival of these lower life forms. Exposure to very low concentrations of Cd^{2+} (ranging from 10 to 100 nM $CdCl_2$) had no effect or slightly stimulated phagocytosis in bivalve species. Somewhat higher doses (10–100 μM $CdCl_2$) on the other hand suppressed phagocytosis in worm as well as bivalve species.

In the kidney of vertebrates, receptor-mediated endocytosis is essential in the reabsorption of plasma proteins from the renal ultrafiltrate. Chronic exposure to Cd^{2+} leads to proteinuria. In vitro as well as in vivo models demonstrated that exposure to Cd^{2+} diminished endocytosis in kidney cells. This effect was coupled to a decreased activity and/or amount of the endosomal V-ATPase. Thus, the acidification of the endosomes was impaired, causing a fall in receptor-ligand dissociation and a reduced recycling of the receptor, which reduced the overall efficiency of endocytosis. The impaired endocytosis would then lead to a decreased reabsorption of filtered proteins and thus proteinuria. In addition, it might also derange intracellular vesicle trafficking causing loss of specific transporters from the brush border membrane of the kidney.

The Effect of Cadmium on Integrity of the Transporting Epithelium

Cells of transporting epithelia and vascular endothelia are attached to each other by specialized junctional complexes which determine the transepithelial permeability and regulate the transport of substrates across the epithelium. These junctional complexes are composed of specific junction-associated proteins such as integrins, cadherins, connexins, etc., and are closely associated with the cytoskeleton.

In in vitro models, Cd^{2+} causes loosening of the intercellular junctions, followed by a rapid decline of the transepithelial electrical resistance. Electron microscopy showed that the electron density of the intracellular plaques that are associated with the adhering junctions decreased markedly. This suggested that Cd^{2+} might cause proteins, involved in linking membrane-associated cell adhesion molecules to the

cytoskeleton, to dissociate and possibly diffuse into the cytosol. Thus, adhesion would disappear at this site, leading to a breakdown in the linkage between the junctional complexes and the cytoskeleton. This mechanism could explain the temporal relationship between the Cd^{2+}-induced breakdown of cell-cell junctions and the dramatic change in cell shape from a flat to a round appearance. A possible candidate site to be affected by Cd^{2+} is the Ca^{2+}-dependent cell adhesion molecule E-cadherin, which plays a role in the Ca^{2+}-dependent cell-cell adhesion. In vitro models of exposure to Cd^{2+} showed that the amount of E-cadherin was decreased, and this coincided with the disruptions of cell-cell junctions. In addition, Cd^{2+} has been shown to have similar effects on several other cadherins as well as on the actin cytoskeleton in various experimental in vitro models. In addition, the effect of Cd^{2+} on E-cadherin distribution is similar to that caused by the removal of extracellular Ca^{2+}. This suggests a direct effect on E-cadherin, displacing Ca^{2+} from its binding site due to the higher affinity of Cd^{2+} for these sites, changing the adhesive properties of the molecule and possibly its interaction with the actin.

In rats exposed to $CdCl_2$, the patterns of N-cadherin, E-cadherin, and β-cadherin localization in the epithelium were profoundly changed. This alteration in cadherin localization was not secondary to cell death, and in addition, Cd^{2+} only induced very low levels of oxidative stress. Taken together, this suggests that the cadherin/catenin complex might be a very early target of Cd^{2+}-induced toxicity in the proximal tubule in vivo, which confirms the data collected using in vitro models as described above.

The causal mechanisms need to be studied further, but given the importance of cadherins as regulators of epithelial function, the disruption of cell-cell junctions in the epithelium might help to explain some of the Cd^{2+}-induced changes in epithelial function (Prozialeck et al. 2003; Prozialeck and Edwards 2010).

Concluding Remarks

When discussing the literature and comparing the in vivo and in vitro situations, we must keep in mind the experimental model and the range of Cd^{2+} concentrations as well as the Cd^{2+} species used.

Indeed, most studies use the free, ionic form of Cd^{2+} to study its effect on transport or epithelial integrity. However, in vivo, practically all Cd^{2+} that reaches the systemic circulation is bound to proteins and other materials in the blood, e.g., (Sabolic et al. 2010), which makes it difficult to extrapolate the results of in vitro studies to the in vivo situation.

Acute in vitro experiments trying to discover direct effects of Cd^{2+} on cell membrane transporters need to be considered with caution. With a few exceptions, the extrapolation to the in vivo situation may not be entirely justified. The doses of Cd^{2+} applied in the in vitro experiments are often a few orders of magnitude higher than those encountered in vivo. It is possible that Cd^{2+} does not affect the transport proteins and transport directly in vivo but rather indirectly via oxidative stress, destruction of the cytoskeleton and/or disruption of cell-cell contacts, suppression or stimulation of expression of transporters, cell death, or still other indirect pathways. To unravel the molecular mechanisms of changes in membrane transport functions due to Cd^{2+}, experimental work is necessary in conditions that are much closer to the in vivo situation (Van Kerkhove et al. 2010).

Cd, Element 48, [7440-43-9]

Definition

Cadmium is a metallic element in the second transition series, Group IIB (12).

General Cadmium Chemistry

Cadmium (Cd, atomic weight, 112.41; atomic number 48) is a nonabundant, toxic metallic element usually found associated with minerals such as ZnS and other zinc ores. One mineral form, greenockite (CdS), is significant, but the usual Cd source is the oxide in industrial slag associated with the refining of Zn or Pb. The industrial uses of Cd include anticorrosion coatings, nickel-cadmium rechargeable batteries, and in neutron moderating alloys. Cadmium sulfide is used as a bright yellow pigment, and all cadmium chalcogenides (CdS, CdSe, CdTe) are used in semiconductor, photonic, and nanoparticle materials and for research.

Cd is in the "zinc group" of the periodic table and exhibits the common +2 oxidation state of this group arising from the loss of two *s*-orbital electrons; specifically, Cd(II) has the stable [Kr] $3d^{10}$ electronic configuration. The +2 oxidation state dominates the inorganic chemistry of Cd; its chemistry is similar to that of zinc and other M(II) cations, even though Cd(II) exhibits significant ionic radius differences (Shannon 1976) compared with essential M(II) cations, except for Ca(II) (Table 1). Many Cd(II) compounds are isomorphous with Mg(II). The Cd(II) cation is soluble in a wide range of aqueous solutions, but a number of its compounds (e.g., CdS, $Cd_3(PO_4)_2$) are quite *insoluble*. Cd(II) is a borderline acid in the hard/soft sense; thus, it can interact with a range of biological ligands that include oxygen, sulfur, and nitrogen donor atoms. Like Zn(II), the Cd(II) ion prefers a four-coordinate, tetrahedral environment, but its biological coordination chemistry is not limited to this arrangement. Placement of the ion in a wide variety of proteins leads to Cd(II) sites with coordination numbers ranging from three to six and geometries that include trigonal, square planar, square pyramid, trigonal bipyramid, and octahedral. Some distorted geometrical coordination environments and sites lacking one ligand are also observed in the protein crystal data (Henkel and Krebs 2004). The hydrolysis of Cd(II) is comparable to other transition metal ions; (Lide 2009) Cd(II) is slightly less susceptible to hydrolysis than Zn (II) or Ni(II) but significantly more susceptible to hydrolysis than the alkaline earth metal cations, Ca (II) and Mg(II) (Table 2). The reduction potential of Cd(II) to the neutral metal is −0.402 V, about half that of zinc. The $Cd/Cd(OH)_2$ redox couple is utilized in rechargeable batteries.

The full $3d^{10}$ electronic configuration of Cd(II) renders this transition metal cation diamagnetic and spectroscopically silent to paramagnetic resonance or electronic spectroscopy. Analysis of Cd may be conducted by standard methods of metal analysis, including various forms of titrimetry for concentrated samples, and with atomic absorption spectroscopy or neutron activation analysis for dilute samples. Bulk material or consumer products containing Cd may be analyzed by X-ray fluorescence. Finally, ^{111}Cd and ^{113}Cd nuclei are NMR active and are used for evaluating the biochemistry of Cd compounds and characterizing solid- or solution-state Cd compounds. Cadmium NMR is also used to evaluate Zn-binding sites in proteins by replacing Zn with Cd in in vitro experiments.

Cadmium, Physical and Chemical Properties, Table 1 Comparison of M(II) ionic radii (Å) (Shannon 1976)

Coordination number	4	5	6	7	8	12
Cd(II)	0.78	0.87	0.95	1.03	1.10	1.31
Ca(II)	–	–	1.0	1.06	1.12	1.34
Mg(II)	0.57	0.66	0.72	–	0.89	–
Mn(II) (high spin)	0.66	0.75	0.83*	0.90	0.96	–
Zn(II)	0.60	0.68	0.74	–	0.90	–

*Mn(II) CN = 6 has a low-spin value of 0.67

Cadmium, Physical and Chemical Properties, Table 2 Comparison of M(II) hydroxide solubility product; a larger pK_{sp} indicates a more favorable reaction (Lide 2009)

Hydroxide	K_{sp}	pK_{sp}
$Cd(OH)_2$	7.2×10^{-15}	14.1
$Zn(OH)_2$	3×10^{-17}	16.5
$Ni(OH)_2$	5.47×10^{-16}	15.3
$Mn(OH)_2$	2×10^{-13}	12.7
$Mg(OH)_2$	5.61×10^{-12}	11.3
$Ca(OH)_2$	5.02×10^{-6}	5.3

Ingestion and inhalation are the major routes of contamination from Cd metal, alloy, or compound sources in foods, agricultural chemicals, dust, and primary cigarette smoke. Cd is cleared slowly from the body and presents a chronic health hazard. The element is considered a carcinogen, probably via indirect mechanisms, the most effected organs being the lungs, testes, and prostate. Cd causes other disease, especially in the lung and in bone, notably affecting bone mineralization processes. Acute doses of Cd (>200 ppm bloodstream concentration) are nephrotoxic and also target the liver. Cd(II) may affect various Zn(II)- and Ca(II)-dependent biochemical pathways, protein-binding sites, and related processes. Targeted therapy for Cd(II) poisoning in the form of chelation agents is problematic due to selectivity issues; Zn(II) and Ca(II) supplementation may provide some alleviation of the effects of Cd-induced disease and biological overload.

Synonyms

Calbindin D_{28k}=calbindin=calbindin D28=D-28K=Vitamin D–dependent calcium-binding protein, avian-type; EF-hand superfamily = calmodulin superfamily = troponin superfamily; Gene name: CALB1=CAB27

Definitions

EF-hand: helix-loop-helix motif obeying a 29-residue consensus sequence with hydrophobic and Ca^{2+}-ligating residues in defined positions, typically forming a pentagonal bipyramidal coordination sphere.

Hexa EF-hand (HEF) proteins: Ca^{2+}-binding proteins containing six EF-hand motifs.

Domain: Independent folding unit.

Subdomain: Super-secondary motif which is part of a domain.

Deamidation: Spontaneous hydrolysis of a carboxamide to a carboxylic acid via a cyclic intermediate. Deamidation of asparagine typically leads to isoaspartate and aspartate in a 2:1 molar ratio.

Chromophoric chelator: Metal-binding dye which changes its optical spectrum upon chelation.

Discovery and Prevalence

Calbindin D_{28k} was originally purified from chicken intestine (Wasserman and Taylor 1996) and has since been found in many species and tissues. In mammals, calbindin D_{28k} is noted for its abundance in brain, kidney, and sensory neurons. In brain, the expression pattern of calbindin D_{28k} in particular neuronal subtypes is distinctly different from those of the homologous proteins calretinin and secretagogin. In birds, calbindin D_{28k} is expressed in the intestine, whereas in mammals, the intestinal role appears to be carried out by the smaller protein calbindin D_{9k}.

Sequence

The amino acid sequence of calbindin D_{28k} is highly conserved; human and rat calbindin D_{28k} share 257 identities over 261 residues (98.5% identity), whereas the human and chicken sequences are only 80% identical. The sequence is dominated by six EF-hand motifs and is characterized by a high prevalence of acidic residues. The connecting linkers are considerably longer than in many other EF-hand proteins, including calmodulin and calbindin D_{9k}. The human sequence is shown below with the four canonical and two variant EF-hand loops highlighted with solid and dotted underlining. Differences in the rat and the chicken sequences are displayed above and below the human version, respectively, indicating the positions that differ.

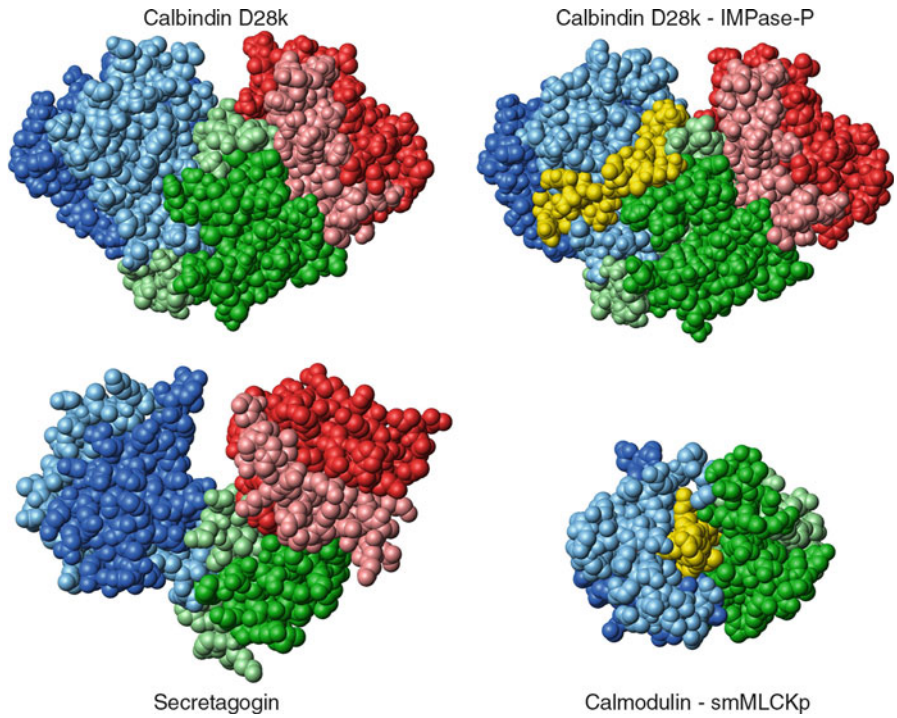
Posttranslational Modifications

Different types of chemical modifications of specific residues affect the structure and function of calbindin D_{28k}. There are five cysteine residues in human calbindin D_{28k}, located at positions 94, 100, 187, 219, and 257, while chicken and rat contain four each. All cysteine residues are located in the linker regions connecting the EF-hand subdomains, except for cysteine 257, which is located at the end of the very last EF-hand helix, near the C-terminal residue 261. The cysteines are sensitive to changes in redox potential. An intramolecular disulfide bond between residues 94 and 100 has been observed in the Ca^{2+}-bound form of human and rat calbindin D_{28k} (Vanbelle et al. 2005; Hobbs et al. 2009). The three C-terminal cysteine residues can also be modified with one glutathione each (Cedervall et al. 2005a, see further below). As shown by mass spectrometry, an extra modification, consistent with the conversion of a cysteine thiol to a sulfenic acid or a disulfide to a disulfide-S-monoxide, can form in the human protein. The cysteine residues can also be S-nitrosylated with S-nitrosoglutathione, which leads to structural changes in the protein (Tao et al. 2002). Calbindin D_{28k} is additionally susceptible to deamidation at residue N203 at neutral and higher pH. The deamidation reaction goes through a cyclic intermediate and converts N203 into a 1:2 mixture of aspartate and iso-aspartate (Vanbelle et al. 2005). The deamidation is slower when the protein is Ca^{2+} loaded, and is avoided by purifying the protein at slightly acidic pH (Thulin and Linse 1999). Mutating N203 to D, and Q182 to E eliminates the possibility to deamidate and provides a homogeneous calbindin D28k sample with a uniquely defined NMR spectrum (Helgstrand et al. 2004).

The EF-Hand

The EF-hand represents one of the most abundant Ca^{2+}-binding motifs. This 29 helix-loop-helix structure ligates one Ca^{2+} ion, although some EF-hands lack Ca^{2+}-binding functionality. The motif was discovered in parvalbumin by Kretsinger and coworkers, in which helices E and F are folded in a manner reminiscent of a hand, with helices E and F corresponding to the index finger and thumb, respectively.



Calbindin D_{28k},
Fig. 1 Structure. Space filling models of the calbindin D_{28k} NMR structure (2G9B.pdb), calbindin D_{28k} modeled with bound IMPase peptide (coordinates kindly provided by Drs. Bobay and Cavanagh), secretagogin crystal structure (2BE4.pdb), and a crystal structure of the calmodulin sMLCK-peptide complex (1CDL.pdb). The color coding is as follows: EF1 *blue*, EF2 *light blue*, EF3 *green*, EF4 *light green*, EF5 *red*, and EF6 *pink*. Bound peptide is shown in *yellow*

The canonical EF-hand loop (underlined with a solid line in the sequence above) consists of 12 residues and includes all the Ca^{2+}-coordinating residues, although residues 1 and 12 are part of the flanking helices. The loop displays a high degree of conservation, commonly including glutamate, aspartate, glutamine, and serine residues. Another hallmark is the highly conserved glycine at position 6. In each site, the central Ca^{2+} is coordinated in a pentagonal bipyramidal geometry to carboxyl oxygens of residues 1, 3, 5, and 12 (bidentate), a backbone amide carbonyl oxygen of residue 7, and an oxygen derived from a water molecule, which is hydrogen bonded to the side chain of residue 9. However, the Ca^{2+} ion is somewhat flexible in its coordination demands, both in terms of geometry and number of coordinating oxygen atoms.

In general, EF-hand proteins contain a large number of surface charges and display high solubility and high thermal stability, particularly in the Ca^{2+}-loaded state. Eukaryotic proteins have thus far been shown to contain between 2 and 12 EF-hands (Permyakov and Kretsinger 2011) in which the motif is found almost exclusively in pairs, as exemplified by a single pair in calbindin D_{9k} and two pairs in calmodulin.

Domain Organization and the HEF Family

Single EF-hands, derived from their constituent proteins, contain significant hydrophobic patches and have a tendency to oligomerize (Cedervall et al. 2005b). The interactions between naturally occurring EF-hand partners can be very strong and selective and have been used to determine the domain organization for calbindin D_{28k} (Linse et al. 1997; Berggård et al. 2000a). Remarkably, all six EF-hands of this protein interact in a single globular domain. Among the hexa EF-hand (HEF)-proteins, calretinin and secretagogin show a high degree of similarity to calbindin D_{28k}, but with some distinct structural and functional features. Studies by Palczewska et al. indicate that calretinin contains two globular domains, one consisting of EF1 and EF2 and the other of EF3-EF6. Secretagogin is not fully separated into two independent domains and its crystal structure reveals a deep cleft in the structure between EF1-EF2 and EF3-EF6 (Fig. 1). The three proteins appear to share an evolutionary origin, with four moderate or high affinity Ca^{2+} sites, although their expression patterns within neuronal subtypes appear distinct. Other, less studied HEF proteins are Eps15 homology domain, *Plasmodium falciparum* surface

protein, calsymin and CREC proteins, including reticulocalbin (Permyakov and Kretsinger 2011).

Structure

A high-resolution structure has been solved by NMR spectroscopy for Ca^{2+}-loaded rat calbindin D_{28k} in the reduced form (Kojetin et al. 2006; Fig. 1). This confirms the single globular domain (Linse et al. 1997) and provides detailed information on the three-dimensional structure of calbindin D_{28k}. Within the domain, the EF-hands are organized in pairs, as they occur in the sequence (EF1 with EF2, EF3 with EF4, and EF5 with EF6) with significant contacts between the pairs. For example, the EF1-EF2 pair is proximal to EF3-EF4 and the latter pair packs against EF6. Within each pair, structured as a four helix bundle, are seen the typical contacts, for example, the loop-loop interactions between the short anti-parallel β-strands positioned at the same end of the bundle, the hydrophobic contacts between the residues at position 8 of each loop, which dock into the protein core, and various contacts between the helices. The relatively long linkers connecting the EF-hands display extensive close interactions with one another. The linker between EF2 and EF3 contacts the EF3 to EF4 linker, and the EF4-EF5 linker contacts the sequence connecting EF5-EF6.

Based on the high-resolution structure (Kojetin et al. 2006; Figs. 1 and 2) and interaction data (Åkerfeldt et al. 1996; Linse et al. 1997; Cedervall et al. 2005b; Kordys et al. 2007), the following properties of each individual EF-hand are known.

EF1 (residues 15–43) is a canonical EF-hand containing one of the four high affinity sites and is found in a semi-open conformation in the Ca^{2+}-bound state of calbindin D_{28k}. It pairs with EF2 but also contacts EF4 (e.g., Phe17 of EF1 packs against Leu153 of EF4). It has a hydrophilic side facing the solution, but a significant number of hydrophobic groups are seen both on the opposite side and on the edges of this EF-hand. As an individual synthetic peptide, EF1 folds upon Ca^{2+} binding and its dimerization is Ca^{2+} dependent.

EF2 (residues 57–85) does not have a standard loop sequence and does not bind Ca^{2+}. As a separate peptide, it displays random coil structure, but in the intact protein, it is folded in a helix-loop-helix conformation with a more extended loop than the other EF-hands. It pairs with EF1 and engages in hydrophobic contacts with EF4. EF2 provides a large fraction of the target-binding surface of calbindin D_{28k}.

EF3 (residues 102–130) is a canonical EF-hand containing one of the four high affinity sites and in the Ca^{2+}-bound state of calbindin D_{28k} is found in a relatively closed conformation. It pairs with EF4 and contacts both EF2 and EF6. As an individual sequence, EF3 has significant secondary structure even in the absence of Ca^{2+} and forms dimers both with and without Ca^{2+} present. Ca^{2+} binding promotes further association into higher oligomers.

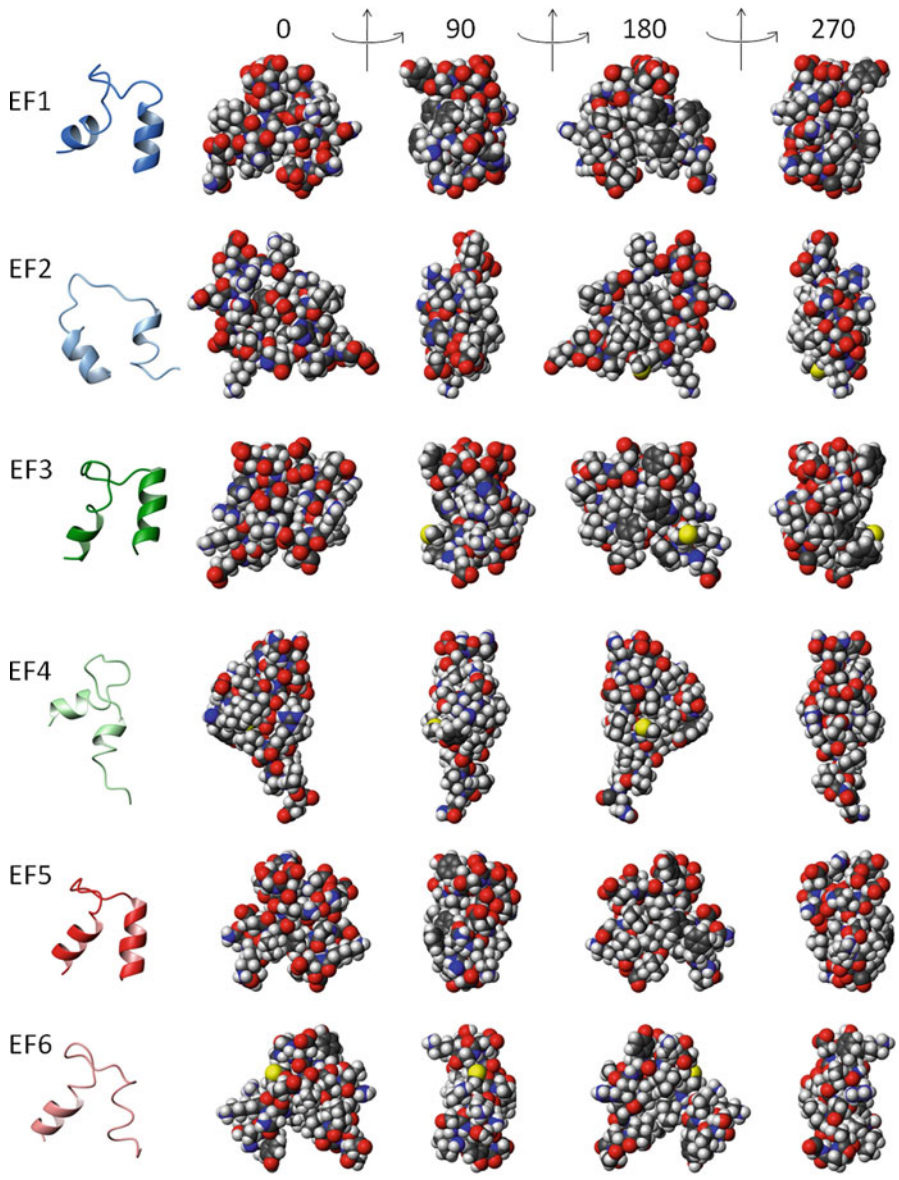
EF4 (residues 146–174) is a canonical EF-hand containing one of the four high affinity sites. EF4 forms a pair with EF3 and also contacts EF1, EF2, and EF6. Thus, EF4 appears to play the most central role in the generation of a single globular domain with the other EF-hands as it displays short-range interactions with all EF-hands except EF5. This is reflected in the distribution of hydrophobic side chains, which decorate all sides of the EF4 surface. Its fold is more flat than the other EF-hands and it is deeply inserted in the intact protein. As a separate peptide, EF4 folds upon Ca^{2+} binding; however, dimerization and Ca^{2+} binding are not energetically coupled for this fragment.

EF5 (residues 190–218) is a canonical EF-hand containing one of the four high affinity sites. This is the most peripheral EF-hand in calbindin D_{28k}, which exhibits no short-range interactions beyond the pairing with EF6. As a separate peptide, EF5 displays some secondary structure in the absence of Ca^{2+}, but the helical content increases upon Ca^{2+} binding and its dimerization is Ca^{2+} dependent. EF5 has one hydrophilic side facing the surface and the hydrophobic side chains are buried in the interface with EF6.

EF6 (residues 231–259) does not have a standard EF-hand loop sequence: EF6 binds Ca^{2+} very weakly and is Ca^{2+}-free at physiologically relevant Ca^{2+} concentrations. Still its fold is very similar to a Ca^{2+}-loaded EF-hand. EF6 pairs with EF5 and displays short-range interactions also with EF3 and EF4.

Calcium-Binding Properties

Calbindin D_{28k} contains four Ca^{2+} binding sites with physiologically relevant affinity (Berggård et al. 2002a; Venters et al. 2003). At physiological Kcl

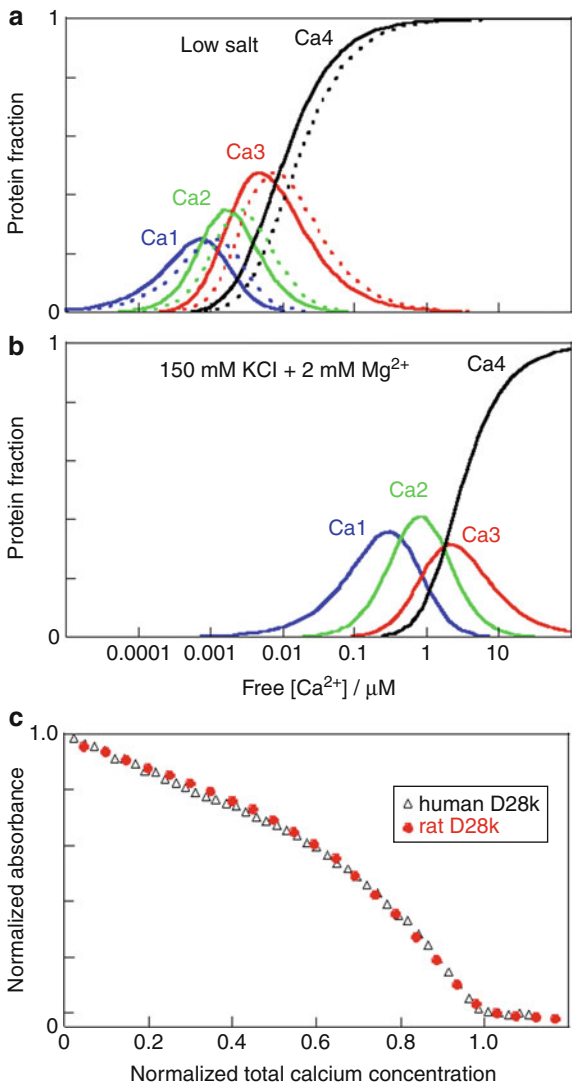


Calbindin D_{28k}, Fig. 2 The six EF-hands of calbindin D_{28k}. Space filling models with hydrogen atoms in *white*, aliphatic carbons in *gray*, aromatic carbons in *dark gray*, oxygens in *red*, nitrogens in *blue*, and sulfur in *yellow*. Each EF-hand is shown in four orientations related by 90° rotations as indicated, and the *left-most* orientation is also shown in *ribbon* representation

concentration, the average Ca^{2+} affinity for human calbindin D_{28k} is $K=2.4\ 10^6\ M^{-1}$ ($K_D=0.41\ \mu M$). Dissecting the chicken protein into single EF-hand peptides helped assign the high affinity Ca^{2+} binding functionality to EF-hands 1, 3, 4, and 5, while EF-hand 6 binds Ca^{2+} with very low affinity and EF-hand 2 does not appear to bind Ca^{2+} even at very high concentration (Åkerfeldt et al. 1996).

Two modes of Ca^{2+} binding have been reported for intact calbindin D_{28k}: parallel with a low degree of positive cooperativity for human and chicken calbindin D_{28k} (Fig. 3a, Berggård et al. 2002a; Leathers et al. 1990), and sequential for the rat protein with at least two separate binding events (Venters et al. 2003).

Rat and human calbindin D_{28k} have very similar sequences (98.5% identical); however, the Ca^{2+} binding properties of rat and human protein have not been studied under the same conditions. The different binding modes reported therefore most likely reflect the paradoxical combination of high thermodynamic stability toward denaturation and high sensitivity to solution conditions and chemical modification, including deamidation. Moreover, the apo form seems to



Calbindin D_{28k}, Fig. 3 Ca^{2+} binding to calbindin D_{28k}. (**a**–**b**) Fraction of protein in complex with 1, 2, 3, or 4 Ca^{2+} ions bound as a function of free Ca^{2+} concentration, calculated from the macroscopic Ca^{2+}-binding constants determined at low ionic strength in the presence of Quin2 for human calbindin D_{28k} under oxidizing (*solid lines*) and reducing conditions (*dotted lines*). (**c**) Raw data (absorbance at 263 nm versus total Ca^{2+} concentration) at low ionic strength for reduced rat (*red filled circles*) and human (*open black triangles*) calbindin D_{28k} in the presence of Quin2. The absorbance at 263 nm reflects the Ca^{2+} loading level of Quin2 with higher absorbance in its Ca^{2+}-free state. The data were fitted using CaLigator (André and Linse 2002)

exist in different folding states depending on its environment, and it is suggested that this will affect the Ca^{2+} binding mechanism (Hobbs et al. 2009; Kojetin et al. 2006). To find out whether rat and human proteins behave in a similar manner under identical conditions, the rat protein was cloned in Pet3a plasmid, expressed, and purified at pH 6 as described for human protein (Thulin and Linse 1999), a procedure that is known to provide a homogenous protein devoid of deamidation. Figure 3d includes the new Ca^{2+} binding data for reduced rat calbindin D_{28k} in comparison with reduced human protein in the presence of the chromophoric chelator Quin2. Under these conditions, the two proteins produce highly similar data.

At neutral or higher pH, the human protein deamidates at residue N203, and two major isoforms arise, one with Asp203 and one containing the rearranged residue, iso-Asp203. The Asp203 form binds four Ca^{2+} ions with high affinity and positive cooperativity, similarly to the wild type, while the iso-Asp203 form exhibits sequential Ca^{2+} binding (Vanbelle et al. 2005; Fig. 3c).

Structural Transitions upon Ca^{2+} Binding

Calbindin D_{28k} is a highly hydrophobic protein both in the absence and presence of Ca^{2+}; however, the exposure of hydrophobic surfaces changes in response to Ca^{2+} binding as seen by changes in the ANS fluorescence spectrum (Berggård et al. 2000b). There is also a change in tertiary structure involving aromatic side chains as evidenced by near-UV CD spectroscopy. Ca^{2+} binding leads to a conformational change which is very different from that seen for calmodulin (Berggård et al. 2002a; Kojetin et al. 2006). In calmodulin, there is a major change from closed to open domains, revealing target-binding surfaces, while the change in calbindin D_{28k} appears to involve more subtle changes in the packing of EF-hands relative to one another.

Binding of Other Metal Ions

The EF-hand is sufficiently flexible to adapt to the coordination of Mg^{2+}. Calbindin D_{28k} thus binds Mg^{2+} to the same four sites as Ca^{2+}. At physiological salt concentration (0.15 M KCl), the average Mg^{2+} affinity for calbindin D_{28k} is $1.4 \cdot 10^3$ M^{-1} (K_D=0.71 mM), that is, 1,700-fold lower than for Ca^{2+}. Considering that the Ca^{2+} concentration changes from ca. 100 nM in the resting state to 1–10 µM upon cellular

activation, and the intracellular concentration of Mg^{2+} is relatively constant at 1–2 mM, Mg^{2+} is still a relevant physiological competitor. The apparent Ca^{2+} affinity is reduced by a factor of 2 in the presence of 2 mM Mg^{2+} but the positive cooperativity of Ca^{2+} binding is more pronounced (Berggård et al. 2002a). Renal calbindin D_{28k} appears to play a role in both Ca^{2+} and Mg^{2+} transport.

A number of EF-hand proteins have been shown to bind other divalent metal ions with rather high affinity, for instance, calretinin, which is closely related to calbindin D_{28k} and has been shown to bind both Zn^{2+} and Cu^{2+}. Similarly, calbindin D_{28k} was recently shown to bind three Zn^{2+} ions to sites different from the Ca^{2+}-binding sites and involving at least one of the four histidine residues (His80; Bauer et al. 2008). The Zn^{2+}-loaded state is structurally different from the Ca^{2+}-loaded state and binding of the two metal ions shows negative allostery. Given that the Zn^{2+} site with the highest affinity (K_D=1.2 μM at low ionic strength) is about two orders of magnitude weaker than the Ca^{2+}-sites and the very low free Zn^{2+}-concentration in the cell, calbindin D_{28k} will under normal conditions not be ligated to Zn^{2+}. However, there could be a role for Zn^{2+} binding in cell types with high concentrations of Zn^{2+}, as in pancreatic cells, or temporarily, when the concentration of Zn^{2+} is elevated, for instance during conditions triggering apoptosis.

Target Binding

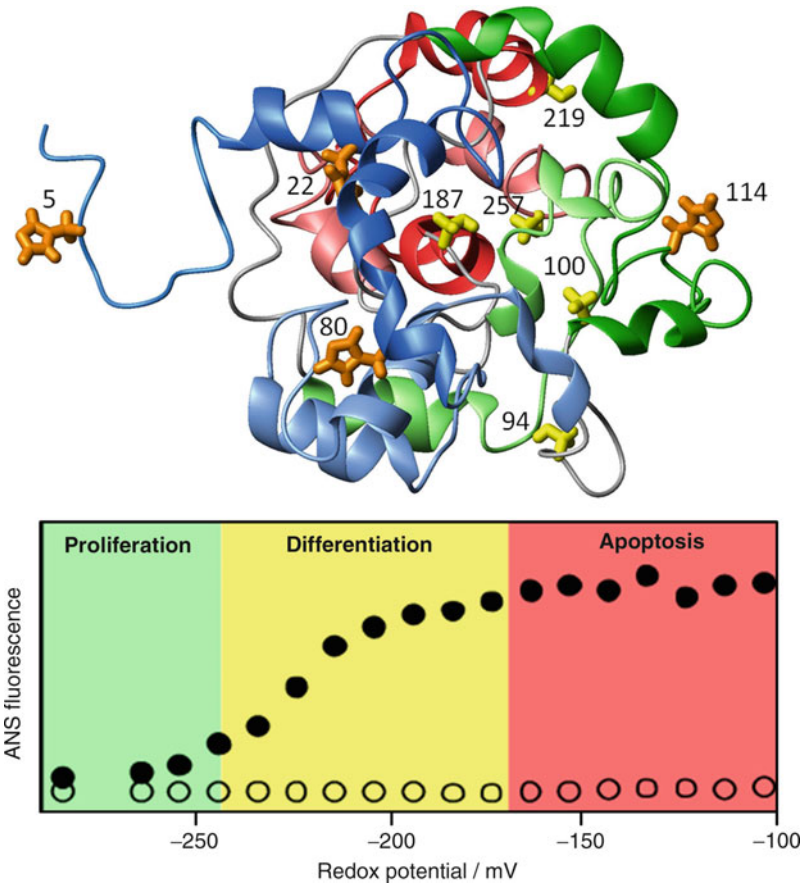
Several target protein have been reported to bind to calbindin D_{28k}, for example, IMPase (discovered by Berggård et al. 2002b and confirmed by several investigators, for example, Schmidt et al. 2005; Kordys et al. 2007), RAN-binding protein (Kordys et al. 2007), TRPV5 (Lambers et al. 2006), and caspase-3 (Bellido et al. 2000). The target-binding surface of calbindin D_{28k} has been mapped using high-resolution NMR spectroscopy and peptides from target proteins (Kojetin et al. 2006; Kordys et al. 2007). The binding site seems to involve EF2, EF4, and the linker between EF2 and EF3 (Fig. 1). In the case of IMPase, the interaction with calbindin D_{28k} leads to enhanced enzymatic activity to regenerate *myo*-inositol from *myo*-inositol monophosphate. The effect of calbindin D_{28k} is more pronounced under conditions approaching apoptosis, for example, at mild acidosis (Berggård et al. 2002b). TRPV5 is a plasma membrane Ca^{2+} entry channel, and calbindin D_{28k} associates with the channel and tightly buffers the incoming Ca^{2+} to prevent channel inactivation (Lambers et al. 2006).

Redox Regulation

Each cysteine exerts a unique influence on the structure and function of calbindin D_{28k} as revealed by a series of cysteine to serine mutations (Cedervall et al. 2005a). The interplay between the cysteine residues is complex. Cysteines 94 and 100 form a disulfide bridge under nonreducing conditions (Vanbelle et al. 2005), and are necessary for a redox-driven structural change to take place. This change occurs within physiologically relevant redox potentials (between –250 and –175 mV) and results in an altered exposure of hydrophobic surfaces (Fig. 4). Both Ca^{2+} binding and IMPase target activation are affected by the redox potential. The redox-regulated structural change occurs on the tertiary level with no observable differences in the secondary structure content, as judged by far UV CD spectroscopy. The reduced form of calbindin D_{28k}, in which residues 94 and 100 are present as free thiols, displays a slightly higher affinity for Ca^{2+} than the oxidized state (Fig. 3a, b; Vanbelle et al. 2005; Cedervall et al. 2005a). Under reducing conditions, IMPase is less activated by calbindin D_{28k}. Upon oxidation and disulfide bond formation, the hydrophobic surface of calbindin D_{28k} increases, as evidenced by increased ANS binding. The redox potential in cells is mainly controlled by the ratio of reduced and oxidized glutathione. At physiologically relevant glutathione concentrations, cysteine residues 187, 219, and 257 can each react with one glutathione (Cedervall et al. 2005a). Glutathione modifications of residues 187 and 219 further increase the exposure of hydrophobic surfaces in calbindin D_{28k}. These results suggest an intricate interplay between the cysteine residues present in calbindin D_{28k}, which affects how it regulates target proteins, including IMPase.

Stability Toward Denaturation

Calbindin D_{28k} is highly soluble and also highly stable toward thermal denaturation. The Ca^{2+} form does not denature below 100ºC and boiling can be used as an



Calbindin D_{28k},
Fig. 4 Redox regulation. *Top*: *Ribbon* representation of rat calbindin D_{28k} (2G9B.pdb) with Cys 94, 100, 187, 219, and Ser 257 (Cys in the human protein) in yellow, His 5, 22, 80, and 114 in *orange*. The EF-hands colored as in Fig. 1. *Bottom*: Structural transition as a function of redox potential (higher ANS fluorescence reflects more extensive exposure of hydrophobic surfaces on the protein) for wild-type human calbindin D_{28k} (*filled circles*) and a mutant where all five cysteines have been mutated to serine (*open circles*)

efficient purification step that precipitates many contaminants. Release of Ca^{2+} reduces the stability, and unfolding of the apo form can be observed in the presence of urea. At pH 7, the urea concentration at the transition midpoint is 4.5 M for the reduced protein. The stability is pH dependent between pH 6 and 8, with higher stability at pH 6. The oxidized protein displays a more cooperative denaturation process (Cedervall et al. 2005a). Glutathione modification further modulates the urea unfolding process.

pH Sensing

The structure and function of apo-calbindin D_{28k} is very sensitive to small changes in the proton concentration near or close to neutral pH. A change from a pH of 6.5–7.8 results in distinct tertiary structural changes, as indicated by a variety of spectroscopic methods (near-UV CD, ANS fluorescence, tryptophan fluorescence, and UV absorbance spectroscopy); however, the secondary structure remains unaffected, as deduced by far UV CD spectroscopy. The Ca^{2+}-loaded protein is less sensitive to pH changes. The structural changes that take place in response to a variation in both pH and Ca^{2+} concentration near neutral pH suggest that these represent important means physiologically by which calbindin D_{28k} modulates its interactions with target proteins. This has, for example, been shown to be the case with IMPase, which displays an increased activation upon calbindin D_{28k} binding at slightly acidic conditions (Berggård et al. 2002b).

Calcineurin

Jagoree Roy and Martha S. Cyert
Department of Biology, Stanford University, Stanford, USA

Synonyms

Calcineurin: Ca^{2+}-/calmodulin-dependent protein serine/threonine phosphatase; PP2B; PP3

Immunosuppressant: Cyclosporin A (CsA); FK506; Tacrolimus; Calcineurin inhibitor

Docking site: PxIxIT; LxVP; Docking motif

Definition

Calcineurin: Calcineurin is a phosphatase that reverses the modification of proteins by kinase-mediated phosphorylation on either serine or threonine residues. Calcineurin requires Ca^{2+} and Ca^{2+}-bound calmodulin for full activity. In different classification systems, calcineurin has also been labeled as PP2B or PP3.

Immunosuppressant: Drugs that inhibit the function of the immune system are termed immunosuppressants. Two commonly used immunosuppressants are cyclosporin A and FK506 (also called tacrolimus). Both of these immunosuppressants are also inhibitors of calcineurin.

Docking site: Docking sites, also termed docking motifs, are short linear sequences, 4–8 amino acids in length, which are contained within a substrate protein and mediate the interaction of that substrate with its cognate enzyme. In substrates of calcineurin, two such docking sites have been identified; these are termed PxIxIT and LxVP, based on the sequence of these sites in a particularly well-studied calcineurin substrate, i.e., the NFAT family of transcription factors. Docking sites do not interact with the active site of CN and are located in regions of the substrate that are distinct from residues that are dephosphorylated by calcineurin.

Introduction

Calcineurin (CN) is a highly conserved, protein serine/threonine phosphatase that is regulated by Ca^{2+} and calmodulin. Originally identified as a calmodulin-binding protein, CN received its name due to its Ca^{2+}-binding properties and abundance in neuronal tissue. Subsequent discovery of its phosphatase activity in 1982 led to its classification as protein phosphatase 2B (PP2B). It is now termed PP3 and is the third member of the phosphoprotein phosphatase (PPP) family of serine/threonine phosphatases (PP1-PP7), which also includes the major protein phosphatases, PP1 and PP2A (Shi 2009).

In 1991, identification of CN as the target of the immunosuppressive agents cyclosporin A (CsA) and tacrolimus (FK506) established the enzyme's critical role in T-cell activation (Aramburu et al. 2000; Rusnak and Mertz 2000). Because of its clinical importance, CN has received considerable attention, and wide use of CsA and FK506 as CN inhibitors has revealed its many functions in organisms as diverse as yeast and humans.

Structure of CN

CN is a heterodimer, composed of a catalytic (CN-A) and regulatory subunit (CN-B), and in its active form, binds one molecule of Ca^{2+}/calmodulin (Aramburu et al. 2000; Rusnak and Mertz 2000), see Fig. 1. CN-A contains four regions: a globular catalytic domain, followed by an α-helical region that binds CN-B, a calmodulin-binding domain, and a C-terminal autoinhibitory (AI) domain, which blocks the catalytic site and keeps CN inactive under basal conditions (Aramburu et al. 2000; Rusnak and Mertz 2000). Proteolytic removal of this domain results in constitutive enzyme activity, and a peptide encoding the AI sequence inhibits CN in vivo and in vitro.

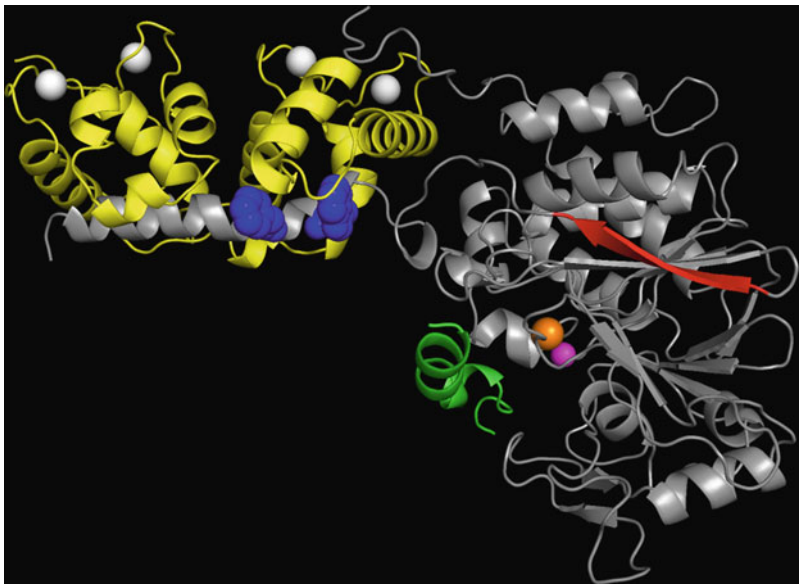
The regulatory subunit of CN, CN-B, is a highly conserved Ca^{2+}-binding protein consisting of two lobes, each of which contains a pair of Ca^{2+}-binding EF-hand domains. Sites in one lobe have tenfold lower affinity for Ca^{2+} than those in the other lobe (Aramburu et al. 2000; Rusnak and Mertz 2000). The N-terminal glycine of CN-B is myristoylated in all species, promoting thermal stability of the enzyme.

Mechanism of Activation

Ca^{2+} activates CN through two distinct mechanisms: First, via Ca^{2+} binding to CN-B and subsequently by the binding of activated calmodulin to CN-A. At low cellular concentrations of Ca^{2+} ($<10^{-7}$ M), only the high-affinity Ca^{2+}-binding sites on CN-B are occupied and the enzyme is inactive. A rise in $[Ca^{2+}]$ to 1 μM results in occupation of the low-affinity Ca^{2+}-binding sites on CN-B and limited activation of CN. This basal activity is greatly stimulated upon further binding of Ca^{2+}-bound calmodulin to CN-A, which results in a conformational change that displaces the AI domain from the catalytic active site (Aramburu et al. 2000; Rusnak and Mertz 2000). This cooperative mode of activation enables CN to respond to small and localized changes in cellular Ca^{2+}.

Metal-Dependent Catalysis

The catalytic core of CN is similar to other phosphoesterases and consists of a dinuclear metal active center, composed of one Zn^{2+} and one Fe^{2+}



Calcineurin, Fig. 1 X-ray structure of calcineurin (based on Protein Data Bank (PDB) accession code 1AUI (Kissinger et.al. 1995)). CN-B is shown in *yellow* and its bound Ca^{2+} ions are shown in *white*. CN-A, residues 14–373, shown in *silver*. The β-14 sheet that binds the "PxIxIT" docking motif is shown in *red* and residues that interact with the "YLxVP" motif are shown in *blue*. CN-A residues 469–486, encoding the AID, shown in *green*. The active site is marked by Zn^{2+} (*purple*) and Fe^{2+} (*orange*) ions. Note that residues 374–468 of CN-A, which include the calmodulin-binding domain, are not visible in the crystal structure

cofactor (see Fig. 1). The phosphoesterase motif, comprised of three β sheets and two α helices in a β–α–β–α–β format, provides a scaffold for interaction with the two metal ions, which are 3–4 Å units apart. Highly conserved residues coordinate these ions and form a bridge between them (Aramburu et al. 2000; Rusnak and Mertz 2000). Conservation of this active-site structure between CN and other phosphoesterases such as λ–phosphatase suggests a common catalytic mechanism involving direct transfer of the phosphoryl group to a metal-coordinated water molecule (Shi 2009). The identity of the metal cofactors, however, varies in different members of the family.

For CN, Fe^{2+} rather than Fe^{3+} is likely required for catalysis, and the redox state of the active site iron ion may regulate enzyme activity. Purified CN is sensitive to oxidizing agents such as H_2O_2, and anaerobic conditions are required to retain full activity of the purified enzyme (Ghosh et al. 2003). Superoxide dismutase protects CN from inactivation both in vitro and in vivo (Aramburu et al. 2000), and association of SOD1 (Cu-Zn superoxide dismutase) with CN is observed in vivo (Agbas et al. 2007).

CN Interaction with Substrates and Regulators

CN has restricted substrate specificity; however, the phosphosites it regulates share little or no sequence similarity. In fact, unlike serine/threonine protein kinases, CN and related phosphatases act poorly on short peptide substrates, and dephosphorylation is only moderately influenced by residues flanking the phosphosite. Instead, CN recognizes short stretches of amino acids in its substrates, termed docking motifs. These docking motifs are distinct from the substrate's phosphosites and interact at low affinity with surfaces of CN that are spatially distinct from its catalytic site (Li et al. 2011; Roy and Cyert 2009).

The first docking motif for CN was identified in NFAT (Nuclear Factor of Activated T cells), a family of four closely related transcription factors that mediate CN-regulated gene expression in T cells and many other tissues (see below). A region of NFAT that bound directly to CN was identified, and its consensus within the NFAT family is defined as a six amino acid "PxIxIT" motif. The PxIxIT motif, whose actual

sequence consensus is considerably broader than the name indicates, has now been identified in CN-regulated proteins from many different organisms, and is present in most, but not all, substrates (Li et al. 2011; Roy and Cyert 2009).

PxIxIT interacts both with the active and inactive forms of CN and mediates substrate binding to a region of CN that is removed from its active site. PVIVIT, a nonnative PxIxIT peptide that was selected in vitro for increased affinity for CN, interacts with a hydrophobic channel on the surface of CN-A (Li et al. 2011; Roy and Cyert 2009) (see Fig. 1). This mode of enzyme-substrate interaction is evolutionarily conserved; the structurally analogous region on PP1 interacts with the RVxF docking motif that is shared by most PP1-interacting proteins. Mutation of conserved residues in this hydrophobic surface abrogates substrate binding in vitro and severely compromises CN function in vivo. Conversely, mutations in the PxIxIT motif in substrates that prevent binding to CN also disrupt dephosphorylation (Li et al. 2011; Roy and Cyert 2009).

Native PxIxIT sites vary considerably in sequence and affinity for CN, and this motif is a major determinant of overall substrate affinity for CN. Mutating the PxIxIT sequence of Crz1, the CN-activated transcription factor from yeast, to increase or decrease its affinity for CN, results in corresponding changes in Crz1-CN-binding affinity, the extent of Crz1 dephosphorylation, and the amount of Crz1-dependent transcription generated by a defined Ca^{2+} signal (Li et al. 2011; Roy and Cyert 2009). Similarly, replacement of the PxIxIT motif in the mammalian CN substrate, NFAT, with the high-affinity PVIVIT sequence, results in increased NFAT dephosphorylation and activity in vivo (Li et al. 2011; Roy and Cyert 2009). The PxIxIT motif, therefore, influences substrate recognition and also fine-tunes the Ca^{2+} dependence of substrate regulation in vivo. Furthermore, PxIxIT sequences are a general mode of protein interaction with CN and are found in CN regulators and inhibitors, such as RCANs, CAIN/Cabin-1, and the A238L viral inhibitor, and in scaffold proteins such as AKAP-79/150 (discussed below).

A second docking motif in CN substrates, with the four amino acid consensus, "LxVP," interacts only with the active, Ca^{2+}-/calmodulin-bound form of the enzyme and may position residues for dephosphorylation at the active site. The LxVP motif, first defined as a conserved sequence in NFAT family members is required for their dephosphorylation by CN, and has now been identified in several other mammalian and yeast substrates. Although the structure of LxVP bound to CN has yet to be determined experimentally, computer modeling and mutational studies predict that it recognizes a hydrophobic groove formed by residues in both CN-A and CN-B, which is also the binding site for immunosuppressants (Roy and Cyert 2009) (see Fig. 1). This surface is accessible only after Ca^{2+} and Ca^{2+}/calmodulin bind to and activate CN. Thus, rather than mediating independent modes of substrate binding to CN, PxIxIT and LxVP may interact sequentially with the enzyme to coordinate substrate recognition and subsequent presentation of phosphosites to the active site. Additional docking motifs in CN substrates may yet be identified – PP1 contains three protein-interaction surfaces and each is conserved in CN (Roy and Cyert 2009). Additional docking sites could act in concert with PxIxIT and LxVP or define distinct mechanisms of substrate recognition by CN.

Immunosuppressant-Binding Sites Overlap with Substrate Docking Regions in CN

Characterization of the LxVP motif provided new insights into the mechanism by which CsA and FK506 inhibit CN. These immunosuppressants (ISs) inhibit CN when complexed with the immunophilin proteins (IPs), cyclophilin, and FKBP, respectively. The IS-IP complexes competitively inhibit CN dephosphorylation of peptide and protein substrates. However they do not block the active site and do not inhibit dephosphorylation of para-nitrophenol phosphate (p-NPP), a small molecule that can readily diffuse into the CN active site and does not require docking (Aramburu et al. 2000; Rusnak and Mertz 2000). X-ray crystallography revealed that both IS-IP complexes bind to the same region of CN, i.e., the hydrophobic groove formed by residues in CN-A and CN-B that is the proposed binding site for LxVP (Aramburu et al. 2000; Rusnak and Mertz 2000; Roy and Cyert 2009). Mutations in this region of CN reduce binding of both IS-IPs and the LxVP motif, and the ISs compete with LxVP for CN binding

(Roy and Cyert 2009). Thus, IS-IP apparently inhibits CN by preventing LxVP sites in substrates from interacting with CN.

Physiological Roles for CN

Regulation of Gene Expression

In mammals, CN regulates gene expression through dephosphorylation of several transcription factors (Creb, Mef2, CRTC-1, Elk-1, etc.), but is best known for its regulation of the Nuclear Factor of Activated T cells (NFAT) family of transcription factors (NFAT1-4) (Aramburu et al. 2000; Crabtree and Schreiber 2009; Rusnak and Mertz 2000). NFATs were originally identified as key factors for T lymphocyte activation, and CsA and FK506, suppress the immune response by inhibiting CN-mediated dephosphorylation of NFAT. In resting T cells, NFAT proteins are phosphorylated and cytoplasmic. Antigen binding increases intracellular [Ca^{2+}] and activates CN, which dephosphorylates NFAT and triggers its rapid accumulation in the nucleus. NFAT cooperates with other transcription factors to induce expression of genes, such as IL-2, whose products are required for T-cell activation and the cellular immune response (Crabtree and Schreiber 2009). This pathway couples Ca^{2+} signals to gene expression in a rapid and reversible manner and mediates key Ca^{2+}-dependent processes in many tissues. In skeletal muscle, CN/NFAT contributes to muscle fiber-type specification because in slow-twitch, but not fast-twitch muscles, Ca^{2+} signals generated in response to neuron firing allow sufficient accumulation of NFAT in the nucleus to trigger gene expression (Schiaffino 2010). CN/NFAT signaling also plays critical roles in heart, lungs, vasculature, and neuronal tissue development, and misregulation of CN/NFAT signaling is a major factor underlying several diseases (Crabtree and Schreiber 2009).

CN Environmental Stress Response Pathway in Yeast and Fungi

NFAT arose late in evolution and is only present in vertebrates. However, CN similarly regulates gene expression in simpler eukaryotes such as yeast and other fungi. In *Saccharomyces cerevisiae*, cytosolic [Ca^{2+}] increases during environmental stress, i.e., exposure to osmotic or heat shock, metal ions, and alkaline or cell wall stress, and CN is essential under these conditions (Cyert 2003). Like NFAT, the yeast transcription factor, Crz1 (CN-regulated zinc-finger protein), rapidly accumulates in the nucleus upon dephosphorylation by CN, where it activates a transcriptional response that promotes cell survival. Crz1 and NFAT both contain PxIxIT sites (Roy and Cyert 2009), but are otherwise evolutionarily unrelated. The CN/Crz1 signaling pathway is conserved in diverse fungi including *Schizosaccharomyces pombe* and the pathogens such as *Candida albicans*, *Aspergillus fumigatus*, *Magnaporthe grisea*, *Ustilago hordei*, and *Cryptococcus neoformans*, where it is required for virulence (Cervantes-Chavez et al. 2011; Stie and Fox 2008; Zhang et al. 2009). Thus, this Ca^{2+}-/CN-dependent signaling pathway is a favored solution to a common microbial problem – the need to adapt to a constantly changing environment. In *S. cerevisiae*, CN's role in promoting survival during environmental stress extends beyond its regulation of gene expression. Additional CN substrates include Slm1 and Slm2, related PH domain-containing proteins that are required for stress-induced endocytosis, and Hph1, an ER-localized protein that associates with the posttranslational translocation machinery and may stimulate the translocation of proteins required for survival into the ER during stress (Roy and Cyert 2009; Piña et al. 2011).

Regulation of Protein Trafficking

CN regulates protein trafficking in cells as diverse as neurons and yeast. During synaptic transmission, Ca^{2+} influx triggers neurotransmitter release through exocytosis of synaptic vesicles and also promotes the retrieval and recycling of synaptic vesicles by their subsequent endocytosis (synaptic vesicle endocytosis or SVE). CN coordinately dephosphorylates a group of nerve terminal proteins, called the dephosphins, that are essential for SVE and include dynamin I, syndapin, amphiphysin, synaptojanin, epsin 1, eps 15, and AP180 (Cousin and Robinson 2001). Dephosphorylation of the dephosphins regulates their interactions with other proteins or, in the case of dynamin I, its enzymatic activity. Subsequent rephosphorylation of these proteins enables them to stimulate further rounds of SVE. Thus CN coordinates the Ca^{2+} signal generated by neuron membrane depolarization with SVE. Regulation of endocytosis by CN is evolutionarily conserved and

occurs in the nerve cord and intestinal epithelium of *C. elegans* (Song and Ahnn 2011). In the mammalian brain, regulation of SVE by CN is key for neuronal communication and the response to chronic stimulation such as in drug addiction.

In the hippocampus, CN also promotes endocytosis of the AMPA receptor in postsynaptic densities of excitatory synapses by dephosphorylating the GluR1 subunit. This dephosphorylation requires CN targeting by AKAP79/150, a scaffolding protein that colocalizes CN and several kinases with the AMPA receptor. This NMDA-dependent downregulation of the AMPA receptor is critical for long-term depression (LTD), a key component of synaptic plasticity, and is one of the molecular processes that mediates many aspects of learning and memory. At the behavioral level, forebrain-specific CN knockout mice display reduced levels of LTD and impaired working memory (Li et al. 2011; Kvajo et al. 2010).

Regulation of the Cytoskeleton

In many cells, Ca^{2+} signals act locally through CN- and Ca^{2+}-dependent kinases to reorganize the cytoskeleton during motility. In cultured *Xenopus* neurons, Ca^{2+} inhibits neurite outgrowth through CN-dependent remodeling of the actin cytoskeleton (Lautermilch and Spitzer 2000). Paradoxically, Ca^{2+} mediates opposing responses in migrating neurons, i.e., – attraction to or repulsion from an extracellular guidance cue, with the outcome determined by the relative activities of CN and Ca^{2+}-/calmodulin-dependent kinases (Wen et al. 2007). The magnitude of the Ca^{2+} signal is critical for this decision, as CN is activated at low Ca^{2+} concentrations that fail to activate CAM kinase. CN substrates that regulate actin dynamics include GAP-43, an actin-binding protein that is highly concentrated in growth cones and promotes actin polymerization when phosphorylated, and Slingshot, a phosphatase that dephosphorylates and activates ADF (actin-depolymerizing factor)/cofilin, a major regulator of actin polymerization (Lautermilch and Spitzer 2000; Wen et al. 2007). Cofilin is phosphorylated by LIM kinase, and the balance of LIM kinase vs. Slingshot activity determines whether neurons are attracted or repulsed by BMP-7 gradients (Wen et al. 2007). Ca^{2+} signals activate CN, causing dephosphorylation of Slingshot, which locally activates cofilin to promote growth cone repulsion.

Regulation of the Cell Cycle

Ca^{2+} and calmodulin regulate the cell cycle in many eukaryotes by controlling protein kinases and CN (Kahl and Means 2003). In *Xenopus laevis*, unfertilized eggs are arrested at metaphase of the second meiotic division and a Ca^{2+} spike evoked by fertilization releases arrest by activating CAM kinase II and CN. Fzy/Cdc20, a regulator of the APC (anaphase-promoting complex), which degrades cyclin, may be a critical CN target in this process (Li et al. 2011). During meiosis in *Drosophila*, CN releases cells from metaphase I arrest and is regulated by the RCAN, Sarah (Sra) (see below) (Takeo et al. 2010). CN also regulates G1; CsA induces G1 arrest in several mammalian cell types, and CN promotes the cyclin D1 synthesis in fibroblasts (Kahl and Means 2003). In *S. cerevisiae*, CN is reported to modulate the G2 to M transition by regulating the Swe1 kinase, which inhibits Cdk1 and mediates cell cycle arrest in response to stress (Miyakawa and Mizunuma 2007).

Regulation of Apoptosis

Apoptosis, or programmed cell death, occurs in some tissues during normal development and, in many cell types, during stress and injury. Apoptosis is triggered by a combination of extrinsic signals and intrinsic factors, which lead to mitochondrial dysfunction, cytochrome c release, and caspase activation. Ca^{2+} is a critical control factor for apoptosis, especially in cardiac cell death triggered by heart attack and failure and, for neuronal death, during stroke and neurodegenerative disease (Mukherjee and Soto 2011). Activation of CN and calpain, the Ca^{2+}-regulated protease, is critical for induction of Ca^{2+}-dependent apoptosis. CN dephosphorylates Bad, a member of the Bcl2 protein family, causing it to translocate to mitochondria where it stimulates cytochrome c release (Aramburu et al. 2000). Activation of calpain during apoptosis further enhances CN signaling through degradation of Cabin1/Cain, an endogenous inhibitor of CN (see below).

Regulation of Ion Channels, Pumps, Exchangers

CN regulates ion channels in many tissues, particularly in neurons and cardiomyocytes. In neurons, CN directly regulates activity of Ca^{2+} channels, including the NMDA receptor and the L-type voltage-gated Ca^{2+}, $Ca_v1.2$ (Li et al. 2011). The scaffolding protein

AKAP-79/150 (see below) interacts with $Ca_v1.2$, CN, and PKA and targets both modulators to the channel. PKA and CN have opposing roles in channel regulation, with PKA increasing current amplitude and CN reversing this effect. Thus, channel opening initiates a negative feedback loop by locally activating CN and promoting its own dephosphorylation; in addition, CN is thought to activate NFAT that localizes to the mouth of the channel, thus directly tying channel activity to transcriptional activation (Li et al. 2011). In cardiomyocytes, CN also modulates $Ca_v1.2$ activity; however, in this tissue, CN interacts directly with the channel and does not require AKAP79/150. Recent evidence suggests that CN positively regulates $Ca_v1.2$ in this tissue and acts independently of PKA; however, its mechanism and function are not yet fully elucidated (Tandan et al. 2009). Other ion channels regulated by CN include TRESK, a two-pore domain K^+ channel expressed widely in the immune system and neuronal tissues that may play a role in nociception (Li et al. 2011). CN-dependent activation of TRESK negatively regulates neuronal excitability by promoting the background or leak K^+ conductance that maintains negative membrane potential. CN also regulates a critical ion pump, i.e., the Na^+/K^+ ATPase. Activation of the Na^+/K^+ ATPase by CN promotes critical extrusion of Na^+ in the kidney, explaining in part the nephrotoxic effects of CsA and FK506, whereas in neurons, glutamate binding to NMDA receptor activates influx of both Ca^{2+} and Na^+, and CN-mediated activation of Na^+/K^+ ATPase activity protects cells from glutamate toxicity (Aramburu et al. 2000). CN also controls ion balance by regulating ion exchangers, including negative regulation of the Na^+/Ca^{2+} exchanger, NCX1, in cardiomyocytes and the vacuolar Ca^{2+}/H^+ exchanger, Vcx1, in *S. cerevisiae* (Cyert 2003; Katanosaka et al. 2005).

CN-Dependent Regulation of Other Signaling Pathways

Several CN substrates, including KSR2 and DARPP-32, mediate Ca^{2+}-dependent regulation of other major signaling pathways to allow coordination of Ca^{2+} signals with other second messengers in the cell and promote cross talk between signaling pathways.

DARPP-32 is a key regulator of dopamine-induced signaling in the brain. Dopamine is the primary neurotransmitter involved in reward pathways, and changes in dopaminergic neurotransmission are implicated in many disorders including Parkinson's, schizophrenia, and drug and alcohol abuse. Dopamine elicits an increase in cAMP resulting in PKA-dependent phosphorylation of DARPP-32 on thr-34. This form of DARPP-32 inhibits PP-1, which reverses PKA phosphorylation of many proteins, and thereby amplifies PKA-dependent signaling. In contrast, glutamate generates Ca^{2+} signals through the NMDA receptor, stimulating CN to dephosphorylate DARPP-32, which activates PP-1 and antagonizes PKA-dependent signaling (Kvajo et al. 2010). This modulation of DARPP-32 allows signals from different neurotransmitters to be integrated to control behavior. A closely related PP-1 inhibitor, Inhibitor-1 (I-1), is similarly regulated by CN and PKA and coordinates hormonal signaling in the heart, liver, and other tissues (Aramburu et al. 2000; Rusnak and Mertz 2000).

In pancreatic β-cells and neurons, Ca^{2+} signals stimulate ERK/MAP kinase signaling through CN-dependent dephosphorylation of KSR2, a scaffold for the ERK/MAP kinase signaling pathway. In pancreatic β-cells, glucose stimulation causes Ca^{2+}-dependent ERK activation, which results in insulin secretion. Dephosphorylation of KSR2 by CN abrogates its binding to 14-3-3 proteins, resulting in KSR2 translocation to the cell surface where it binds to ERK and its upstream kinases and promotes their activation by Ras. An LxVP motif in KSR2 is required for CN binding and this Ca^{2+}-dependent activation. Similarly, KSR2 mediates Ca^{2+} activation of ERK/MAP kinase signaling in neurons, evoked by K^+-induced depolarization (Li et al. 2011).

Modulation of CN Activity by Endogenous Protein Regulators

CN catalytic activity is regulated in vivo by several classes of regulators. The conserved RCAN family has been linked to both Down's syndrome and cancer and is comprised of three genes in humans, each with multiple splice isoforms. Regulation of CN by RCANs is complex; these proteins are regulators and substrates of CN and have both positive and negative effects on signaling (Roy and Cyert 2009). In the case of the single yeast RCAN, Rcn1 and human RCAN1-4, the proteins are present at low level under basal conditions and are transcriptionally induced under CN signaling conditions, i.e., by Crz1 and NFAT,

respectively. When present at high levels, the proteins bind to and inhibit CN, thus forming a negative feedback loop. RCANs utilize both PxIxIT and LxVP docking motifs to bind CN and may inhibit CN function by preventing substrate access to the enzyme. However, a peptide encoding the last exon of human RCAN1 inhibits CN activity toward p-NPP and peptide substrates in vitro, suggesting that catalytic activity is also directly inhibited (Li et al. 2011; Roy and Cyert 2009).

RCANs can also positively regulate CN. Yeast mutants lacking Rcn1 are deficient for CN signaling, and mice deleted for RCAN1 and RCAN2 display properties characteristic of CN-deficient mice, including reduced expression of NFAT-dependent genes and a decreased propensity to develop cardiac hypertrophy (Li et al. 2011). RCAN phosphorylation is required for this positive effect, which occurs through an undetermined mechanism. RCAN phosphorylation also triggers its ubiquitin/proteosome-mediated degradation and can be reversed by CN-dependent dephosphorylation producing yet another layer of negative feedback on CN signaling. Thus, unraveling each of RCAN's effects on CN signaling remains an exciting if somewhat daunting challenge for the future.

Cabin1/Cain also inhibits CN through an undetermined mechanism. Cabin1/Cain is highly expressed in the brain in a pattern that mirrors that of CN, and it binds to CN-A via *a* C-terminal proline-rich domain that likely contains a PxIxIT motif. Cabin1/Cain binds to amphiphysin, one of the dephosphins through which CN regulates SVE. Overexpression of Cabin1/Cain in HEK293 cells decreases endocytosis, and during SVE, Cabin1/Cain inhibition of CN is thought to promote rephosphorylation of the dephosphins to terminate endocytosis. Cabin1/Cain also inhibits CN signaling during T-cell activation. In activated T lymphocytes, PKC phosphorylates Cabin1/Cain, increasing its affinity for CN and providing negative feedback on signaling (Liu 2003).

Because of CN's key role in T-cell activation, it is targeted by viral proteins to dampen the host immune response. A238L, made by African swine fever virus, contains two domains: the C-terminal 80 amino acids bind to and inhibit CN and the rest of the protein inhibits NFκB, which activates additional immune responses. A238L contains a PxIxIT motif; however, the mechanism by which it inhibits CN is unknown (Roy and Cyert 2009).

CN Targeting Proteins

In vivo, CN can be directed to specific substrates by scaffolding proteins. AKAP79 in humans and its rodent homologue AKAP150 contains defined binding sites for CN, PKA, and PKC (Li et al. 2011). AKAP79/150 also interacts with substrates for these enzymes and is required for regulation of these substrates in vivo. As discussed above, in hippocampal neurons, AKAP79/150 facilitates modification of the $Ca_v1.2$ L-type Ca^{2+} channel by PKA and CN. In cells that express mutant AKAP79/150 lacking the CN-binding site, the channel fails to be regulated by the phosphatase, and the PKA interaction motif of AKAP79/150 must be present for the channel to be phosphorylated by this kinase. Similarly, during LTD, AKAP79/150 localizes CN and PKA for regulation of AMPA receptor endocytosis by cobinding these regulators and adaptors, such as PSD-95, that interact with the AMPA receptor (Li et al. 2011). AKAP79/150 contains a PxIxIT docking motif and was initially characterized as an inhibitor because CN bound to AKAP is inactive in vitro. However, in vivo, CN is thought to interact dynamically with AKAP79/150 and partition between AKAP-bound and substrate-bound states, with the AKAP7/150 maintaining a high local concentration of the enzyme.

In cadiomyocytes, the Ca^{2+}-and integrin-binding protein 1 (CIB1) specifically targets CN to the cell membrane, where it is activated by Ca^{2+} influx through the L-type channel and activates NFAT (Heineke et al. 2010). CIB1 is specifically upregulated during cardiac hypertrophy (see below). Interestingly, CIB1 interacts with CN via CN-B rather than CN-A, showing that both subunits can mediate specific interactions with other proteins.

Impact of CN on Mammalian Diseases

CN signaling is altered in a growing list of pathologies, some which are associated with chronic activation of CN, such as neurodegenerative diseases and cardiac hypertrophy, while in others, such as diabetes and Down's syndrome, CN signaling is compromised. CN also contributes to cancer progression, where its role varies by cell type.

CN is Chronically Activated in Neurodegenerative Disease

Hyperactivation of CN is strongly associated with neurodegenerative disorders such as Alzheimer's (AD) and Huntington's (HD) disease (Mukherjee and Soto 2011). During these and other neurodegenerative diseases, misfolded, aggregated proteins accumulate in cells, causing ER stress and provoking Ca^{2+} release from the ER. The resulting elevation in CN activity can be further enhanced by proteolytic cleavage of the CN-A AID by caspases and/or inactivation of Cabin1/Cain by calpain. Brain samples from AD patients are enriched in truncated, constitutively active forms of CN-A, and chronic activation of CN promotes neuronal death through dephosphorylation of BAD and induction of apoptosis. In HD, CN further contributes to neuronal death by dephosphorylating huntingtin, which reduces huntingtin's ability to promote secretion of neurotrophic factors such as BDNF (brain-derived neuronal growth factor). CN also causes synaptic dysfunction by inactivating CREB, increasing endocytosis of AMPA receptors and misregulating SVE. CN inhibitors reduce the abnormal focal swelling observed in dendrites and axons during neurodegenerative disease and, as indicated by studies with mouse models, have significant therapeutic potential (Mukherjee and Soto 2011).

CN Signaling in Heart Disease

Activation of CN signaling accompanies heart disease and results in cardiac hypertrophy. CN is both necessary and sufficient to induce cardiac hypertrophy in rodent models and does so primarily by activating NFAT and MEF2, both of which induce expression of genes required for the pathology (Heineke and Molkentin 2006). Inhibition of CN with FK506, CsA, or transgenic expression of CN inhibitor proteins alleviates hypertrophy. Cib1, which is upregulated during pathological but not physiological cardiac hypertrophy, promotes stress-induced, Ca^{2+}-dependent activation of CN in this process by positioning the enzyme near the L-type Ca^{2+} channel (Heineke et al. 2010).

CN in Diabetes

Pathophysiological responses that result from abrogation of CN signaling are sometimes revealed as complications associated with clinical use of FK506 or CsA. These CN inhibitors impair insulin production by pancreatic β cells, and patients receiving them often develop diabetes mellitus. CN/NFAT signaling is required for insulin transcription and for other aspects of β cell function. CN may also directly regulate insulin secretion (Heit 2007).

CN in Skin Cancer

Treatment with CsA or FK506 also results in significantly increased risk for squamous cell carcinoma (Wu et al. 2010). In keratinocytes, inhibition of CN/NFAT signaling leads to increased expression of ATF3, an AP-1 family protein that suppresses p53-mediated senescence. Thus, in these cells, the CN/NFAT pathway is required for p53 to function effectively as a tumor suppressor.

CN/NFAT Signaling Is Perturbed in Down's Syndrome

The portion of chromosome 21 that is present in three copies in Down's syndrome patients contains two genes that combine to decrease CN/NFAT signaling: DSCR1 encodes the Rcan1 CN regulator, whose increased dose inhibits CN, and DYRK1a encodes a protein kinase that phosphorylates NFAT and promotes its export from the nucleus. Mice overexpressing Rcan1 and Dyrk1a exhibit many of the same defects associated with Down's syndrome (Li et al. 2011).

Multiple Roles for CN/NFAT in Cancer

Interestingly, individuals with Down's syndrome also exhibit significantly reduced incidence of leukemia and solid tumors as a result of decreased NFAT signaling. Thus, in contrast, the tumor-suppressive role described for keratinocytes, in many cancer cells, the CN/NFAT signaling promotes tumor progression by stimulating proliferation, migration, invasion, and angiogenesis (Mancini and Toker 2009) and may therefore be an attractive therapeutic target.

CN and Schizophrenia

The molecular causes of schizophrenia, one of the most common mental disorders, are poorly understood. CN-deficient mice display behaviors common to this disorder, and genetic studies show that some alleles of PP3CC, which encodes CN-A, are significantly associated with schizophrenia. Thus, identifying CN-regulated processes that are perturbed in schizophrenic patients may provide insight into the causes of the disorder (Kvajo et al. 2010).

Future Perspectives: Development of Novel Strategies to Modulate CN Signaling

CN's many associations with pathology suggest a huge therapeutic potential for drugs that target this phosphatase. However, CN is ubiquitously expressed, and the multiple side effects associated with immunosuppressive therapy illustrate the need for drugs that are either tissue specific or disrupt CN-dependent regulation of particular substrates. Inhibitors of substrate binding, like PVIVIT and LxVP, could potentially be tailored for specificity. Also, several small molecule inhibitors of CN have been discovered: CN585, a noncompetitive, reversible inhibitor (Erdmann et al. 2010), PD144795, which also has anti-HIV and anti-inflammatory properties (Rusnak and Mertz 2000), and the INCA compounds, which are allosteric inhibitors of CN/NFAT (Roy and Cyert 2009). Elucidating how CN recognizes and dephosphorylates its substrates and identifying the mechanisms by which its endogenous protein regulators act may yield novel strategies to modify the activity and function of this critical enzyme in vivo.

Definition

Extracellular matrix is the network of polysaccharides and glycoproteins that occupies the extracellular space of invertebrate and vertebrate tissues. Many matrix proteins bind calcium ions, which serve to stabilize individual domains or the interface between domains, or to mediate interactions between different components of the extracellular matrix. Mutations of calcium-binding residues in matrix proteins cause protein misfolding and human diseases.

The extracellular matrix (ECM) is defined as the aggregate of all secreted molecules that are immobilized in the extracellular space of animal bodies. ECMs can be highly ordered, with distinct morphological features (e.g., aligned fibers) visible in electron micrographs. Other ECMs can have an amorphous appearance, but they nevertheless contain typical ECM proteins (e.g., in the brain). The functions of ECM are manifold, but may be summarized as either mechanical or instructive. In vertebrates, the various forms of ECM lend mechanical stability to tissues and organs, such as bone, tendons, cartilage, blood vessels, skin, and many others. Far from being a passive scaffold for tissue formation, however, the ECM regulates the development and functions of almost all cell types in animals. Cell-ECM interactions are mediated by a variety of cellular receptors and are crucial for cell survival, proliferation, polarity, differentiation, and migration. Furthermore, by acting as a medium for

the diffusion and delivery of morphogens and growth factors, the ECM plays a major role in the establishment of instructive gradients during development. The essential nature of ECM molecules for animal development and homeostasis is underscored by their conservation in even the simplest invertebrates. Furthermore, a number of human diseases are caused by genetic or acquired defects in ECM structure or cell-ECM communication (Reichardt 1999; Hynes 2009).

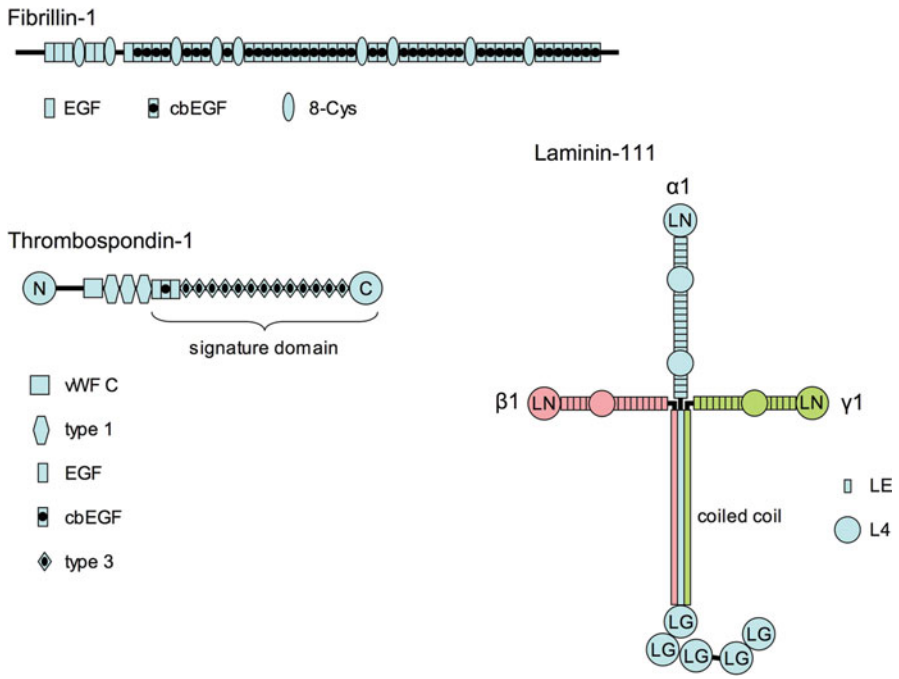
In contrast to the cytosol of cells, the extracellular compartment of vertebrate tissues and organs is characterized by a high and constant concentration of calcium. This concentration is commonly assumed to be the same as in blood plasma, that is, 1.2 mM, but it is important to realize that experimental verification for this assumption is often lacking. Local fluctuations in calcium concentration may exist in certain tissues and conceivably have a regulatory role. All ECM molecules fold in the lumen of the endoplasmic reticulum, where calcium is abundant, and are partially assembled into supramolecular structures during their passage through the secretory pathway. To what extent calcium ions are involved in these pre-secretion processes is largely unknown. As will be discussed below, there are several ECM proteins whose functions depend critically on the presence of calcium. It is commonly assumed that the role of calcium in these proteins is structural, and the harsh conditions of many extracellular compartments certainly seem to favor domains with robust folds strengthened by disulfide bridges and/or metal ion–binding sites.

The major classes of ECM molecules are collagens, non-collagenous glycoproteins, and proteoglycans. There are ~30 different collagen types in humans. Type I, II, III, V, and XI collagens assemble into supramolecular fibrils, which are a prominent feature of many vertebrate ECMs. Collagen fibrils are a major constituent of bone and teeth, the two mineralized tissues that contain a large amount of inorganic calcium in the form of hydroxyapatite. Several non-collagenous phosphorylated proteins, for example osteopontin, are important for bone mineralization, but recent results suggest that the collagen fibrils themselves may have a role in this process. Proteins are assumed to promote biomineralization by nucleating hydroxyapatite crystals, but the precise mechanisms have remained obscure due to a lack of structural information. The non-fibrillar collagen types form irregular sheets (type IV collagen), polygonal three-dimensional networks (types VIII and X collagen), or other assemblies. The crystal structure of the C-terminal NC1 domain of type X collagen revealed a tight homotrimer with a cluster of four calcium ions near the trimer axis, but the closely related type VIII collagen NC1 trimer is stabilized in a different manner, without the need for calcium ions.

Proteoglycans consist of a core protein, to which are attached one or more glycosaminoglycan chains. These GAG chains are linear polysaccharides that are modified by sulfation. Many of the proteoglycan functions are carried out by the GAG chains, but the core proteins have important functions as well. Calcium is not believed to play a major role in proteogylcan biochemistry. One notable exception is the calcium-dependent interaction of the C-type lectin domain of the aggrecan core protein with tenascin.

Among the non-collagenous ECM proteins, calcium binding is critical for the structure and function of fibrillins, thrombospondins, and laminins, as well as for collagen binding by the EF-hand protein SPARC. It is worth noting that all of these proteins are evolutionarily ancient and found in even the simplest animals. The remainder of this brief survey will describe these important proteins in more detail.

Elastic fibers, which are abundant in elastic tissues, such as the aorta, arteries, skin, lung, and ligaments, are composed of a core of covalently cross-linked elastin surrounded by a mantle of microfibrils. The major component of the microfibrils are two large (~350 kD) glycoproteins, fibrillin-1 and fibrillin-2 (Kielty 2006). Apart from their functions in elastic fibers, the fibrillins also play an important role in the extracellular control of transforming growth factor β and bone morphogenetic protein signaling. The two fibrillins have a modular architecture, consisting of 47 epidermal growth factor (EGF)-like domains interspersed with eight transforming growth factor β-binding protein-like (TB) domains or eight-cysteine domains (Fig. 1). Forty-three of the 47 EGF domains have a consensus sequence for calcium binding, which was first identified in the calcium-binding EGF (cbEGF) domains of blood coagulation factor IX. Extensive structural and biophysical studies of fibrillin cbEGF pairs have revealed that the calcium ions are bound near the domain interfaces and serve to stabilize the extended conformation of cbEGF tandems



Calcium and Extracellular Matrix, Fig. 1 Domain organization of fibrillin-1, thrombospondin-1, and laminin-111. Fibrillin-1 consists of multiple epidermal growth factor (EGF)-like domains, most of which are of the calcium-binding type (cbEGF), interspersed with eight-cysteine (8-Cys) domains. Thrombospondin-1 is a heterotrimer consisting of an N-terminal domain; an α-helical trimerization domain; a von Willebrand factor type C (vWF C) domain; multiple thrombospondin type 1, type 2 (EGF), and type 3 domains; and a C-terminal domain. The three laminin-111 chains consist of a laminin N-terminal (LN) domain and multiple laminin-type EGF (LE) domains interspersed with laminin 4 (L4) domains, followed by an α-helical region that forms a coiled coil in the laminin-111 heterotrimer. The laminin α chain additionally contains five laminin G (LG)-like domains at its C-terminus

(Handford et al. 2000). The dissociation constants of the calcium ions depend on the context: While individual fibrillin cbEGF domains bind calcium with low affinity, cbEGF domains flanked by their neighboring domains bind calcium with dissociation constants of $\leq$300 μM. The cbEGF domains of fibrillin are, therefore, likely to be largely saturated with calcium at the physiological calcium concentration.

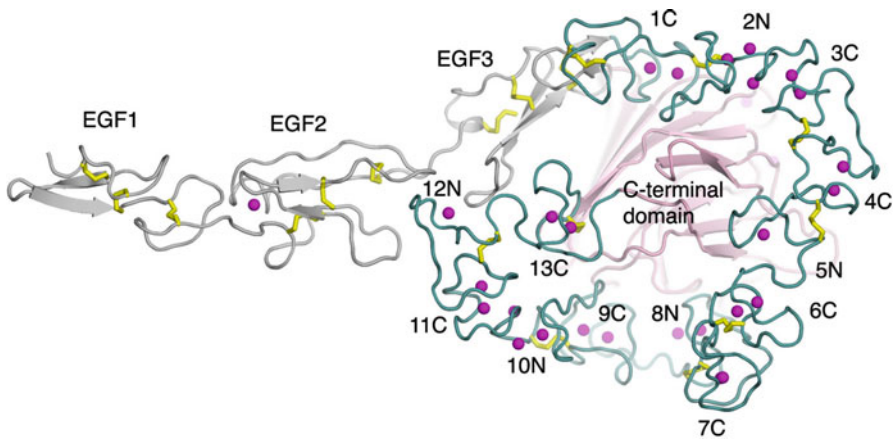
How the fibrillin molecules associate to form the microfibrils of ~10 nm diameter has been the subject of much research and debate, and a consensus on the microfibril structure has yet to be reached. All the current microfibril models feature lateral packing of fibrillin molecules, but differ in the stagger between adjacent fibrillin molecules and in the extent to which the fibrillin molecules are folded back on themselves in the microfibril. Microfibrils extracted from tissues appear as beads on a string in rotary shadowing electron micrographs, with bead-to-bead distances varying from ~50 to ~150 nm depending on the tissue source and extraction procedure used. It is likely that essential microfibril-associated proteins are lost upon extraction. Indeed, the filamentous inter-bead regions are not seen in quick-freeze deep-etch micrographs of ciliary zonule microfibrils, suggesting that there is still much left to learn about the microfibril structure in situ. Mutations in fibrillin genes cause two genetic disorders in humans: Marfan syndrome (fibrillin-1) and congenital contractural arachnodactyly (fibrillin-2). Missense mutations causing Marfan syndrome affect all regions of the fibrillin-1 molecule, including cbEGF residues involved in calcium binding. It has been shown that the latter mutations weaken the domain interfaces in a manner that is consistent with the structural models.

Thrombospondins (TSPs) are a family of calcium-binding glycoproteins that are characterized by their oligomeric nature and a typical modular architecture containing calcium-binding motifs not found in any

other metazoan protein. Mammalian TSP-1 and TSP-2 are trimers and consist of an N-terminal domain, followed by an α-helical oligomerization domain, a von Willebrand factor type C domain, three thrombospondin type I domains, three EGF domains (the second of which is of the cbEGF type), a stretch of 13 calcium-binding type 3 repeats (to be described), and a C-terminal lectin-like domain (Fig. 1) (Carlson et al. 2008). Mammalian TSP-3, TSP-4, and TSP-5 are pentamers and lack the type I repeats. TSP-5, also called cartilage oligomeric matrix protein (COMP), additionally lacks the N-terminal domain. The best studied member, TSP-1, is not primarily a structural ECM protein, but is involved in regulating cellular processes, such as angiogenesis, synaptogenesis, and inflammation. TSP-5/COMP, on the other hand, appears to serve an important structural role in cartilage and may be regarded as a bona fide ECM protein. Mutations in the COMP gene cause two skeletal disorders in humans: pseudoachondroplasia and multiple epiphyseal dysplasia (Briggs and Chapman 2002).

TSP-1 was initially isolated from human platelets, and its biochemical properties and ultrastructure were found to be very sensitive to calcium removal. When the sequence of TSP-1 was elucidated in 1986, it was noticed that the type 3 repeats contain aspartic acid-rich motifs that resemble the calcium-binding EF-hand motif. The structural details of calcium binding by TSPs were eventually revealed by two crystal structures nearly two decades later. The first crystal structure established the novel mode of calcium binding by the type 3 repeats (Kvansakul et al. 2004), and the second structure showed how the EGF domains, the type 3 repeats, and the C-terminal domain are assembled into an intricate superstructure, which was termed the "TSP signature domain" (Carlson et al. 2008). In the signature domain, the type 3 repeats surround a core of 26 calcium ions, creating an unprecedented structure termed "the wire" (Fig. 2). There are two variants of the type 3 repeat, N-type and C-type, which differ in length and in some details of the calcium coordination. The full wire has the sequence 1C-2N-3C-4C-5N-6C-7C-8N-9C-10N-11C-12N-13C; it lacks a conventional hydrophobic core and is stabilized by the 26 calcium ions and 8 disulfide bridges. Each repeat contains a D-X-D-X-D/N-G-X-X-D/N-X-X-D/N motif that typically binds two calcium ions (the few deviations from the consensus are of no importance here). The first ion is coordinated by the side chains at positions 1, 3, 5, and 12 of the consensus motif; the second calcium ion is coordinated by the side chains at positions 3, 5, and 12. The coordination spheres of the calcium ions are completed by an asparagine side chain at position 14, 15, or 19, main chain carbonyl oxygens, and water molecules. The wire is wrapped around the globular C-terminal domain, and the third EGF domain also contributes prominently to the superstructure of the TSP signature domain. The lectin-like C-terminal domain of TSPs binds 3–4 calcium ions, and there is some evidence that these ions mediate interactions with other ECM proteins. Detailed biophysical measurements support the view that the TSP signature domain behaves essentially as a single unit. A total of 22–27 calcium ions were detected by atomic absorption spectroscopy and equilibrium dialysis, in good agreement with the structural results. Interestingly, only about ten of these ions are exchangeable, suggesting that most of the calcium ions in the type 3 repeats may be bound very tightly. Missense mutations in COMP that cause pseudoachondroplasia and multiple epiphyseal dysplasia frequently affect residues involved in calcium coordination, suggesting that they may destabilize the entire signature domain and thereby lead to the intracellular aggregation of COMP that is characteristic of these skeletal disorders. The disease mechanism is likely to be complex, but endoplasmic reticulum stress due to misfolded COMP protein is now widely believed to be an important contributor.

The laminins constitute a family of adhesive glycoproteins that are characteristic components of basement membranes (BMs), a sheet-like type of ECM that underlies all epithelia and surrounds muscle, peripheral nerve, and fat cells. Laminins are essential for embryo development, as well as for tissue function in adult animals. Laminins are large, cross-shaped molecules consisting of three polypeptide chains (α, β, and γ). The three short arms of the cross are composed of one chain each, while the long arm is an α-helical coiled coil of all three chains, terminating in a tandem of five laminin G (LG)-like domains provided by the α chain (Fig. 1). The human genome encodes five α, three β, and three γ chains, which are assembled into at least 15 laminin heterotrimers (Aumailley et al. 2005). Laminin-111 (α1β1γ1) has long been known to be a calcium-binding protein: In the presence of ≥50 μM calcium at 37°C,



Calcium and Extracellular Matrix, Fig. 2 Crystal structure of the thrombospondin-2 signature domain (pdb 1yo8; Carlson et al. 2008). Disulfide bridges are in *yellow*, and calcium ions are shown as *magenta spheres*. The signature domain consists of three epidermal growth factor (EGF)-like domains; 13 calcium-binding type 3 repeats, grouped into either N- or C-type repeats (1N, 2C, 3N, and so on); and a C-terminal lectin-like domain

laminin-111 aggregates in solution, a process that is believed to mimic the biologically relevant polymerization of laminin at the cell surface. Laminin aggregation in solution is reversible, and the polymer can be dissociated by calcium chelation or cooling to 4°C. Biochemical experiments and genetic evidence from mouse mutants have established that laminin polymerization is mediated by the laminin N-terminal (LN) domains at the tips of the three short arms. However, there is currently no structural information to explain how calcium mediates laminin short arm interactions.

The five LG domains at the C-terminus of laminin α chains contain important binding sites for cellular receptors, including integrins, α-dystroglycan (α-DG), heparan sulfate proteoglycans, and sulfated glycolipids. Of greatest interest here is the interaction of the LG4-LG5 pair with α-DG, which is critical for muscle function and has long been known to require calcium. The LG domain is a β-sandwich, the core of which adopts the jelly roll topology found in numerous lectins and other proteins (Timpl et al. 2000). Both LG4 and LG5 have a calcium ion bound to one edge of the β-sandwich. The coordination of these ions is identical in the two LG domains, with the calcium ion bound by two aspartic acids and two main chain carbonyl oxygens. In all crystal structures of laminin LG domains, the coordination shell of the calcium ion is completed by an acidic buffer molecule or an acidic side chain from a neighboring molecule in the crystal lattice. This observation suggests that an acidic α-DG moiety might be recognized by the LG calcium site(s). Mutagenesis of the calcium-binding aspartic acid residues in the laminin α2 LG4-LG5 pair has shown that the calcium site in LG4, but not the one in LG5, is essential for α-DG binding. Consistent with this result, LG4 has been shown to contain the α-DG-binding site in the laminin α1 chain. LG domains also occur in the BM proteins agrin and perlecan, and α-DG binding to these proteins is likely to follow the principle established for laminin. The α-DG moiety recognized by laminins, agrin and perlecan has remained elusive. α-DG is a heavily glycosylated protein and it was recently shown that a rare carbohydrate modification involving a phosphodiester bond is essential for laminin binding.

SPARC (secreted protein acidic and rich in cysteine), also called osteonectin or BM-40, is a small (~43 kDa) glycoprotein that is not a structural ECM component itself, but interacts with collagens and may play a role in collagen secretion and fibril formation (Bradshaw 2009). SPARC consists of an acidic N-terminal segment, a follistatin (FS)-like domain, and a characteristic α-helical domain containing two EF-hand calcium-binding motifs (EC domain). The second of the EF-hands has a canonical motif; the first EF-hand has an unusual one-residue insertion into the canonical motif. Despite this deviation from the consensus, the EF-hand pair of SPARC binds two calcium ions with high affinity (dissociation constants of ~50 and ~500 nM, respectively), ruling out a regulatory role of the EF-hands in the extracellular milieu. The collagen-binding site of SPARC has been located

by mutagenesis: it resides in the EC domain and is composed of the loop connecting the two EF-hands and a long α-helix that is cradled by the EF-hand pair. The collagen-binding site is only partially accessible in intact SPARC, and proteolytic cleavage of an obstructing loop increases the affinity for collagen tenfold. Recent biochemical and structural studies have revealed the mode of collagen binding. SPARC binds to a unique Gly-Val-Met-Gly-Phe-Hyp (Hyp is hydroxyproline) motif in fibrillar collagens. The phenylalanine residue appears to be particularly important for binding, as it is inserted into a deep pocket in the EC domain of SPARC that forms only upon collagen binding. Calcium is not directly involved in collagen recognition, but the intimate involvement of the loop connecting the EF-hands explains why calcium chelation abrogates collagen binding.

Synonyms

Calcium and mitochondria

Definition

Calcium: An alkaline earth metal having atomic number 20, typically found in the 2+ oxidation state.

Mitochondrion (plural: mitochondria): An intracellular organelle noted for being the site of oxidative phosphorylation and for producing over 90% of the ATP in a typical animal cell.

Importance of Mitochondrial Ca^{2+} Transport

Mitochondrial Ca^{2+} transport is known to perform three functions: (1) to activate steps in the metabolic pathways and increase the rate of ATP production, (2) to modify the shape and distribution of cytosolic Ca^{2+} transients, and (3) to induce the mitochondrial permeability transition in mitochondrially induced apoptosis or programmed cell death. These functions are extremely important. Intramitochondrial free Ca^{2+} concentration ($[Ca^{2+}]_m$) activates important steps in the metabolic pathways, such as pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, isocitrate dehydrogenase, and the F_1F_0 ATP synthase, which taken together can increase the rate of ATP production by oxidative phosphorylation by a factor of around 3 (Balaban 2009). Many types of cells, particularly energetically active neurons like those of the basal ganglia, could not survive and function without this increased

ATP production. In energetically active tissue like the heart under high pumping load, where Ca^{2+} transients control muscle contraction as well as ATP supply, Ca^{2+}'s role in matching the supply of ATP with demand is critically important to avoiding heart failure (Balaban 2009). Furthermore, recent studies have shown other signaling mechanisms which function through mitochondrial Ca^{2+} uptake such as the suppression of prosurvival microautophagy by the release of Ca^{2+} through inositol trisphosphate receptors (IP3R) and its subsequent uptake by mitochondria (Cardenas 2010). It has been known for some time that mitochondria change the shape and distribution of cytosolic Ca^{2+} transients. In an extreme example of this, mitochondria set up a "firewall" completely shielding regions of the pancreatic acinar cells from Ca^{2+} transients (Gunter 2004). The mitochondrial role in apoptosis or programmed cell death has been recognized since the 1990s. Often, excessive mitochondrial Ca^{2+} uptake leads to induction of the mitochondrial permeability transition (MPT) by opening the permeability transition pore (PTP), and this can be central to the mitochondrion's role in controlling apoptosis or programmed cell death. The MPT will be discussed below.

Known Mechanisms of Mitochondrial Ca^{2+} Transport

The Uniporter

The mitochondria of all vertebrates and many other forms of animal life have been found to sequester large amounts of Ca^{2+}. The mechanism through which this uptake occurs was found through several different types of experiments to be a Ca^{2+} uniporter (Gunter 1990) or a mechanism which transports Ca^{2+} down its electrochemical gradient without coupling that transport to the transport of any other ion. The essential evidence was: (1) When Ca^{2+} uptake was energized by substrate oxidation, it could be inhibited by metabolic inhibitors but not by oligomycin, an inhibitor of the F_1F_0 ATP synthase, while if it was energized by ATP hydrolysis, it could be inhibited by oligomycin but not by metabolic inhibitors. This showed that uptake was being driven by the common denominator of these two energization schemes, the membrane potential ($\Delta\psi$). (2) Passive swelling experiments showed that the uptake was not mediated by exchange of Ca^{2+} for 2 K^+ or for 1 or 2 H^+ but seemed independent of the transport of other ions. (3) The membrane potential dependance of uptake showed that the thermodynamic driving force for this transport was the electrochemical Ca^{2+} gradient, as would be expected of a uniporter (Gunter 1990).

The Ca^{2+} uniporter transports Ca^{2+} and other ions in the selectivity series $Ca^{2+} > Sr^{2+} >> Mn^{2+} > Ba^{2+} >> La^{3+}$. It will also transport other lanthanides but very, very slowly. The uniporter shows a second-order concentration dependance and has a Hill coefficient close to 2 (Gunter 1990). The form of the $\Delta\psi$ dependance is consistent with the equations for diffusion down the electrochemical Ca^{2+} gradient. The combined concentration and membrane potential dependance is given by:

$$v = V_{max}\left(\frac{[Ca^{2+}]^2}{K_{0.5}^2 + [Ca^{2+}]^2}\right)\left(\frac{e^{\Delta\phi/2}(\Delta\phi/2)}{\sinh(\Delta\phi/2)}\right), \quad (1)$$

where $\Delta\phi = 2bF(\Delta\psi - \Delta\psi_0)/RT$. In this expression, V_{max}, $K_{0.5}$, b, and $\Delta\psi_0$ are fitting parameters while v is the velocity of transport, $\Delta\psi$ is the membrane potential, and F, R, and T are the Faraday constant, the gas constant, and the Kelvin temperature, respectively. The values of b and $\Delta\psi_0$ found for rat liver mitochondria were 1 and 91 mV, respectively (Gunter 1990). The values of $K_{0.5}$ found in the literature vary over a wide range undoubtedly because very rapid Ca^{2+} uptake decreases $\Delta\psi$. For that reason, it is likely that the actual value of $K_{0.5}$ is near 10 μM (Gunter 1990). The highest value for transport velocity reported in the literature is 1,750 nmol/mg/min, and even that value was probably decreased because of effects of Ca^{2+} uptake on $\Delta\psi$ (Gunter 1990). The uniporter's second-order dependance has been shown to be due to the existence of an activation site as well as a transport site. Ca^{2+} as well as other ions such as Pr^{3+} have been shown to activate the transport of the ions in the selectivity series. The most commonly used inhibitors of the uniporter are ruthenium red, Ru 360, a component of ruthenium red, which has about tenfold more potency, and lanthanides (Gunter 2009). Many drugs and other factors have been found to inhibit the uniporter (see Gunter 2009). Polyamines such as spermine and spermidine have been shown to increase Ca^{2+} transport via the uniporter at low Ca^{2+} concentrations (Gunter 1990).

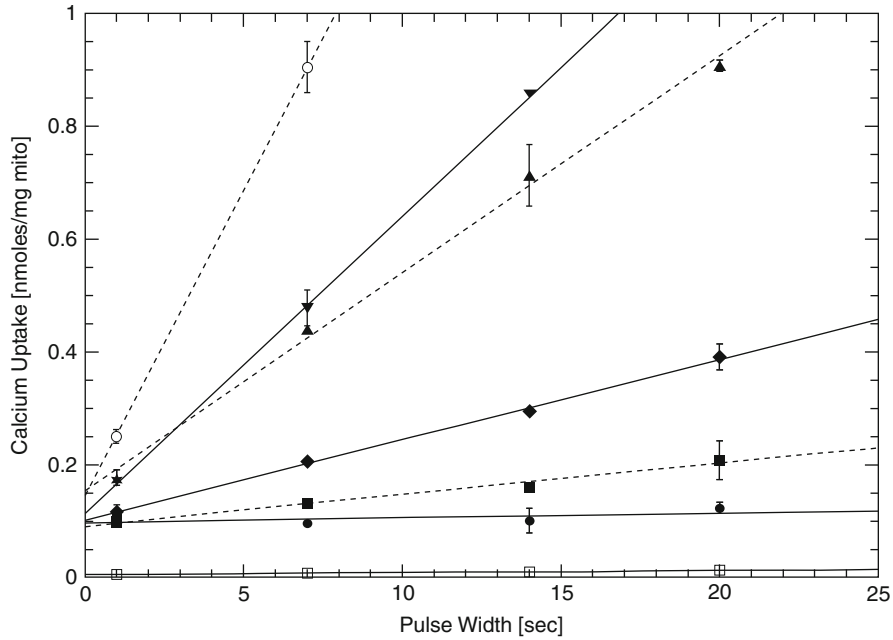
The Ca^{2+} conductance of the mitochondrial inner membrane has also been studied using electrophysiological techniques, and specific characteristics of conductance associated with the mitochondrial Ca^{2+} uniporter have been identified. It has been identified as a specific high conductance channel with more than one conductance state.

Recently, Perocchi et al. set up a clever strategy utilizing RNA interference (RNAi) to identify a component of the uniporter, which they call MICU1 (Perocchi 2010). The MitoCarta proteomic inventory of mouse mitochondrial proteins was used to identify 18 proteins which were found in the inner membrane and were expressed in vertebrates and kinetoplasmids, as is the uniporter but not in yeast. Of these, 13 proteins had RNAi agents already available. They quantified mitochondrial Ca^{2+} uptake using a Hela cell line expressing the bioluminescent Ca^{2+} indicator mitochondrial aequorin. By following the effects on Ca^{2+} uptake of the RNAi agents for these 13 mitochondrial peptides, they identified one of these proteins, MICU1, whose knockdown also knocked down Ca^{2+} uptake independently of effects on $\Delta\psi$, cell number, and oxidation rate. This work and a number of further controls identified this protein as being a component of the mitochondrial Ca^{2+} uniporter.

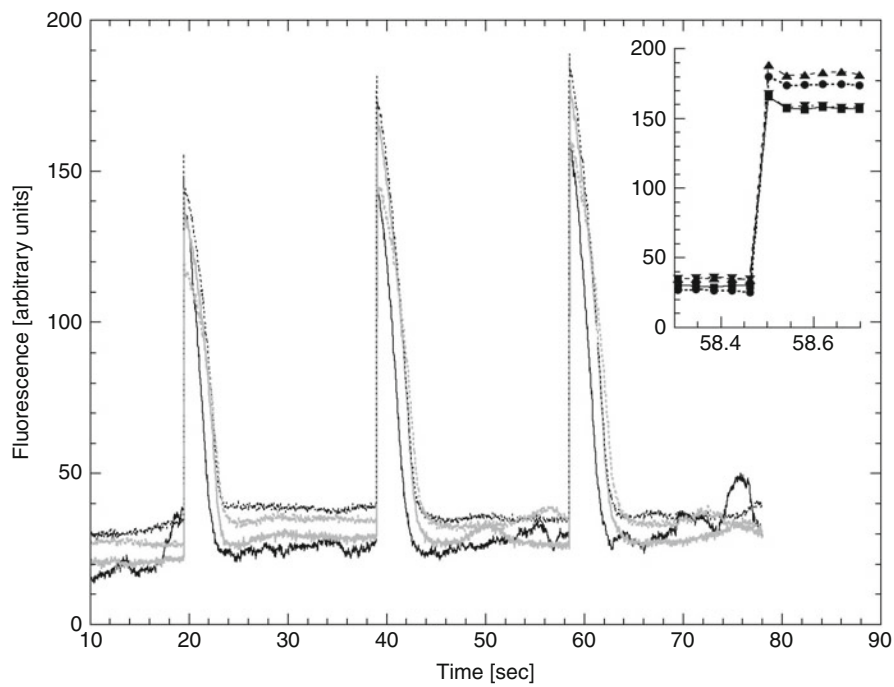
The RaM

Another mechanism of mitochondrial Ca^{2+} uptake was discovered using a system designed to generate transients of free Ca^{2+} concentration ($[Ca^{2+}]$) inside a fluorescence cuvette, which had the same appearance as transients seen in the cytosol of cells (Gunter 2004). The apparatus consisted of a computer-controlled pipetter used in conjunction with a fluorescence spectrometer. Buffered Ca^{2+} was injected into a cylindrical cuvette by the pipetter to initiate the transient. After an appropriate time, the transient was ended by injection of a strong Ca^{2+} chelator. This system was designed to explore how mitochondrial uptake of Ca^{2+} from transients like those seen in the cell cytosol might differ from that seen when Ca^{2+} was added to a suspension of isolated mitochondria. The results provided evidence both for uptake via the Ca^{2+} uniporter and also via another mechanism which sequestered a limited amount of Ca^{2+} very rapidly (Gunter 2004). Because of the speed of Ca^{2+} uptake, this second uptake mechanism was called the "rapid mode of uptake" or RaM. The initial evidence showed that fits to uniporter velocity at different $[Ca^{2+}]$ did not converge at zero uptake, as was expected, but at a significant uptake, indicating that some form of uptake had occurred before the first time point in each line of fit (see Fig. 1). Strong evidence for this mechanism was found in isolated rat liver and heart mitochondria. More limited data also suggested its existence in rat brain and avian heart (Gunter 2004). A different type of experiment using an even more rapid Ca^{2+} transient was set up to determine the uptake time of this RaM mechanism. This experiment used "caged Ca^{2+}," a UV labile Ca^{2+} chelator, which breaks up when exposed to UV and releases the Ca, to generate the rapid Ca^{2+} transients. In this set of experiments, rat liver mitochondria were loaded with the fluorescent Ca^{2+} indicator Flo 4 and bound to a cover slip. They were covered with medium containing the "caged Ca^{2+}" and then exposed to brief flashes of UV. By following Ca^{2+} uptake into individual mitochondria using these techniques, it was shown that complete RaM uptake of Ca^{2+} from the transients only required 25–30 ms (see Fig. 2) (Gunter 2004).

The RaM mechanisms in both liver and heart mitochondria sequester Ca^{2+} from a Ca^{2+} transient very rapidly. The RaM will also sequester Ca^{2+} from a $[Ca^{2+}]$ significantly below 200 nM, a much lower concentration than that necessary for uniporter uptake. RaM uptake into both types of mitochondria is inhibited by exposure of the mitochondria to $[Ca^{2+}]$ above 140–160 nM just prior to exposure to the Ca^{2+} transient. Ruthenium red (RR) inhibits Ca^{2+} uptake via the RaM in both liver and heart mitochondria but inhibits more strongly in liver mitochondria. RR inhibition of the RaM mechanism is not as strong as RR inhibition of the uniporter. Ca^{2+} uptake via the RaM is stopped by Ca^{2+} from the transient binding to an external inhibition site. This greatly limits the amount of Ca^{2+} that can be sequestered via the RaM mechanism. Ca^{2+} uptake via the RaM in both liver and heart is increased by the presence of physiological levels of spermine in the medium; however, it is increased much more in liver (by a factor of 6–10) than in heart (by a factor of 2). Around 1 mM, ATP or GTP increases RaM uptake in liver mitochondria by about a factor of 2 but not in heart. Ca^{2+} uptake via the RaM into heart mitochondria is significantly increased by [ADP] in the range around 20 μM and inhibited by 1 mM AMP,



Calcium and Mitochondrion, Fig. 1 Ca uptake vs pulse width as a function of pulse height for rat liver mitochondria. Pulses were made using 2.4 mM EGTA and 2.7 mM $^{45}CaCl_2$-buffered with HEDTA to a free calcium in the pulse medium of 1 μM. The experiment was run in HEPES-buffered 150 mM KCl (pH 7.2) with 5 mM K-succinate present with mitochondria at a concentration of 0.5 mg/ml. The pulse heights are as follows: □, 474 ± 14 nM with ruthenium red; ●, 165 ± 12 nM; ■, 307 ± 7 nM; ◆, 408 ± 8 nM; ▲, 567 ± 8 nM; ▼, 719 ± 2 nM; ○, 877 ± 9 nM. *Error bars* are 1 standard deviation (Reprinted from Gunter, T. E., Buntinas, L.,Sparagna, G. C., and Gunter, K. K. (1998) The Ca^{2+} Transport Mechanisms of Mitochondria and Ca^{2+} uptake from Physiological Type Ca^{2+} Transients. Biochim. Biophys. Acta 1366, 5–15 with permission from Elsevier Science)



Calcium and Mitochondrion, Fig. 2 Fluorescence response (Fluo 4) indicating intramitochondrial free Ca^{2+} concentration in four individual mitochondria during 3 UV pulses of 0.5 ms duration, which release Ca^{2+} from "caged Ca^{2+}." Ram uptake is complete in less than 40 ms, however, $[Ca^{2+}]_m$ remains high in the mitochondrial matrix for seconds. The inset shows a time-expanded view of uptake during the third pulse (Reprinted from Gunter, T. E., Yule, D. I., Gunter, K. K., Eliseev, R. A., and Salter, J. D. (2004) Calcium and Mitochndria. FEBS Lett. 567, 96–102 with permission from Elsevier Science)

however, not in liver mitochondria. Because the length of time that RaM transport is active prior to Ca^{2+} binding to the external inhibition site seems to decrease as transient $[Ca^{2+}]$ increases, the total amount of uptake per transient does not increase greatly as the transient amplitudes increase. After Ca^{2+} binding to the external Ca^{2+} inhibition site and cessation of Ca^{2+} uptake via the RaM, RaM Ca^{2+} uptake can be activated again by exposing the mitochondria to $[Ca^{2+}]$ below 100 nM. In liver mitochondria, RaM activity is completely restored in less than 1 s. In heart mitochondria, complete restoration takes over 1 min. However, this does not mean that there is no RaM uptake into heart mitochondria in much shorter times. RaM activity may be half recovered in 10–12 s but takes a much longer time to completely recover. Maximum Ca^{2+} uptake via the RaM mechanism from a single transient into liver mitochondria can be as high as 8 nmol/mg protein, but it is less in heart mitochondria (Gunter 2004). 8 nmol/mg protein is about twice the amount estimated by McCormack to be necessary to activate the intramitochondrial Ca^{2+}-dependent metabolic reactions that activate ATP production (Gunter 2004). Uptake per pulse via the RaM into heart mitochondria is less than that into liver mitochondria, but because the number of Ca^{2+} transients per min is so much larger in heart than in liver, the amount of uptake via the RaM per unit time may be similar.

Interesting results, probably related to those discussed on the RaM, were also reported using pig heart mitochondria. In these studies, Ca^{2+} uptake was measured by the intramitochondrial Ca^{2+} indicator Rhod-2, NADH by NADH fluorescence, and fast oxygen use by calibrating hemoglobin as an O_2 indicator (Gunter 2004). In this work, the time resolution of the transient generating system was around 100 ms. The results showed Ca^{2+} uptake in around 100 ms, increased NADH production within 200 ms, and rapid use of O_2 in oxidative phosphorylation within 270 ms. The maximum responses in terms of ATP production did not come from very large Ca^{2+} transients but from Ca^{2+} transients around of 560 nM, decreasing at both higher and lower concentrations (Gunter 2004). 560 nM is close to the average size for Ca^{2+} transients in the cytosol. This shows that rapid uptake of Ca^{2+} from transients of relatively low $[Ca^{2+}]$ can activate oxidative phosphorylation in heart mitochondria.

Ryanodine Receptor

A ryanodine receptor (RYR) has been reported to exist in the mitochondrial inner membrane of rat and mouse cardiac muscle cells. Like the RYRs present in the endoplasmic or sarcoplasmic reticutum (ER or SR) of many types of cells, these could represent another rapid mechanism of Ca^{2+} uptake (Gunter 2009). Unlike the RYR of the SR of cardiac muscle cells (RYR2), the one present in the mitochondrial membrane was of the RYR1 type. This receptor has not been found in the mitochondria of liver cells.

Evidence for a Ca^{2+}/H^+ Exchanger

A genome-wide high-throughput RNA interference screen was conducted by Jiang et al. to identify genes that control Ca^{2+} flux in drosophila S2 cells (Jiang 2009). Mitochondrially targeted ratiometric pericam was used at different wavelengths to monitor both Ca^{2+} (measuring the fluorescence change at 405 nm) and H^+ (measuring the fluorescence change at 488 nm) flux in these cells. Through this methodology, CG4589, the drosophila analog of the human gene Letm1, was identified as a gene strongly affecting both $[Ca^{2+}]_m$ and $[H^+]_m$. Prior to this time, Letm1 had been shown to be a K^+/H^+ exchanger involved in mitochondrial volume control (Jiang 2009) and to be a candidate gene for seizures in Wolf-Hirschhorn syndrome (Jiang 2009). At low $[Ca^{2+}]$ uptake, this mechanism appears to be faster than the uniporter (Jiang 2009). Following work in S2 cells, Hela cells, and reconstituted Letm1 in liposomes, the authors concluded that Letm1 is a $Ca^{2+}/1\ H^+$ exchanger, which takes up Ca^{2+} down to 50 nM but whose effects are not observed above 1 μM where only evidence for the uniporter is seen. The authors found that uptake via this mechanism increases the alkalinity of the mitochondrial matrix similar to uptake via the uniporter, and that knockdown of Letm1 increases the membrane potential significantly. They suggested that this mechanism generally functions as an uptake mechanism, as would be expected of a $Ca^{2+}/1\ H^+$ exchanger.

Efflux Mechanisms

Since Ca^{2+} can move passively down its electrochemical gradient when moving from the external space into the matrix space, it must be energetically uphill for it to move from the matrix to the external space.

Assuming that $[Ca^{2+}]_o = 100$ nM, $[Ca^{2+}]_i = 300$ nM, T = 25 ° C or 298°K and $\Delta\psi = 180$ mV, a mole of Ca^{2+} ions would lose

$$\begin{aligned} &2.303RT \log\left(\left[Ca^{2+}\right]_o / \left[Ca^{2+}\right]_i\right) + 2F\Delta\psi \\ &= 2.303RT \log(0.333) + 2F(0.18) \\ &= 32.01 \text{ kJ}, \end{aligned} \quad (2)$$

in moving from the external space into the matrix, and this same amount of energy must be supplied from some source before the Ca^{2+} can be transported back to the external space. Energy for Ca^{2+} efflux could be supplied either from the energy of cations moving inward via a passive exchanger, anions moving outward via a passive cotransporter, or from the mitochondrial ETC or ATP hydrolysis for an active mechanism. Experiments have identified two separate transport mechanisms which mediate efflux of Ca^{2+} from mitochondria. Both appear to be present in all vertebrate mitochondria in which this has been carefully studied; however, the Na^+-dependent mechanism is dominant in heart, brain, and many other types of mitochondria, while the Na^+-independent mechanism is dominant in liver and kidney mitochondria (Gunter 2009).

Na^+-Dependent Efflux

The work on the nature of this mechanism has suggested that it is a passive exchanger of Na^+ ions for Ca^{2+}(Gunter 1990). Li^+ may substitute for Na^+ on the mechanism and Sr^{2+} for Ca^{2+}; however, the mechanism does not transport Mn^{2+} (Gunter 1990). The kinetics for efflux via this mechanism have been fit to the form:

$$v = V_{max}\left(\frac{[Na^+]^2}{K_{0.5}^2 + [Na^+]^2}\right)\left(\frac{[Ca^{2+}]}{K_{Ca} + [Ca^{2+}]}\right), \quad (3)$$

for both heart and liver mitochondria (Gunter 1990). For heart mitochondria, V_{max} has been found to be 18 nmol/mg/min, K_{Ca} to be near 10 nmol/mg protein, and K_{Na} to be 7–12 mM (Gunter 1990). For liver mitochondria, V_{max} has been found to be 2.6 ± 0.5 nmol/mg/min, K_{Ca} to be 8.1 ± 1.4 nmol/mg protein, and K_{Na} to be 9.4 ± 0.6 mM (Gunter 1990). The V_{max} for this mechanism has been found to be around 30 nmole/mg/min for brain mitochondria making it even faster than in heart mitochondria. The Na^+ electrochemical gradient closely follows the proton electrochemical gradient because of a very fast Na^+/H^+ exchanger in the mitochondrial inner membrane (Gunter 2009). Therefore, the Na^+ electrochemical gradient is about the same as the proton electrochemical gradient ($2.303RT\Delta pH + F\Delta\psi$), and twice the energy of the Na^+ electrochemical gradient, at the values of $[Ca^{2+}]_o$, $[Ca^{2+}]_i$, $\Delta\psi$, and T used in the section above yields 46.15 kJ/mole. This suggests that this efflux mechanism could function as a $Ca^{2+}/2Na^+$ exchanger. However, it is not enough to show that it could function as this type of exchanger under normal conditions; it must be shown to function as this type of exchanger under the most extreme conditions, known as "null point conditions." In other words, the mechanism must be able to receive enough energy from two times the energy of the Na^+ gradient at the point where the Ca^{2+} gradient is as high as the mechanism will pump against. This is the point where the velocity of the efflux becomes zero because the energy of the Ca^{2+} concentration gradient has grown too large for it to pump outward at a higher Ca^{2+} gradient. This type of analysis was carried out by Baysal et al. (Gunter 2009) for this Na^+-dependent efflux mechanism, and it was found that there was not enough energy in twice the energy of the Na^+ electrochemical gradient to account for this efflux up to the null point. At the time the original work was published, it was believed that the Na^+-dependent efflux mechanism was nonelectrogenic; however, further work showed that the mechanism was actually electrogenic (Gunter 2009), and the simplest mechanism consistent with all of the data is a $Ca^{2+}/3Na^+$ exchanger.

CGP37157 and tetraphenylphosphonium (TTP) (Gunter 2009) are the most commonly used inhibitors of this mechanism; however, many drugs inhibit it (see Gunter 2009).

A protein previously identified as an nNa^+/Ca^{2+} exchanger (NCLX) has recently been associated with the Na^+-dependent Ca^{2+} efflux mechanism (Palty 2010). NCLX had already been shown to exchange Ca^{2+} for Li^+ as the mitochondrial Na^+-dependent Ca^{2+} efflux mechanism has been shown to do. Gold-labeled NCLX antibodies allowed the observation of gold particles on the inner membrane within the cristae of NCLX-overexpressing SHSY-5Y cells. Mitochondrial Na^+-dependent Ca^{2+} efflux was enhanced in NCLX-overexpressing cells, reduced by expression of siRNA effective in knockdown of

NCLX, and NCLX was inhibited by CGP-37157, which also inhibits mitochondrial Na^+-dependent efflux. Mitochondrial Na^+/Ca^{2+} exchange was blocked in cells expressing an inactive mutant form of NCLX.

Na^+-Independent Efflux

The Na^+-independent Ca^{2+} efflux mechanism transports not only Ca^{2+} but also Sr^{2+}, Mn^{2+}, and Ba^{2+} from the mitochondrial matrix to the external space (Gunter 1990). It is believed to be nonelectrogenic (Gunter 2009). Since it is very difficult to quantify transport of H^+ because its concentration is dominated by the water equilibrium ($H^+ + OH^- = H_2O$) and binding, the mechanism was believed by many to be a passive $Ca^{2+}/2\ H^+$ exchanger. However, the "null point" method, discussed in the section above, was developed to test whether or not this mechanism had enough energy from the inward transport of two protons to transport 1 Ca^{2+} ion outward. The results showed that enough energy was not available from the transport of two protons inward to transport a Ca^{2+} outward at the null point; therefore, the mechanism cannot be a passive $Ca^{2+}/2\ H^+$ exchanger (Gunter 2009)}, and there must be an additional source of energy available to this mechanism. There have been several publications suggesting that a passive $Ca^{2+}/2H^+$ exchanger could not explain the properties of this transport mechanism (see Gunter 1990). It has been found, for example, that that inhibitors of electron transport inhibit this mechanism independently of their effect on pH gradient (Gunter 1990). This suggests that it may receive some energy from the mitochondrial ETC and therefore be an active $Ca^{2+}/2H^+$ exchanger (Gunter 2009). This mechanism is inhibited by CN^-, low levels of uncouplers, and very high levels of both ruthenium red and tetraphenyl phosphonium (Gunter 1990).

The kinetics for this mechanism in liver mitochondria take the mathematical form:

$$v = V_{max}\left(\frac{[Ca^{2+}]^2 + a[Ca^{2+}]}{K_m^2 + [Ca^{2+}]^2 + 2a[Ca^{2+}]}\right), \qquad (4)$$

where V_{max}, K_m, and a are fitting parameters. The values of these parameters for liver mitochondria are $V_{max} = 1.2 \pm 0.1$ nmol/mg/min, $K_m = 8.4 \pm 0.6$ nmol/mg, and $a = 0.9 \pm 0.2$ nmol/mg (Gunter 1990).

The Mitochondrial Ca^{2+}-Induced Permeability Transition

When mitochondria are exposed to high $[Ca^{2+}]_m$ often in the presence of other inducers, a large pore can open in the mitochondrial inner membrane and dissipate the membrane potential and pH gradient. This is called the mitochondrial permeability transition (MPT), and the pore is called the permeability transition pore (PTP). This MPT is believed to occur in almost all types of mitochondria. Somewhat similar behavior has even been seen in yeast mitochondria. Pore opening causes rapid mitochondrial swelling. The PTP is sometimes classified as a Ca^{2+} efflux mechanism because it does cause Ca^{2+} to leave the matrix space; however, it has no specificity and rapidly transports all small ions and molecules with a molecular weight below around 1,500 Da. Cyclosporin A is a very potent inhibitor of the MPT, and it has been shown to function by binding to a mitochondrial protein, cyclophillin D. Induction of the MPT has been associated with binding of cyclophillin D to the pore protein, and knockout or knockdown of cyclophillin D decreases the probability of inducing the MPT. Pore opening can usually also be reversed by chelating the Ca^{2+}. While long-term opening of the PTP leads to cell death, transient opening of the pore or flickering has been reported and may have a physiological role. Pore opening is one of the ways in which mitochondria can control induction of apoptosis. Many workers believed that the adenine nucleotide translocase (ANT) was the core PTP protein; however, MPT induction has now also been seen when this protein is knocked out. Therefore, it has been suggested that the ANT only represents one of a set of proteins which can function as core PTP proteins. It is necessary to understand the primary characteristics of the MPT in order to understand the way mitochondria handle Ca^{2+}. Many good review articles are available on the MPT (see for example Halestrap 2010).

Questions and Issues

Fluorescent Ca^{2+} indicators led to the discovery that mitochondria were usually exposed to $[Ca^{2+}]_c$ of 85–100 nM except during Ca^{2+} transients when the

average cytosolic concentration might temporarily go above 1 μM. Calculations based on the known activity of the mitochondrial Ca^{2+} uniporter at that time suggested that the uniporter was not able to sequester sufficient Ca^{2+} from the observed Ca^{2+} transients to activate the process of oxidative phosphorylation. This dilemma led to the discovery of two independent pathways by which sufficient Ca^{2+} might be sequestered by mitochondria. One of these pathways led to the discovery of mitochondrial mechanisms which can sequester Ca^{2+} from lower [Ca^{2+}] sources such as the RaM, the ryanodine receptor, and the Ca^{2+}/1 H^+ exchanger, mechanisms with higher Ca^{2+} affinity than the uniporter. These were discussed above. There are numerous reports in the literature of Ca^{2+} uptake into mitochondria both very rapidly and also from $[Ca^{2+}]_c$ much lower than that which can be sequestered via the uniporter. Many questions still exist about the function of these mechanisms. The other pathway led to the discovery of high Ca^{2+} microdomains. Currently, it seems likely that mitochondria sequester Ca^{2+} through one or more of these higher affinity mechanisms and also through the uniporter acting within high [Ca^{2+}] microdomains.

The heart of the microdomain hypothesis was the early recognition that mitochondria are often found close to the Ca^{2+} release sites on sarcoplasmic or endoplasmic reticulum (SR or ER). Immediately following release of Ca^{2+} from stores within the SR or ER, the concentration of Ca^{2+} in the regions between the SR or ER and mitochondria can be high enough (over 50 μM) for a significant amount of uptake to occur into the mitochondria, and activation of ATP production can occur. Most of the work showing that this view is realistic was carried out on cultured cells using increasingly sophisticated fluorescent probes. Today, this generally means probes that are expressed genetically and are often ratiometric and targeted to the site of interest in the cell. Excellent reviews of this work can be found, and recent work has directly measured the [Ca^{2+}] in the microdomains using sophisticated fluorescence techniques (Shin 2010).

An obvious question is why are there redundant mechanisms providing intramitochondrial Ca^{2+} for activation of ATP production? First, having the necessary ATP supply is simply too important not to have some kind of backup (Balaban 2009). Second, in some cell types, there are plenty of mitochondria which are not exposed to microdomains, so the mechanisms are not necessarily redundant. One clear case is the mitochondria moving inside the neurites of nerve cells, which must produce considerable ATP.

Another important question about the mitochondrial Ca^{2+} transport system relates to the observation that the velocity of the uptake mechanisms seems much larger than that of the efflux mechanisms. This is not so much an issue with uptake via the RaM where the uptake per pulse is limited by Ca^{2+} binding to the external inhibition site, but it is an issue for uniporter uptake within high Ca^{2+} microdomains, where the amount of uptake could be considerable. The problem is that over the long term, total influx and total efflux must be about the same, otherwise, if influx dominates, as the kinetics seems to suggest, the mitochondria sequester more and more Ca^{2+} and probably undergo the MPT. Taking heart as a case in point, the largest transport velocity for the uniporter measured for heart mitochondria was 1,750 nmol/mg/min (Gunter 1990), and even this rate was probably decreased by decreases in $\Delta\psi$ caused by the rapid Ca^{2+} uptake. The portion of the heart beat cycle covered by the transient is significant, and the V_{max} for the Na^+-dependent efflux mechanism is only 18 nmol/mg/min (Gunter 1990). Furthermore, the only faster efflux mechanism that has been suggested is transient flickering of the PTP. Are the uptake velocities measured in isolated mitochondria faster than physiological?

Another question is whether the RaM is actually a high-conductance conformation of the uniporter complex, as has been suggested (Gunter 2004; Gunter 2009), or could it possible be the Ca^{2+}/1 H^+ exchanger? It does share with the exchanger the characteristic of being able to sequester Ca^{2+} from low [Ca^{2+}]. The former seems more likely, since the exchanger does not seem as fast as the RaM; however, it should also be kept in mind that the very fast transport per site calculations for the RaM (Gunter 2004), suggesting that it functioned as a simple pore, was estimated on the assumption that the number of RaM mechanisms was the same as that for the uniporter. It could also be a slower mechanism present in much higher numbers. More data is necessary to settle this question.

While we know quite a bit about how mitochondrial Ca^{2+} transporters function in isolated mitochondria,

and while we are learning much more about how they function in cells, many questions still remain unanswered. The advent of the use of molecular techniques in this important field should allow many of these questions to be answered.

Definition

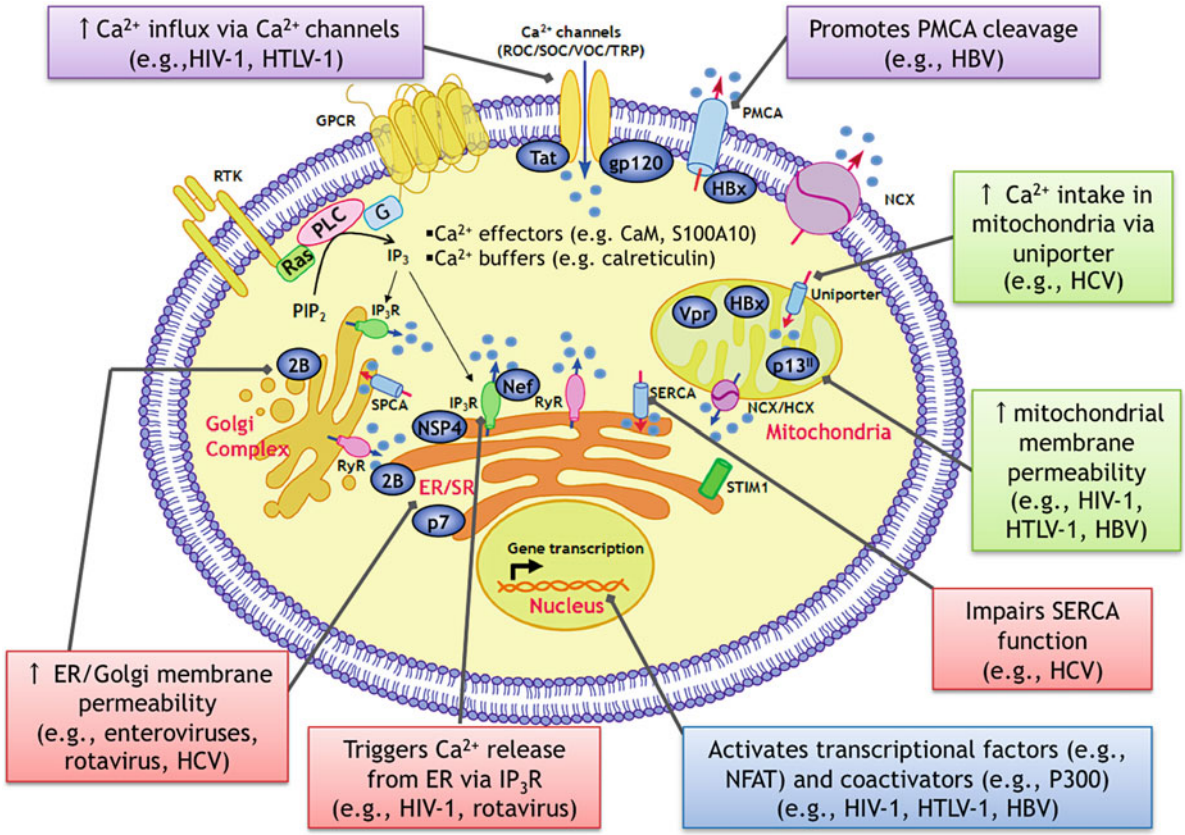
Calcium: A metallic element with atomic number of 20. Calcium is one of the most abundant elements on earth. It usually exists as oxidation form with an oxidation state of +2. Ca^{2+} plays essential roles to regulate a variety of biological events.

Apoptosis: A type of cell death featured by chromatin condensation, chromosomal DNA fragmentation, blebbing, and cell shrinkage. Unlike necrosis, apoptosis is a programmed cellular event to eliminate the cells without releasing the harmful materials.

Calcium homeostasis: A mechanism by which the cell or body regulates calcium concentration at the correct level.

Introduction

Ca^{2+}, a universal "signal for life and death," acts as an important intracellular messenger inside eukaryotic cells to regulate a wide range of cellular processes, including cell motility, secretion, muscle contraction, gene transcription, cell proliferation, and apoptosis (► Calcium in Biological Systems). The diversity of Ca^{2+} signals is achieved by the exquisite choreography of a repertoire of signaling components, including



Calcium and Viruses, Fig. 1 The choreography of Ca^{2+} signaling and examples of virus-induced disruption of Ca^{2+} homeostasis (Adapted with permission from reference Zhou et al. 2009). See text for details on the Ca^{2+} signaling components. Viral proteins are capable of perturbing the intracellular Ca^{2+} homeostasis by (1) modulating Ca^{2+} pumps and/or channels on the plasma membrane (e.g., Tat and gp120 of HIV-1, HBx of HBV), (2) triggering Ca^{2+} release from internal stores via IP_3R (e.g., NSP4 of rotavirus and Nef of HIV) or altering membrane permeability and pump activity of internal stores (e.g., 2B of coxsackievirus, p7 of HCV, and core protein of HCV), (3) disrupting mitochondrial membrane permeabilization or potential (e.g., Vpr of HIV-1, $p13^{II}$ of HTLV-1, core protein of HCV and HBx of HBV) and (4) activating Ca^{2+}-responsive transcriptional factors or coactivators, such as p300 (e.g., $p12^{I}$ of HTLV-1 and Vpr of HIV-1) in the nucleus. Additionally, a variety of viral proteins interact with important cellular CaBPs, such as CaM, S100A10, and calreticulin, to remodel the Ca^{2+} signaling network. Calcium ions are shown as *blue dots*

receptors, ion channels, pumps, exchangers, Ca^{2+} buffers, Ca^{2+} effectors, Ca^{2+}-sensitive enzymes, and transcriptional factors that reside in distinct cellular compartments (Berridge et al. 2003). The Ca^{2+} signaling system undergoes constant remodeling to meet the specific spatiotemporal requirements in a flexible yet precise manner. This flexibility, on one hand, allows the host cell to adjust to various stimuli, such as viral infection. On the other hand, viruses may take advantage of the universal Ca^{2+} signal to create a tailored cellular environment to meet their own demands (Fig. 1).

Viruses choose Ca^{2+}, instead of other metal ions (e.g., Mg^{2+}, K^{+}, Na^{+}), to benefit their own life cycles because of the irreplaceable and important physiochemical and physiological nature of Ca^{2+}: First, Ca^{2+} has been chosen by nature through evolution as a versatile second messenger to regulate almost all cellular events. Evolving as intimate intracellular parasites that are adept at hijacking the host cell machinery, viruses can conveniently target Ca^{2+} signals to affect a diverse range of downstream effectors and pathways to maximize virus replication, while still

achieving their coexistence with host cells. Second, a >10,000-fold gradient of Ca^{2+} is maintained across the plasma membrane, which is substantially larger than the dynamic range of monovalent K^+ and Na^+ (<100-fold) and Mg^{2+} (<10-fold) in mammalian cells. This enables the viruses to easily manipulate Ca^{2+} gradients between membranous compartments to transduce information encoded by any particular spatiotemporal Ca^{2+} pattern. Third, acute change of K^+ and Na^+ at the millimolar range is more likely to cause osmotic shock and/or to abruptly disrupt membrane potential than the change of Ca^{2+} (at nM or μM level), thereby circumventing these detrimental effects on host cells.

Viruses appropriate or hijack the Ca^{2+} signaling network in various ways that favor virus entry, virus replication, virion assembly, maturation, and/or release (Zhou et al. 2009; Chami et al. 2006). The common scenarios encountered during virus – Ca^{2+} interplays, as summarized and briefly exemplified in the following paragraphs, include the following:

- Viral proteins disrupt Ca^{2+} homeostasis by altering membrane permeability and/or manipulating key components of the Ca^{2+}-signaling toolkit.
- Ca^{2+} directly binds to viral proteins to maintain structural integrity or functionality.
- Critical virus-host interactions depend on cellular Ca^{2+}-regulated proteins or pathways.

Disruption of Calcium Homeostasis During Viral Infection

The Ca^{2+} concentration in different compartments of the cell is strictly maintained (Fig. 1) (Putney 1998). The cellular ionized Ca^{2+} gradient approximately follows the order of extracellular space ($[Ca^{2+}]_o$: $\sim 10^{-3}$ M) > endoplasmic reticulum/sarcoplasmic reticulum (ER/SR) ($[Ca^{2+}]_{ER}$: $\sim 10^{-4}$ M) > cytosol ($[Ca^{2+}]_{CYT}$: $\sim 10^{-7}$ M to $\sim 10^{-5}$ M). Following signal stimulation or alteration in the membrane potential, $[Ca^{2+}]_{CYT}$ may be elevated by 100-fold from 10^{-7} M to 10^{-5} M. This is made possible by Ca^{2+} from two major sources: the extracellular space and the internal Ca^{2+} stores (mainly ER or SR). Extracellular Ca^{2+}, sensed by the extracellular Ca^{2+}-sensing receptor, is believed to maintain the long-term Ca^{2+} homeostasis by replenishing the internal calcium stores, whereas the internal calcium stores are directly responsible for the changes in $[Ca^{2+}]_{CYT}$ through the activity of two major ER-resident Ca^{2+} release channels, e.g., the ryanodine (RyR) receptor and the inositol 1,4,5-triphosphate (IP3) receptor. At the resting state, $[Ca^{2+}]_{CYT}$ is maintained at submicromolar range by extruding excessive Ca^{2+} outside of the plasma membrane via plasma membrane Ca^{2+}-ATPase (PMCA; ▶ Calcium ATPases) and Na^+/Ca^{2+} exchanger (NCX) or by pumping Ca^{2+} back into internal stores through sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) (▶ Calcium ATPases), secretory pathway Ca^{2+}-ATPase, and the mitochondrial uniporter. The Ca^{2+} signals are delivered by affecting the activity of Ca^{2+} buffers, Ca^{2+} effectors, and Ca^{2+}-regulated enzymes (▶ Calcium-Binding Proteins, Overview). The signals can also have "long-term" effects by modulating the activity of several Ca^{2+}-responsive transcriptional factors including nuclear factor of activated T cells (NFAT), cyclic AMP response element-binding proteins (CREB), and downstream regulatory element modulator (DREAM).

How Does the Altered Ca^{2+} Signaling Benefit the Life Cycle of a Virus?

Most often, albeit not always, viral infection tends to cause an increase in $[Ca^{2+}]_{CYT}$ by using strategies outlined below. The modest increase of $[Ca^{2+}]_{CYT}$ may benefit the life cycle of viruses in the following ways:

First, a modestly elevated $[Ca^{2+}]_{CYT}$ would activate or accelerate a number of Ca^{2+}-dependent enzymatic processes in the cytosol, as well as Ca^{2+}-sensitive transcriptional factors (e.g., NFAT), to promote virus replication or to establish persistent infection. The Ca^{2+} released from ER can be readily uptaken by mitochondria. A modest increase in mitochondrial matrix Ca^{2+} may activate Ca^{2+}-dependent Krebs cycle dehydrogenases and increase production of ATP, thereby meeting a higher demand for energy to aid virus replication.

Second, the decrease of Ca^{2+} in ER and Golgi complex disrupt the protein trafficking and sorting pathways, which effectively perturb the host defense mechanism against viral infection by alleviating host antiviral immune responses and escaping premature clearance by the host. Intracellular accumulation of ER or Golgi-derived secretory vesicles, where viral RNA replication takes place for some RNA viruses

(e.g., enteroviruses as discussed below), creates a microcosmic environment favoring viral replication.

Third, Ca^{2+}-flux between ER and mitochondria plays a critical role in determining the fate of host cells when exposed to apoptotic stimuli, such as viral infections. Modulation of ER-mitochondria Ca^{2+} coupling may either prevent apoptosis or induce apoptosis, depending on the stages of the viral life cycle and types of viruses. Apoptosis is usually elicited as an innate defense mechanism to counteract viral infection and control virus production. In general, an anti-apoptotic strategy is employed by the viral to prevent host immune clearance and promote virus replication in the early or middle stage of infection. Meanwhile, a viral infection may induce apoptosis to aid egress of virions to the outside and dissemination of progeny at a later stage.

The dysregulated Ca^{2+} signaling scenario observed during enterovirus infection can probably best illustrate some of the points outlined above. A typical enterovirus contains a single-stranded, plus-sense RNA genome encoded by four structural proteins (VP1–4) and ten nonstructural proteins ($2A^{pro}$, 2B, 2C, 3A, 3B, $3C^{pro}$, $3D^{pol}$, 2BC, 3AB, and $3CD^{pro}$) that are produced by a proteolytic processing cascade from a single translational precursor. Among those, the 2B protein can induce substantial decrease (~40%) of Ca^{2+} in ER and Golgi complex by direct permeabilization of the ER/Golgi membrane. Such dramatic change in intracellular Ca^{2+} serves two purposes (van Kuppeveld et al. 2005): (a) It inhibits intracellular protein trafficking pathways, thus favoring virus replication and downregulating host antiviral immune response. A reduced intravesicular Ca^{2+} level would result in the inhibition of vesicular protein transport and accumulation of ER/Golgi-derived vesicles, where the replication complex forms and viral RNA replication takes place. (b) It exerts an anti-apoptotic activity on infected cells. Upon enterovirus entry, the cellular apoptotic process is immediately triggered as an innate defense mechanism in response to infection, but is abruptly suppressed during the middle stage of infection. The apoptotic process resumes at late stage after viral replication. The perturbation of Ca^{2+} homeostasis at 2–4 hours post infection (hpi) coincides with the inhibition of the apoptotic cell response triggered at about 2 hpi. Thus, the middle-stage interruption of apoptosis is linked to downregulated ER-mitochondrial Ca^{2+} fluxes that prevent cytotoxic Ca^{2+} overloading in mitochondria (▶ Calcium and Mitochondria). Overall, 2B-induced reduction of Ca^{2+} in ER/Golgi provides the virus a favorable cellular environment and optimal time window for viral RNA and protein synthesis. The exquisite synchronization of rise in $[Ca^{2+}]_{CYT}$ and anti-apoptotic activity allows virus particles to complete assembly before cell lysis.

What Strategies Do Viruses Devise to Alter Intracellular Ca^{2+} Signaling?

Although different viruses use a wide range of ways to perturb the cellular Ca^{2+}-signaling network, one still can discern mechanistic similarity and find common themes shared among viruses (Fig. 1) (Zhou et al. 2009).

Modulation of Ca^{2+} Channels or Pumps in the Plasma Membrane

The plasma membrane provides a solid boundary between the inside and outside of the cell. Ionic concentration gradients are maintained across the plasma membrane by a number of ion channels, pumps, and exchangers.

In excitable cells (e.g., muscle and neuronal cells), any external stimulus that depolarizes the plasma membrane is capable of activating voltage-gated or receptor-operated Ca^{2+} channels (VOC/ROC) and eliciting swift Ca^{2+} flux into cytoplasm. During a viral infection, these Ca^{2+} entry components may become the immediate targets of attack. For instance, two viral proteins encoded by the genome of human immunodeficiency virus 1 (HIV-1), the glycoprotein gp120 and the transcriptional transactivator Tat, are able to elicit the elevation of $[Ca^{2+}]_{CYT}$ in mammalian cells. The increase in $[Ca^{2+}]_{CYT}$ is attributable to the activation of L-type voltage-gated Ca^{2+} channels and *N*-methyl-D-aspartate (NMDA) receptors. External application of recombinant gp120 to fetal neurons and astrocytes causes a dose-dependent rise of $[Ca^{2+}]_{CYT}$ up to ~2 μM and induces neurotoxicity in these cells. Similarly, Tat-induced dysregulation of Ca^{2+} homeostasis leads to neurotoxicity and contributes to HIV-related dementia.

In non-excitable cells (e.g., epithelial cells and lymphocytes) that generally do not possess VOC/ROC, the depletion of Ca^{2+} stores often triggers sustained Ca^{2+} entry across the plasma membrane via store-operated Ca^{2+} channels (SOC). $p12^{I}$ encoded by the human

T-lymphotropic virus 1 (HTLV-1) and the core protein encoded by hepatitis C virus (HCV) are among a handful of viral proteins capable of activating SOC channels in T lymphocytes and/or Jurkat T cells. A sustained elevation of $[Ca^{2+}]_{CYT}$ and accompanying high-frequency cytosolic Ca^{2+} oscillation specifically activate NFAT, a transcriptional factor that initiates a highly coordinated choreography of gene expression. Activation of NFAT exerts long-term effects on cells of the immune system by inducing gene expression (e.g., IL-2 and Bcl-2) and further promoting lymphocyte activation and survival to support viral infection.

PMCA and NCX, as the major Ca^{2+} extrusion apparatus, can transport the Ca^{2+} outside of the cell to maintain Ca^{2+} concentration gradient across the plasma membrane. Viruses can directly or indirectly modulate the activity of these components to induce changes in cytosolic Ca^{2+} concentration. For example, overexpression of the hepatitis B virus X protein (HBx) has been shown to stimulate caspase-3-dependent cleavage of PMCA. The decrease in PMCA activity, along with the HBx-mediated release of Ca^{2+} from mitochondria (as discussed below), leads to a net increase in $[Ca^{2+}]_{CYT}$ that enhances HBV DNA replication and increases HBV core assembly. In addition, it activates or promotes Ca^{2+}-responsive pathways that regulate cell survival, apoptosis, and proliferation.

Modulation of ER-Resident Ca^{2+} Release Channels and Pumps

Ca^{2+} immobilization from internal stores (mainly ER) is another important contributor to the intracellular Ca^{2+} increase. IP_3R and RyR are two of the central players in switching on/off Ca^{2+} release from internal stores. The engagement of receptors on lymphocytes or agonist binding to cell surface receptors activates phospholipase C-γ (PLC-γ), which hydrolyzes phosphatidylinositol-4,5-biphosphate (PIP_2) to produce inositol-1,4,5-triphosphate (IP_3). IP_3 activates IP_3R and triggers Ca^{2+} release from ER. The replenishing of Ca^{2+} stores is achieved by Ca^{2+} influx across plasma membrane through SOC channels and pumping of cytosolic Ca^{2+} back to the ER lumen via the SERCA pump. By virtue of ER's roles as a hub in coordinating the ebb and flow of intracellular Ca^{2+}, viruses containing either RNA or DNA genomes have evolved astute means to manipulate IP_3R-mediated Ca^{2+} release (e.g., HIV-1 and rotavirus) or to modulate the activity of SERCA (e.g., HCV).

Nef is an accessory protein encoded by HIV-1 that plays important roles in the pathogenesis of acquired immunodeficiency syndrome (AIDS). Overexpression of Nef could induce a cytosolic Ca^{2+} increase in Jurkat T cells possibly through the interaction with IP_3R and subsequently promote the T cell receptor-independent activation of the NFAT pathway, without notable increase in PLCγ-catalyzed production of IP_3. The activated NFAT further promotes viral gene transcription and replication. Given the observation that a Src-like protein-tyrosine kinase (PTK) coimmunoprecipitates with both Nef and IP_3R, Nef might modulate the IP_3R activity via its interaction with the Src-like PTK.

The double-stranded RNA virus, rotavirus, is the major etiological agent of viral diarrhea in young children. The rotavirus nonstructural glycoprotein NSP4, a multifunctional enterotoxin, has been shown to induce Ca^{2+} release from ER in infected human epithelial cells through a PLC-dependent pathway. Exogenously applied NSP4 can cause diarrhea in rodent pups and increases cytosolic Ca^{2+} concentration via the activation of PLC and the resultant ER Ca^{2+} depletion through IP_3R. In addition, endogenous NSP4 can also be secreted from the apical surface of polarized epithelial cells or released outside after cell lysis, thus exerting exogenous action on neighboring noninfected cells. Several lines of evidence suggest that the NSP4-induced Ca^{2+} release from ER is linked to the stimulation of chloride secretion and diarrhea.

HCV is the major pathogen responsible for non-A non-B hepatitis in humans. It belongs to a family of positive-polarity, single-strand RNA viruses. Transient and stable expression of the HCV core protein in Huh7 cells, a human liver carcinoma line used to study HCV replication, induces ER Ca^{2+} depletion by impairing the function of the SERCA pump. The inhibition of SERCA activity is possibly caused by overexpression of inducible nitric oxide synthase and calreticulin (▶ Calnexin and Calreticulin) in response to HCV core protein–induced ER stress. HCV core protein–induced ER stress further activates the pro-apoptotic Bcl2-associated X protein, which induces opening of the mitochondrial voltage-dependent anion channel, cytochrome *c* release, apoptosis, and eventually liver damage.

ER/Golgi Membrane Permeabilization Induced by Pore-Forming Viral Proteins

Aside from altering the ER Ca^{2+} store level via ER Ca^{2+} release channels as described above, some viruses exploit alternative ways to adjust Ca^{2+} store filling status by directly forming pores on membrane or disrupting membrane permeability of Ca^{2+} stores. This approach is best employed by enteroviruses, HCV, and rotavirus.

The enterovirus 2B protein is characteristic of viroporin, a group of integral membrane proteins containing amphipathic α-helices and capable of forming pores on membrane to aid virion production and dissemination. 2B has been demonstrated to multimerize and form hydrophilic pore when incorporated into liposomes with an estimated pore size of 6 Å. The aqueous pores on membrane allow solutes with molecular mass <1 kDa to pass through freely. The 2B protein of enteroviruses has been shown to directly cause decrease of Ca^{2+} concentrations in subcellular compartments, such as Golgi complex and ER by forming pores on the membranes of these organelles and subsequently causing Ca^{2+} efflux from the lumen of these organelles.

The HCV viroporin p7, a 63-residue hydrophobic protein found in the ER membrane, forms hexamers on artificial lipid membranes and functions like a Ca^{2+} ion channel. These findings suggest that p7 might be responsible for the flow of Ca^{2+} from ER to the cytoplasm in HCV-infected cells, which is crucial for the assembly and release of infectious HCV virions.

The rotavirus NSP4 is primarily embedded in the ER membrane of rotavirus-infected cells and exhibits viroporin activity. Endogenously expressed NSP4 in Sf9 insect cells and HEK293T cells can alter the ER membrane permeability and cause a sustained increase of cytosolic Ca^{2+} concentration that is independent of the aforementioned PLC pathway. The membrane destabilization activity of NSP4 is mapped to residues 47 to 90, which share a structural similarity to those of the enterovirus 2B protein. Elevation of $[Ca^{2+}]_{CYT}$ may facilitate rotavirus replication and assembly of infectious virions (Ruiz et al. 2000).

Disruption of Mitochondrial Membrane Permeabilization and/or Potential

The multifunctional mitochondrion is an integral part of the internal Ca^{2+} pool and functions as a hub of energy production and apoptosis (▶ Calcium and Mitochondria). In mitochondria, Ca^{2+} can easily pass through outer mitochondrial membrane (OMM) pores and cross the inner mitochondrial membrane (IMM) through membrane-embedded channels and transporters. The resting inner membrane potential of the mitochondrion ($\Delta\psi_m$) is maintained at −150 to −180 mV by actively pumping proton across the inner membrane. Disruption of membrane permeability and dissipation of $\Delta\psi_m$ may lead to ATP depletion and cell death. Excess Ca^{2+} in mitochondrial matrix is pro-apoptotic since it activates the opening of PTP and results in loss of $\Delta\psi_m$ and release of cytochrome *c*. In contrast, actions that reduce matrix Ca^{2+} (e.g., downregulation of ER/mitochondria Ca^{2+} flux) may protect host cells from apoptosis (Rizzuto et al. 2004). During viral infection, a number of viral proteins can target mitochondria and exert either pro-apoptotic or anti-apoptotic action by altering mitochondrial Ca^{2+} signaling in host cells, depending on the stages of the viral life cycle.

Mitochondrial Ca^{2+} uptake is mediated by the mitochondrial voltage-dependent anion channel (VDAC) across OMM and the Ca^{2+} uniporter of IMM. The HBx protein encoded by HBV may exert pro-apoptotic effects on infected cells by modulating the activity of VDAC, whereas the HCV core protein does so by enhancing the activity of Ca^{2+} uniporter.

Ca^{2+} exits mitochondria through the opening of a nonselective high-conductance channel permeability transition pore (PTP) in IMM and the Na^+/Ca^{2+} exchanger. The IMM protein adenine nucleotide translocator (ANT) also contributes to the permeability transition. The well-characterized pro-apoptotic reagent, HIV-1 viral protein R (Vpr), may tightly interact with ANT and induce mitochondrial membrane depolarization, Ca^{2+} leakage, and cytochrome c release from mitochondria. The C-terminal fragment of Vpr (residues 52–96), along with ANT, has been shown to form ion channels in synthetic membrane and control mitochondrial membrane permeability. Another viral protein, the HTLV-1 accessory protein $p13^{II}$, is a mitochondrial protein primarily located at IMM. $p13^{II}$ exhibits viroporin activity and may cause welling and depolarization of mitochondria by increasing inner membrane permeability to cations, such as Ca^{2+}, Na^+, and K^+. Such changes are responsible for promoting ceramide-induced or Fas ligand–induced apoptosis in infected T lymphocytes.

In summary, different viral proteins could disrupt intracellular Ca^{2+} homeostasis by targeting the same Ca^{2+} signaling components. Alternatively, to make full use of the limited viral gene products, a single viral protein may sometimes manipulate multiple Ca^{2+} signaling mechanisms by targeting different Ca^{2+}-modulated apparatus.

Ca^{2+}-Modulated Viral Proteins

Ca^{2+}-binding sites in viral proteins can be divided, although oversimplified, into two types: discontinuous and continuous ones (▶ Calcium-Binding Protein Site Types). While both types of Ca^{2+}-binding sites have been found in the proteins of diverse virus families, more is known about virus proteins with discontinuous binding sites. The majority of known viral Ca^{2+}-binding proteins (CaBPs) are structural proteins, including both coat and envelope proteins. In addition, discontinuous sites are found in the envelope-associated neuraminidase protein of influenza B virus and the nonstructural NSP4 protein of rotaviruses.

Coat Proteins

Ca^{2+} binding to coat proteins is required to maintain the structural integrity and/or the proper assembly and disassembly of virions. Viruses with both helical and icosahedral symmetry are represented in this category. Tobacco mosaic virus, a typical helical virus, has been shown to bind Ca^{2+} with apparent affinities <100 μM. With the extracellular Ca^{2+} concentration at mM range, such an affinity would ensure a tight binding of Ca^{2+} to capsid proteins.

Among viruses with icosahedral symmetry, the numbers of bound Ca^{2+} ions and coordinating geometry of the Ca^{2+}-binding sites differ in that the Ca^{2+} ions may be situated between the interacting interfaces of capsid subunits (Fig. 2a) or sit on the symmetric threefold or fivefold axis (Fig. 2b). For example, the virion of cocksfoot mottle virus (CfMV), a plant virus with a single-stranded, positive-sense RNA genome, has an icosahedral capsid composed of 180 copies of the coat protein monomer assembled in $T = 3$ quasi-equivalent symmetry. Each monomer has a jelly-roll β-sandwich topology and can assume one of three slightly different conformations, denoted as quasi-equivalent A, B, and C subunits. These subunits are assembled into asymmetric units which then coalesce to form the icosahedral capsid. Three Ca^{2+} ions, each incorporated between the interacting surfaces of subunits (A–B, B–C, and A–C), function as reusable "glue" to stick adjacent subunits together and stabilize the capsid. Each Ca^{2+} ion is coordinated by two residues from one subunit and three residues from the other interacting subunit (Fig. 2a). Such Ca^{2+}-binding sites seem to adopt an octahedral geometry with only five ligands. A similar scenario is seen in the trimeric VP7 of rotaviruses, but it contains two Ca^{2+} ions at each subunit interface (Aoki et al. 2009). The withdrawal of Ca^{2+} during virus entry is speculated to trigger the uncoating of rotavirus in endosome.

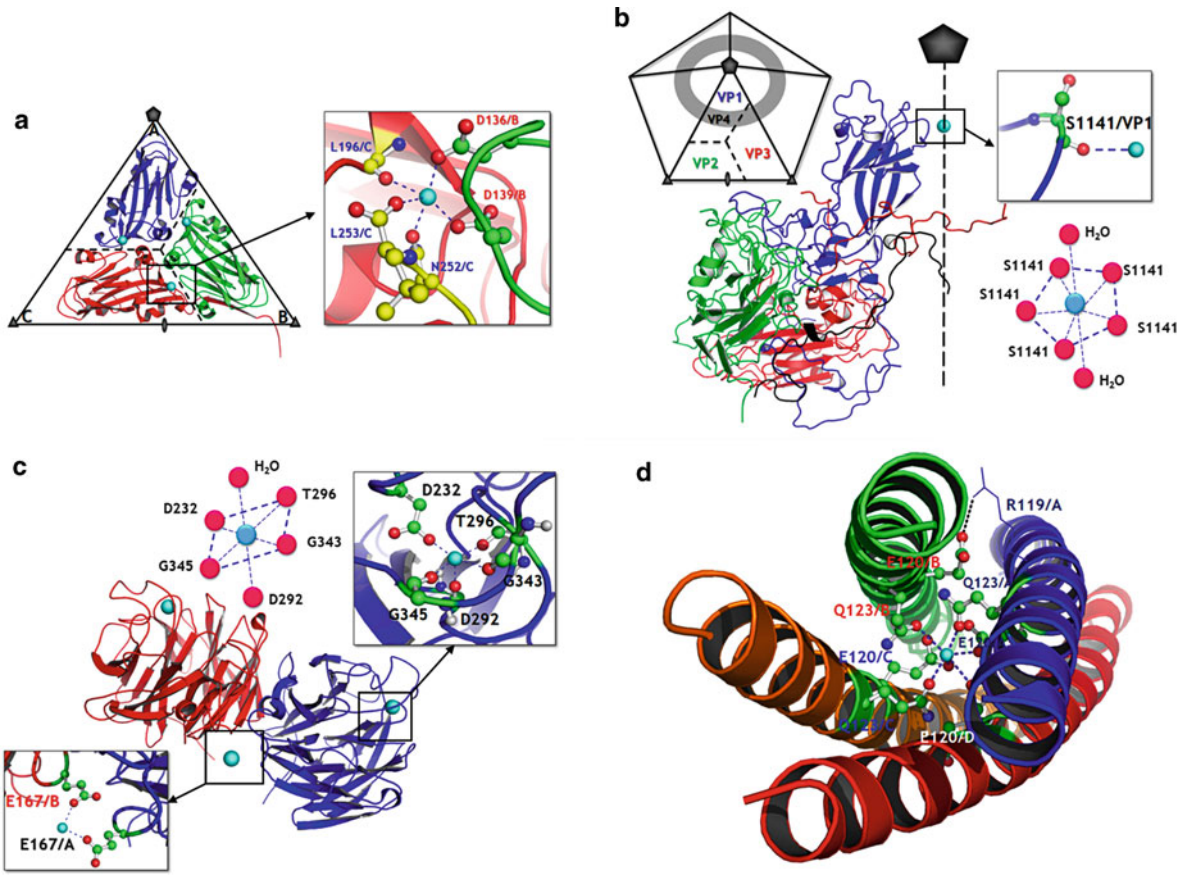
Another example of the incorporation of Ca^{2+} into an icosahedral virus particle is the human rhinoviruses. In the virions of human rhinovirus 1A (HRV1A), HRV3, and HRV14, Ca^{2+} ions are located at the fivefold axis of symmetry (Fig. 2b). With two additional oxygen atoms from water molecules above or below the metal ion as coordinating ligands, the Ca^{2+}-binding pocket forms a pentagonal bipyramidal geometry.

Envelope Proteins

An example of Ca^{2+} binding by a virion envelope protein is the neuraminidase of ortho- and paramyxoviruses, both families of negative-polarity, single-stranded RNA viruses of animals. The neuraminidase catalyzes the cleavage of the glycosidic linkages between the terminal siliac acid residues and the body of carbohydrate moieties on the surface of infected cells. This activity is required for the release of virus from the cell surface. Two distinct Ca^{2+}-binding sites are found in the neuraminidase. One high-affinity site (Fig. 2c) is close to the active site and adopts an octahedral geometry with five coordinating protein ligands and one molecule of water. This Ca^{2+}-binding site is conserved among influenza A virus, influenza B virus, and the parainfluenza viruses. The other site is a relatively low-affinity site, located on the fourfold axis of the tetrameric neuraminidase of the influenza B viruses. The high-affinity Ca^{2+}-binding site is needed for the thermostability and optimal activity of the enzyme, whereas the low-affinity site has been postulated to hold the tetramer together.

Nonstructural Proteins

The rotavirus NSP4 is required for the budding of immature viral particle into the ER lumen and plays



Calcium and Viruses, Fig. 2 Examples of Ca^{2+}-modulated viral proteins (Adapted with permission from reference Zhou et al. 2009). (**a**) 3D representation of the icosahedral asymmetric unit of the cocksfoot mottle virus capsid and the location of the incorporated Ca^{2+} ions (PDB entry: 1ng0). The assembling unit is formed by three subunits, A (*blue*), B (*green*), and C (*red*), that are chemically identical but slightly different in conformational arrangement. Ca^{2+}, situated between the interfaces of neighboring subunits (A–B, A–C, or B–C), is coordinated by oxygen atoms from the side chains of D136 and D139 in one subunit and oxygen atoms from the main chain of L196, the side chain of N252, and the C-terminal carboxyl group of L253 in the other neighboring subunit (*enlarged area*). The *solid pentagon*, *triangle*, and *oval* represent five-, three-, and two-fold axes of the icosahedron. (**b**) Ca^{2+} ion located on the fivefold axis of the capsid of human rhinovirus 3 (HRV3) (PDB entry: 1rhi). The icosahedral capsid of HRV3 is composed of 60 copies of each of the four capsid proteins VP1 (*blue*), VP2 (*green*), VP3 (*red*), and VP4 (*black*). VP1, VP2, and VP3 are exposed to the external surface of the viral particle, whereas VP4 lies in the internal surface. A Ca^{2+} ion is found situated on the fivefold axis of the capsid and coordinated by five oxygen atoms from the main chain carbonyl group of the fivefold symmetry-related S1141 on VP1 (*enlarged area*). With two additional oxygen atoms from water molecules above or below the metal ion as coordinating ligands, the Ca^{2+}-binding pocket forms a pentagonal bipyramidal geometry. (**c**) The 3D structure of neuraminidase of influenza B virus (PDB entry: 1nsb). The cartoon only represents half of the tetrameric form of this enzyme. Three Ca^{2+}-binding sites are found in two identical subunits, A (*blue*) and B (*red*). Each subunit contains one octahedral Ca^{2+}-binding site (*upper panel*). Another site (*lower panel*), coordinated by a fourfold symmetry-related residue, holds the oligomer together. (**d**) The core Ca^{2+}-binding pocket in the oligomerization domain (aa. 95–137) of NSP4 from rotavirus (PDB entry: 2o1j). The domain self-assembles into a paralleled tetrameric coiled coil. Chains A, B, C, and D are shown in *blue*, *green*, *orange*, and *red*, respectively. The Ca^{2+} ion is coordinated by six oxygen atoms from the side chains of Q123 on chains A–D, as well as the side chains of E120 on chains B and D. Calcium ions are shown as *cyan spheres*

a central role in the morphogenesis of rotaviruses, even though it is not incorporated into the virus particle. The rotavirus NSP4 contains a core Ca^{2+}-binding site when it oligomerizes into a functional homo-tetramer. The Ca^{2+} ion is coordinated by the side chains of several residues from the four identical polypeptides within the tetramer (Fig. 2d). Ca^{2+}-binding at this site appears to stabilize the NSP4 tetramer.

In contrast to the relative abundance of discontinuous Ca^{2+} sites, the literature reports on continuous viral Ca^{2+}-binding sites are scarce. The prototype continuous Ca^{2+}-binding site is the EF-hand and EF-hand-like motifs (Zhou et al. 2006). The EF-hand Ca^{2+}-binding motif contains a helix-loop-helix topology, much like the spread thumb and forefinger of the human hand, in which the Ca^{2+} ions are coordinated ligands within the loop. Only four such cases can be found, namely, the transmembrane protein gp 41 of HIV-1, VP7 of rotavirus, VP1 of polyomavirus, and the protease domain of rubella virus (RUBV). Among these, the EF-hand motif within the RUBV nonstructural protease is the most well characterized (Zhou et al. 2007). The Ca^{2+}-binding affinity of this putative EF-hand motif was determined to be ~200–300 μM, which agrees with the Ca^{2+} concentration of late endosomes and lysosomes (400–600 μM), where the RUBV replication complex forms and replication occurs. After removal of the Ca^{2+}-binding site, the protease activity is decreased and rendered temperature sensitive, indicating that the function of Ca^{2+} binding is to stabilize the protease and maintain optimal virus infectivity.

Given the widespread occurrence of EF-hand motifs in cellular proteins and the importance of Ca^{2+} as an intracellular messenger, it is surprising that only three of these motifs were reported in viral proteins. Indeed, a comprehensive search for potential viral EF-hand motifs with bioinformatic approaches resulted in the detection of over 90 putative EF-hand and EF-hand-like motifs in proteins encoded by the genomes of almost 80 different viruses, covering the majority of virus families (Zhou et al. 2009). In contrast to EF-hand motifs in cellular proteins, almost all of these predictions were single EF-hand motifs. These putative EF-hand-motif-containing proteins are involved in a wide range of viral processes. Notably, the functions of almost 20% of the proteins with predicted Ca^{2+}-binding motifs remain uncharacterized.

Calcium and Viruses, Table 1 Interactions between cellular Ca^{2+} binding proteins (CaBPs) and viral proteins

Cellular CaBP	Viral molecular identity	Virus	Consequences of interaction
Annexin II	$p55^{GAG}$	HIV-1	Facilitates virus entry and fusion in macrophages
	Glycoprotein B	CMV	Enhances binding and fusion to membranes
Annexin V	Small HBsAg	HBV	Participates in initial steps of HBV infection
Calmodulin	Nef	HIV-1	Alters T lymphocyte signaling pathway
	gp 160/gp41	HIV-1	Disrupts CaM signaling pathway
	gp 41	SIV

Ca^{2+}-Dependent Virus-Host Interactions

Compared to the paucity of reported viral CaBP's, host cells contain abundant CaBPs. Accordingly, viral proteins utilize a number of important cellular CaBPs, including proteins in the cytoplasm (e.g., annexin, calmodulin, and S100), endoplasmic reticulum (e.g., ERC-55, calreticulin, and calnexin), and extracellular matrix (e.g., fibulin-1) in their replication cycles (listed in Table 1).

Take the ubiquitously expressed calmodulin (CaM) as an example (▶ Calmodulin). CaM consists of two globular and autonomous domains, each of which contains two EF-hand motifs. Through its binding to Ca^{2+} and the concomitant conformational changes that result, CaM is capable of transducing the intracellular Ca^{2+} signal changes into divergent cellular events by binding to an array of cellular proteins. Two HIV proteins, Nef, an accessory protein, and gp160, the glycoprotein precursor, have been shown to interact with CaM in a Ca^{2+}-dependent fashion. Nef is a myristoylated protein expressed early in infection. Nef has been shown to downregulate both CD4 and MHC-Class I cell surface receptors, both important in the cell-mediated response, and to alter T lymphocyte signaling pathways. The latter effect is partially associated with its ability to strongly interact with CaM. In addition to Nef, the precursor gp160/gp41 has been shown to interact with CaM. Such interaction is postulated to disrupt the anti-apoptotic CaM signaling pathway by either reducing the amount of free cytosolic CaM or changing its subcellular localization. A similar CaM-targeting sequence is also detected in simian immunodeficiency virus gp41. In view of the diverse roles of Ca^{2+}/CaM-dependent signaling pathways, the interaction between all these HIV proteins with CaM is expected to play multiple roles to fit the HIV life cycle in response to altered Ca^{2+} signals.

Summary

As briefly described in this entry, viruses constantly disrupt or remodel the intracellular Ca^{2+} signaling network, from direct binding of Ca^{2+} by viral proteins to binding of virus proteins to cellular CaBPs to alteration of Ca^{2+} homeostasis. The remodeled Ca^{2+} network affects multiple steps of virus replication as well as cellular outcomes. The prediction of a large number of poorly characterized, putative EF-hand or EF-hand Ca^{2+}-binding motifs in a diverse collection of virus proteins further expands the repertoire of virus-Ca^{2+} interactions. The Ca^{2+} signaling field has been constantly reinvigorated with the continuous discovery of new components and expansion of the Ca^{2+}-signaling toolkits. It is anticipated that, with the continuing development of new research techniques and tools, more and more virus-Ca^{2+} interplays will be elucidated at molecular levels.

Definition

Sarco(endo)plasmic reticulum Ca^{2+}-ATPase, calcium pump, catalyzes Ca^{2+} transport coupled with ATP hydrolysis into the lumen against ~10,000 time concentration gradient. The ATPase is activated by high-affinity binding of two cytoplasmic Ca^{2+} ions at the transport sites in the transmembrane region and forms an autophosphorylated intermediate by transferring ATP γ-phosphate to a catalytic aspartate (Asp351) in the cytoplasmic region. The subsequent large conformational change disrupts the Ca^{2+} binding sites and releases Ca^{2+} into the lumen and produces the catalytic site for hydrolysis of the Asp351-phosphate bond. Beryllium in beryllium fluoride (BeF_3^-) compound is directly ligated with the catalytic aspartyl oxygen, producing a very stable analog of the covalently bound phosphate at Asp351 with an equivalent tetrahedral structure and bond lengths. The biochemical studies of the Ca^{2+}-ATPase/BeF_3^- complexes with and without bound Ca^{2+} at the transport sites revealed characteristic properties of the phosphorylated intermediates with and without bound Ca^{2+}. The Ca^{2+}-free complex was successfully crystallized and provided an atomic model of the Ca^{2+}-released phosphorylated intermediate. Furthermore, in comparison with the complexes of Ca^{2+}-ATPase with AlF_x (transition-state analogs of the phosphorylation and hydrolysis) and with MgF_4^{2-} (an analog of hydrolysis product complex, Ca^{2+}-ATPase with non-covalently bound inorganic phosphate P_i (HPO_4^{2-})), the structural mechanism of energy coupling in the ATP-driven Ca^{2+} transport has been deeply understood.

Ca^{2+}-ATPase: Function and Reaction Sequence

Sarco(endo)plasmic reticulum Ca^{2+}-ATPase (SERCA) catalyzes ATP-driven Ca^{2+} transport from the cytoplasm into the lumen (Fig. 1). It is a representative member of P-type ion transporting ATPases, which include plasma membrane Ca^{2+}-ATPase; Na^+,K^+-ATPase; H^+,K^+-ATPase (responsible for gastric acid secretion); Cu-ATPases; and Golgi Ca^{2+},Mn^{2+}-ATPase. The ATPases form an autophosphorylated intermediate (*E*P) in the ion transport cycle thereby named "P-type." The family members possess three large cytoplasmic domains: nucleotide-binding (N), phosphorylation (P, which contains the autophosphorylation catalytic aspartate), and actuator (A) domains and ten transmembrane helices (M1–M10) (see Fig. 2 in Cross-Reference by C. Toyoshima). The ion transport sites (high-affinity ion binding sites) consist of residues on M4, M5, M6, and M8. Essential residues in the catalytic site for the ATP hydrolysis and in the ion transport (binding) sites are well conserved among the members, and the ATPases work in the common mechanism for the specific ion transport.

The three members of SERCA (1, 2, and 3) encoded by three different genes (*ATP2A1*, *ATP2A2*, *ATP2A3*) are highly homologous and further form alternative splice variants. SERCA1a and 1b are expressed in skeletal fast-twitch muscle as an adult type and a fetal type, respectively. SERCA2a is expressed in heart muscle, and 2b is in smooth muscle and non-muscle cells as a housekeeping isoform. SERCA3 isoforms are expressed in specific tissues such as in nerve tissues and immune cells. Mutations of SERCA genes cause diseases, such as Brody disease (autosomal recessive disease characterized by exercise-induced impairment in muscle relaxation) and Darier disease (autosomal dominant genetic skin disease with abnormal keratinization). Disruption of SERCA function and expression is related with cancer and diabetes.

In the Ca^{2+} transport cycle by SERCA (Fig. 1), the enzyme is first activated by cooperative binding of two

cytoplasmic Ca^{2+} ions at the high-affinity transport sites ($E2$ to $E1Ca_2$, steps 1–2) and autophosphorylated at a catalytic aspartate (Asp^{351}) with MgATP to produce an ADP-sensitive EP ($E1$P, which reacts rapidly with ADP to regenerate ATP in the reverse reaction, step 3). Upon the $E1$P formation, the bound two Ca^{2+} ions become inaccessible from both cytoplasmic and lumenal sides, thus occluded in the transport sites ($E1PCa_2$). The subsequent isomeric transition (a large structural change) to the ADP-insensitive form ($E2$P) results in rearrangements of the transmembrane helices and consequent disruption of the Ca^{2+} binding sites to deocclude Ca^{2+}, reduce largely its affinity, and open the lumenal gate, thus releasing Ca^{2+} into the lumen (steps 4–5). This Ca^{2+}-release process is very rapid; therefore, the $E2PCa_2$ transient state does not accumulate in the wild-type enzyme. Upon the structural change for the Ca^{2+} release, the catalytic site is largely rearranged so as to gain hydrolytic activity; thereby the Asp^{351}-acylphosphate in the Ca^{2+}-released $E2$P is hydrolyzed to form the Ca^{2+}-unbound inactive $E2$ state (steps 6–7). The Ca^{2+} ligands in the transport sites of the Ca^{2+}-released $E2$P bind protons (totally $2 \sim 3$) from the lumenal side, and these protons are released into the cytoplasm upon the Ca^{2+}-binding $E2 \rightarrow E1Ca_2$. The Ca^{2+} pump is therefore actually Ca^{2+},H^+ pump and electrogenic. Mg^{2+} bound at the catalytic Mg^{2+} subsite is required as a catalytic cofactor in the phosphorylation and dephosphorylation for the Ca^{2+} transport. The transport cycle by SERCA1a turns maximally ~50 times in 1 s, and this rapid turnover is responsible for rapid muscle relaxation. The cycle is totally reversible, e.g., $E2$P can be formed from P_i in the presence of Mg^{2+} and absence of Ca^{2+}, and the subsequent lumenal Ca^{2+} binding at lumenally oriented low-affinity transport sites of $E2$P reverses the Ca^{2+}-releasing step and produces $E1PCa_2$, which is then dephosphorylated to $E1Ca_2$ by ADP. Both the phosphoryl transfer to Asp^{351} from ATP and the Asp^{351}-acylphosphate hydrolysis take place with in-line associative mechanism, and therefore, a trigonal bipyramidal structure of the pentacoordinated phosphorus is formed in the transition states.

The affinity of SERCAs for the transporting Ca^{2+} ($K_d \approx$ sub-μM) is highest among other Ca^{2+} removal systems such as Na^{2+},Ca^{2+} exchanger. Therefore, SERCAs are responsible for setting the submicromolar cytoplasmic Ca^{2+} level in resting cells. Also, the lumenal ~ mM Ca^{2+} level, which is critical for the functions of endoplasmic reticulum, is appropriately set by the SERCA's functional property, i.e., by the lumenally oriented low-affinity Ca^{2+} sites in $E2$P to which lumenal Ca^{2+} binds when its level becomes ~mM level high, thereby causing the lumenal Ca^{2+}-induced feedback inhibition of the pump function.

The Use of Metal Fluoride Compounds Provided Essential Information for Understanding Ca^{2+} Transport Mechanism

The major question on the Ca^{2+}-ATPase is how the catalytic site and transport sites communicate each other to accomplish the energy coupling for the Ca^{2+} transport despite their long-distance separation by ~50 Å. The mechanism has been thought to be brought about by mutual communication via structural changes between the catalytic site in the cytoplasmic domains and the transport sites in the transmembrane domain. It is now actually revealed to be achieved by large motions of cytoplasmic domains coupled with rearrangements of the transmembrane helices. Note that the phosphorylated intermediates decay within a few tens of milliseconds; therefore, exploring and characterizing their structural states have been extremely difficult. One major breakthrough was the development of stable structural analogs of the phosphorylated intermediates with metal fluoride compounds: beryllium fluoride (BeF_3^-), aluminum fluoride (AlF_x), and magnesium fluoride (MgF_4^{2-}), which are analogs of the phosphate group (Danko et al. 2004, 2009, Daiho et al. 2010). The beryllium in beryllium fluoride can be directly coordinated with the catalytic aspartyl oxygen, therefore mimics the covalent acylphosphate bond.

To produce the complexes of Ca^{2+}-ATPase with metal fluoride, the sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA1a) was incubated with these compounds typically in a solution at pH $6 \sim 7$ containing $1 \sim 5$ mM F^-, $10 \sim 50$ μM Be^{2+} or Al^{3+} (for BeF_x or AlF_x), and $1 \sim 15$ mM Mg^{2+} (for its binding at the catalytic Mg^{2+} subsite as required for the metal fluoride binding at the catalytic site as well as for the phosphorylation). For the MgF_x binding, the incubation was made without Be^{2+} and Al^{3+}, otherwise as above. The incubation was performed either in the presence of a saturating concentration of Ca^{2+}

TG thapsigargin

($10 \sim 100$ μM) or in its absence (by removing free Ca^{2+} with EGTA) to obtain the complexes of the Ca^{2+}-ATPase with and without bound Ca^{2+} at the transport sites. The formation of the Ca^{2+}-ATPase complexes with the metal fluoride, i.e., its binding at the catalytic site, was verified by the functional analysis: the loss of the ATPase activity and of phosphorylation from ATP and/or P_i. By these experiments, the complexes of the Ca^{2+}-ATPase with the phosphate analogs were successfully developed, and appropriate conditions for the formation of complexes were established.

The Ca^{2+}-ATPase complexes thus produced were remarkably stable and not decomposed even for ∼a month. With MgF_x binding, the metal fluoride binding was found to be quasi-irreversible, which is probably brought about by chemical nature of fluoride. Namely, it possesses a significantly higher electronegativity than oxygen (actually the highest among all atoms) and a small size, therefore it produces the stronger coordination of the metal fluoride than the phosphate group and fixes the structures analogous to the phosphorylated intermediates. As summarized in Table 1 and as described in detail in the following sections, each of the complexes were successfully ascribed to the intermediate states on the basis of the nature in ligation chemistry of the metal fluoride compounds, and the characteristic properties of the Ca^{2+}-ATPase complexes developed. Detailed biochemical and crystallographic studies of the complexes were enabled by their remarkable stability and revealed hitherto unknown features of the intermediate states and provided the atomic structural models. The structural mechanism of Ca^{2+} transport thus revealed is depicted very nicely as the cartoon model by Toyoshima (see Fig. 2 in Cross-Reference by C. Toyoshima, 2008, 2009).

Ligation Chemistry of Beryllium Fluoride as Compared with Aluminum Fluoride and Magnesium Fluoride

Beryllium ion, Be^{2+}, possesses four coordinate bonds, and the beryllium fluoride compounds are known to adopt the tetrahedral geometry with the Be-F bond length 1.55 Å, thereby making them strictly isomorphous to the tetrahedral phosphate group. Moreover, because of the high charge density due to its small size, the beryllium in beryllium fluoride is able to attract an aspartate-oxygen atom (Asp^{351}-oxygen in the case of Ca^{2+}-ATPase) to coordinate in addition to three F^- and thus generate –O-BeF_3^- adduct with the fourth coordination from the aspartate-oxygen. The -O-BeF_3^- formed with the catalytic aspartate in fact was shown to possess the tetrahedral geometry superimposable with the covalently bound phosphate at the aspartate in the crystallographic studies of phosphotransferases (including the members of the haloacid dehalogenase (HAD) superfamily to which P-type ATPases belong, the bacterial response regulators, and later by the crystal structure of Ca^{2+}-free Ca^{2+}-ATPase complexed with BeF_3^-, *E*2·BeF_3^-, which is the *E*2P ground-state analog (for more details, see reference by Danko et al. (2004) and the references cited in).

Aluminum ion, Al^{3+}, ligates fluoride and forms either AlF_3 or AlF_4^-, depending on pH in the incubation medium, and binds to enzymes. As seen in their crystallographic structural studies, the bound AlF_3 and AlF_4^- possess the planar (trigonal (AlF_3) and square (AlF_4^-)) geometry, in which two oxygen atoms, e.g., from the specific aspartate and from the ADP β-phosphate or the hydrolytic water molecule, coordinate to the aluminum at apical positions. The AlF_x thus coordinated is superimposable (AlF_3) or analogous (AlF_4^-) to the trigonal bipyramidal structure of the pentacoordinated phosphorus in the transition states

of the in-line associative phosphoryl transfer and acylphosphate hydrolysis, which are the case for the Ca^{2+}-ATPase.

As Be^{2+}, Mg^{2+} possesses four coordinate bonds and produces the tetrahedral geometry MgF_4^{2-}, which mimics the phosphate group. However, being distinct from the beryllium, the magnesium in MgF_4^{2-} is not able to (or having much less ability to) attract aspartate-oxygen to coordinate directly, and thus the oxygen atom cannot substitute the fluoride in MgF_4^{2-}. Therefore, MgF_4^{2-} bound to the catalytic site mimics a non-covalently bound P_i (HPO_4^{2-}). In fact, in the crystal structure of the Ca^{2+}-free Ca^{2+}-ATPase (*E*2 state), the magnesium fluoride bound at the catalytic site was shown to be MgF_4^{2-} of which tetrahedral geometry is superimposable to the non-covalently bound P_i. The $E2{\cdot}MgF_4^{2-}$ complex therefore represents the product complex of the *E*2P hydrolysis, $E2{\cdot}P_i$.

Analogs of E2P Without Bound Ca^{2+} During Asp351-Phosphate Hydrolysis

For understanding the Ca^{2+}-free structure and properties of *E*P (*E*2P) and its hydrolysis mechanism, the Ca^{2+}-free Ca^{2+}-ATPase (*E*2 state) was complexed with beryllium fluoride, aluminum fluoride, and magnesium fluoride (Danko et al. 2004). The *E*P formation from ATP and P_i, and ATP hydrolysis were completely inhibited by these compounds, indicating that the metal fluoride compounds were bound to the catalytic site. The complexes thus produced are all very stable and not degraded even after extensive washing for removing unbound metal fluoride. The detailed analyses of the complexes were then performed to reveal and compare their characteristic properties. In the complex formed with beryllium fluoride, lumenal Ca^{2+} at ~mM high concentration is accessible to the transport sites with the low affinity comparable to that in *E*2P (the Ca^{2+}-released state of *E*P formed from P_i). Thus the complex with beryllium fluoride possesses the lumenally oriented transport sites, i.e., lumenally opened Ca^{2+}-release pathway, as *E*2P. The nature of the catalytic site was explored by a hydrophobicity-sensitive fluorescence development of trinitrophenyl (TNP)-AMP, which binds to the ATP binding site with a high affinity. The complex with beryllium fluoride as well as *E*2P developed an extremely high fluorescence ("superfluorescence") of bound TNP-AMP, showing that the catalytic site is strongly hydrophobic and therefore a closed structure excluding nonspecific water molecules (but a specific water molecule attacking the Asp351-phosphate bond). Thus the $E2{\cdot}BeF_x$ complex possesses characteristic properties known for the *E*2P intermediate. The results showed that $E2{\cdot}BeF_x$ is the analog of the *E*2P ground state, which is the state immediately after the Ca^{2+} release with the lumenally opened release pathway and before (ready for) the acylphosphate hydrolysis at the catalytic site. The conclusion agrees with the chemical nature of beryllium fluoride (BeF_3^-), i.e., Be^{2+} in BeF_3^- can be directly coordinated by Asp351-oxygen mimicking the covalent acylphosphate bond. Detailed biochemical analyses further revealed that the complex is completely resistant against (i.e., sterically protected from) protease attacks by trypsin, proteinase K, and V8 protease at their specific cleavage sites on the surface of the cytoplasmic domains. The results indicated that the three cytoplasmic domains are tightly associated with each other producing their compactly organized headpiece structure. The atomic structure solved later clearly showed that the complex is actually $E2{\cdot}BeF_3^-$ and possesses all these biochemically predicted properties, i.e., the lumenally opened Ca^{2+}-release pathway and the closed and hydrophobic catalytic site with direct ligation between Asp351-oxygen and BeF_3^- (Toyoshima et al. 2007, Olesen et al. 2007, Toyoshima 2008, 2009, Møller et al. 2010).

Other two complexes developed, $E2{\cdot}AlF_x$ and $E2{\cdot}MgF_4^{2-}$, were also found to be completely resistant against the proteases as $E2{\cdot}BeF_3^-$; therefore, they possess the compactly organized cytoplasmic domains. However, being distinct from $E2{\cdot}BeF_3^-$, the catalytic site in the two complexes is hydrophilic (no fluorescence development of bound TNP-AMP); therefore, they possess a more opened conformation of the catalytic site to which nonspecific water molecules have entered. Furthermore, in the two complexes, the lumenal Ca^{2+} is inaccessible to the transport sites, and therefore, the lumenal Ca^{2+}-release pathway (gate) is closed. These Ca^{2+}-free complexes probably represent the structural states during and after the *E*2P hydrolysis. In agreement, the ligation chemistry of AlF_x and MgF_4^{2-} and the atomic structures of the Ca^{2+}-ATPase complexes (see review articles by Toyoshima 2008, 2009) clearly showed that the complexes are the analogs of the in-line hydrolysis transition-state $E2P^{\ddagger}$ ($E2{\cdot}AlF_4^-$) and the product

complex of the *E*2P hydrolysis *E*2·P_i (*E*2·MgF_4^{2-}). Thus the three complexes of the Ca^{2+}-free Ca^{2+}-ATPase, *E*2·BeF_3^-, *E*2·AlF_4^-, and *E*2·MgF_4^{2-}, were successfully developed, characterized, and assigned to the structural states in the *E*2P hydrolysis. The distinct nature of the three complexes revealed that, after Ca^{2+} release into the lumen from *E*2PCa_2, the release pathway structure is changed from its opened state to closed state upon the *E*2P hydrolysis (*E*2P → *E*2P‡ and *E*2·P_i), thereby prevents possible Ca^{2+} leakage from the lumen to cytoplasm. The gate closure takes place by and is coupled with the rearrangement of the catalytic site configuration upon the Asp351-phosphate hydrolysis, i.e., in *E*2P ground state → *E*2P‡ transition state.

In the atomic structures of the three complexes, the biochemically predicted characteristic properties are all seen. Furthermore, the ligations of the metal fluoride compounds (phosphate group), attacking H_2O molecule, and the catalytic Mg^{2+} are all seen in the atomic level with the critical residues involved in ligations and catalysis, e.g., the TGES184 outermost loop of the A domain and essential residues of the P domain around Asp351. As predicted, the beryllium in BeF_3^- is directly ligated with the Asp351-oxygen in *E*2·BeF_3^-, the planar AlF_4^- in *E*2·AlF_4 is coordinated with Asp351 and with the attacking water molecule from the apical positions, and MgF_4^{2-} bound in *E*2·MgF_4^{2-} is mimicking the non-covalently bound Pi. The atomic structures demonstrated how the configuration in the catalytic site structure changes (Fig. 2, see also Toyoshima 2009) and consequently how the Ca^{2+}-release gate is closed during *E*2P → *E*2P‡ in the hydrolysis, i.e., the A domain slightly inclines and this motion results in the gate closure.

Analogs of Ca^{2+}-Bound Intermediate States During the Phosphorylation

The complexes of the Ca^{2+}-bound Ca^{2+}-ATPase (*E*1Ca_2) with AlF_x and BeF_x were also developed. The complexes first produced and crystallized are *E*1Ca_2·AlF_4^-·ADP, the transition-state analog of the phosphorylation (*E*1PCa_2·ADP‡) and *E*1Ca_2·AMPPCP, the enzyme·substrate complex analog (*E*1Ca_2·ATP) (Fig. 2, see review articles by Toyoshima 2008, 2009). Their atomic structures revealed that the N and P domains largely move, thereby being cross-linked by ATP binding for the phosphoryl transfer to Asp351 and that the two Ca^{2+} ions at transport sites become occluded upon this structural change. The planar AlF_4^- is coordinated from the apical positions by ADP β-phosphate and Asp351 and thus revealed the transition-state atomic structure in the in-line phosphorylation mechanism.

Then the genuine *E*1PCa_2 analog complex was developed with BeF_x, most probably BeF_3^- (Danko et al. 2009). Its formation required ∼mM level Mg^{2+}, i.e., the Mg^{2+} binding at the catalytic Mg^{2+} subsite, as required for the phosphorylation with ATP. The *E*1Ca_2·BeF_3^- complex possessed two Ca^{2+} occluded in the high-affinity binding (transport) sites and was very stable in the presence of ∼mM lumenal Ca^{2+} at least for 2 weeks. When the lumenal Ca^{2+} was removed, the complex was autoconverted very slowly in ∼10 h at 25°C to *E*2·BeF_3^- releasing Ca^{2+}, as mimicking the *E*P isomerization and Ca^{2+}-release *E*1PCa_2 → *E*2P + 2Ca^{2+}. The *E*1Ca_2·BeF_3^- complex was produced also from *E*2·BeF_3^- by low-affinity lumenal Ca^{2+} binding at the transport sites, as mimicking the lumenal Ca^{2+}-induced reverse conversion *E*2P + 2Ca^{2+} → *E*1PCa_2. The addition of ADP to the *E*1Ca_2·BeF_3^- complex destroyed this complex to *E*1Ca_2 state, as mimicking the reverse decomposition of the ADP-sensitive *E*P (*E*1PCa_2 + ADP → *E*1Ca_2 + ATP). All these properties of *E*1Ca_2·BeF_3^- met requirements as a stable analog of the genuine *E*1PCa_2, the product of the phosphorylation reaction. MgF_4^{2-} was not able to produce a complex with *E*1Ca_2, in agreement with the fact that there is no state with non-covalently bound P_i in the in-line phosphorylation mechanism.

The detailed biochemical analyses of the stable *E*1Ca_2·BeF_3^- complex revealed characteristic properties of *E*1PCa_2 (hitherto unexplored due to its rapid decay) for further understanding of the successive structural events, the *E*P formation, its isomerization, and Ca^{2+} release (Danko et al. 2009). Namely, in the change from the transition-state *E*1PCa_2·ADP‡ to the product-state *E*1PCa_2, the A domain slightly rotates parallel to the membrane plane and thereby comes close to the P domain (but not yet completely as in the Ca^{2+}-released *E*2P). Upon this motion, the transmembrane helices are also rearranged although keeping the Ca^{2+}-occluded state. The structure of *E*1PCa_2 thus produced is now ready for the subsequent large structural changes, i.e., the large rotation of the

A domain and the resulting tight association with the P domain to cause the loss of ADP sensitivity and Ca^{2+} deocclusion and release into the lumen ($E1PCa_2 \rightarrow E2PCa_2 \rightarrow E2P + 2Ca^{2+}$).

$E2PCa_2$ Transient State and Its Analog $E2Ca_2{\cdot}BeF_3^-$

Finally, the transient $E2PCa_2$ state in the EP processing and Ca^{2+}-release $E1PCa_2 \rightarrow E2PCa_2 \rightarrow E2P + 2Ca^{2+}$ was successfully trapped, and its analog was developed with BeF_3^-. This transient state has been postulated but never been identified because of the very rapid Ca^{2+} release after the EP isomerization ($E1PCa_2 \rightarrow E2PCa_2$).

However, a mutation study (Daiho et al. 2007) successfully identified a crucial structural element, i.e., the length of the A/M1-linker (Glu40-Ser48, connecting the A domain and M1) that critically functions for these structural events, and thereby the $E2PCa_2$ transient state was successfully trapped by its mutation. When the linker is elongated by insertion of two or more amino acids, the EP isomerization is markedly accelerated and, surprisingly, the subsequent Ca^{2+}-release $E2PCa_2 \rightarrow E2P + 2Ca^{2+}$ is almost completely blocked. Thus the transient-state $E2PCa_2$ was successfully trapped and identified for the first time by the A/M1-linker elongation. When the linker is shortened by deletion of any single residues within the linker, the EP isomerization $E1PCa_2 \rightarrow E2PCa_2$ is almost completely blocked. Thus the proper length of the linker critically functions for the structural changes $E1PCa_2 \rightarrow E2PCa_2 \rightarrow E2P + 2Ca^{2+}$.

The kinetic and structural properties of the $E2PCa_2$ state trapped by the linker elongation were analyzed in detail. In this state, the bound Ca^{2+} ions are occluded in the transport sites, and the A domain has been largely rotated from its position in $E1PCa_2$ ($E1Ca_2{\cdot}BeF_3^-$) and associated with the P domain at the two positions (at the Val200 loop and at TGES184 loop of the A domain). However, in this state, the hydrophobic interactions among the A and P domains and the top part of M2 at Tyr122, i.e., Tyr122-hydrophobic cluster, are not yet produced properly. Actually, the formation of this hydrophobic cluster has been demonstrated by the substitution mutations of this cluster to be critical for producing the Ca^{2+}-released $E2P$ structure (Yamasaki et al. 2008).

The finding demonstrated that the length of A/M1-linker should be properly long for the $E1PCa_2 \rightarrow E2PCa_2$ isomerization and then appropriately short for the subsequent Ca^{2+}-release $E2PCa_2 \rightarrow E2P + 2Ca^{2+}$. The results dissected and predicted the critical structural changes to occur in these processes with a critical function of the A/M1-linker as follows. In the $E1PCa_2 \rightarrow E2PCa_2$ isomerization, the A domain largely rotates parallel to the membrane plane, thus comes above and docks onto the P domain. Because of the A domain's positioning above the P domain, the A/M1-linker is strained in $E2PCa_2$ state, and the strain thus imposed will cause structural change for the Ca^{2+} release from $E2PCa_2$, i.e., inclination of the A and P domains and the connected helices (M2 and M4/M5), which results in rearrangements of the transmembrane helices so as to disrupt Ca^{2+} sites and deocclude Ca^{2+}, opening the gate, thus releasing Ca^{2+} into the lumen. Upon these motions, the A and P domains and top part of M2 associate and produce the tight hydrophobic interactions, Tyr122-hydrophobic cluster, which stabilizes the inclined and Ca^{2+}-released structure of $E2P$. Also upon these changes, the $E2P$ catalytic site for the acylphosphate hydrolysis is produced. Thus the $E2P$ hydrolysis takes place after the Ca^{2+} release, accomplishing the Ca^{2+} transport and energy coupling.

Then with the elongated A/M1-linker mutant, the analog of $E2PCa_2$, $E2Ca_2{\cdot}BeF_3^-$, was successfully developed by incubating the $E1Ca_2$ state with beryllium fluoride. The complex is remarkably stable, not decomposing at least for 2 weeks. The complex $E2{\cdot}BeF_3^-$ thus produced possesses all the characteristic properties revealed with the trapped $E2PCa_2$. The complex was produced also from $E2{\cdot}BeF_3^-$ by the binding of lumenal Ca^{2+} (at $\sim$ mM level) to the lumenally opened low-affinity transport sites in $E2{\cdot}BeF_3^-$. Thus the $E2Ca_2{\cdot}BeF_3^-$ formation mimicked the $E2PCa_2$ formation in both the forward and reverse reactions, i.e., from $E1Ca_2$ by ATP via the $E1PCa_2$ isomerization and from $E2P$ by the lumenal Ca^{2+} binding to the lumenally opened transport sites. Importantly, AlF_x and MgF_x are not able to produce this $E2PCa_2$ analogous complex either from $E1Ca_2$ or from $E2{\cdot}AlF_4^-$ and $E2{\cdot}MgF_4^{2-}$. BeF_x is thus unique in this regard. The observation agrees with the fact that the transient $E2PCa_2$ state possesses the covalent Asp351-phosphate bond, i.e., the $E2PCa_2$ state is produced only from the states with the covalent acylphosphate bond, $E1PCa_2$ ($E1Ca_2{\cdot}BeF_3^-$) and $E2P$

($E2{\cdot}BeF_3^-$), but not from the transition states (mimicked by $E1Ca_2{\cdot}AlF_x$ and $E2{\cdot}AlF_x$) and the non-covalently bound P_i state (mimicked by $E2{\cdot}MgF_4^{2-}$). The finding shows that the large structural changes for the *E*P isomerization and Ca^{2+} deocclusion/release in the forward and reverse reactions are strictly coupled with the formation of the particular configuration of the acylphosphate covalent bond within the catalytic site. Namely, upon formation of the covalent Asp351-phosphate bond, the Ca^{2+}-ATPase structure becomes ready for its structural isomerization and Ca^{2+}-release processes, but the transition-state structures are not yet prepared.

Concluding Remarks

As described above, the use of beryllium fluoride as the phosphate analog provided essential knowledge for understanding the structural mechanism of energy coupling in the Ca^{2+}-ATPase, the representative member of P-type ion transporting ATPase family. Because of the chemical nature of the beryllium fluoride as well as aluminum fluoride and magnesium fluoride and because of the remarkable stability of the enzymes complexed with these metal fluoride compounds, detailed biochemical and structural studies of many ATPase systems are feasible and being performed.

Synonyms

Proteins: sarco(endo)plasmic reticulum Ca^{2+}-ATPase, SERCA; Plasma membrane Ca^{2+}-ATPase (PMCA).
DNA: ATP2A1-3 (human genes for SERCA1-3); ATP2B1-4 (PMCA1-4)
Biological functions: Ca^{2+}-pump; Ca^{2+}-translocating ATPase

Definition

Enzyme, EC 3.6.3.8; an ATP-powered ion pump that transports Ca^{2+} across the membrane against

a large (up to 15,000-fold) concentration gradient. A representative member of the P-type ATPase family, which is in turn a member of the haloacid dehalogenase superfamily (Burroughs et al. 2006). EC 3.6.3.8 includes sarco(endo)plasmic reticulum calcium ATPase, commonly abbreviated as SERCA, and plasma membrane Ca^{2+}-ATPase, abbreviated as PMCA. As SERCA transports 2 Ca^{2+} ions per ATP hydrolyzed from the cytoplasm into the lumen of sarcoplasmic reticulum and 2 or 3 H^+ in the opposite direction, it may be termed "Ca^{2+}, H^+-ATPase," similarly to Na^+, K^+-ATPase. PMCA transports one Ca^{2+} per ATP.

Biological Function and Amino Acid Sequence Information

In this entry, description is limited almost exclusively to SERCA pumps, as they are much better studied than PMCA. SERCA pumps exist from some bacteria (e.g., *Bacillus subtilis*), fungi (e.g., *Neurospora crassa*), plants to human, although their functional meaning is unclear in some bacterial species (Vangheluwe et al. 2009). In human, three genes (ATP2A1-3) generate multiple SERCA isoforms (SERCA1a,b, SERCA2a–c, and SERCA3a–f) by alternative splicing. SERCA1a is the adult form of the fast twitch skeletal muscle sarcoplasmic reticulum (SR) Ca^{2+}-ATPase and consists of 994 amino acid residues; SERCA1b is the neonatal form having additional seven residues at the C-terminus. In muscle contraction, Ca^{2+} is released from SR into muscle cells through Ca^{2+} release channels and pumped back into SR by SERCA1 to relax muscles cells. The concentration of Ca^{2+} within the muscle cell is maintained at less than micrometer in the relaxed state. SERCA2 is by far the most widespread of all SERCA isoforms and phylogenetically the oldest. SERCA2 has three splice variants and SERCA2a (997 amino acid residues) is the main isoform in cardiac muscle and slow twitch skeletal muscle. SERCA2b is considered to be the housekeeping ATPase and has an extra transmembrane segment at the C-terminus (Brini and Carafoli 2009).

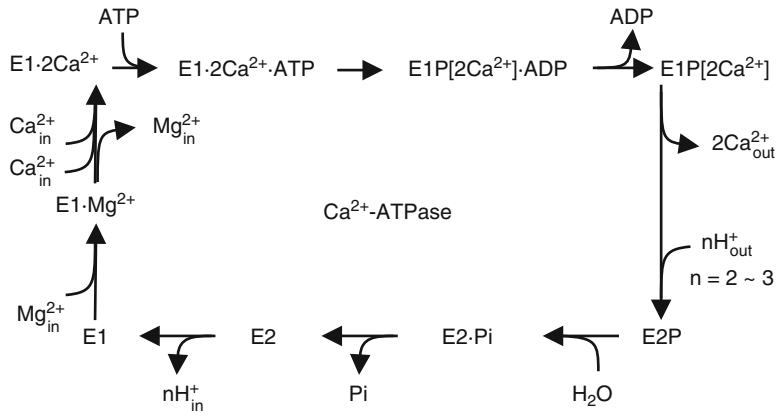
Signature sequence of the P-type ATPase family is written as D-K-T-G-T-[LIVM]-[TI]. The starting Asp is the phosphorylated residue, corresponding to Asp351 in SERCA1a. This signature sequence constitutes motif PS00154 in the PROSITE database and makes P-type ATPase a member of haloacid dehalogenase superfamily (Burroughs et al. 2006). The atomic structure around the phosphorylation site is similar to that of bacterial two-component regulators, which have different supersecondary structures. A database on P-type ATPases is available at http://traplabs.dk/patbase/. Various types of SERCA are reviewed by (Vangheluwe et al. 2009). A complete compilation of all mutagenesis is provided by Andersen (http://sercamutation.au.dk/).

Reaction Cycle

The mechanism of active ion transport by Ca^{2+}-ATPase is conventionally described by E1/E2 theory (Fig. 1) (Inesi 1985). In the E1 state, the Ca^{2+}-binding sites have high affinity and face the cytoplasm in the E1 state, and have low affinity and face the lumenal (or extracellular) side in E2. Hence, Ca^{2+}-ATPase is said to be a member of E1/E2-type ATPase that includes Na^+, K^+-ATPase and gastric H^+, K^+-ATPase among others. This type of ATPases is also called P-type ATPase, because the enzyme is auto-phosphorylated (denoted by "P") at invariant Asp during the reaction cycle, distinct from F_1F_0-type ATPase, for example.

As SERCA1a transfers two Ca^{2+} ions from the cytoplasm and 2 (or 3) H^+ into the cytoplasm, the reaction cycle is electrogenic (Inesi 1985). However, since SR membrane is leaky to all monovalent ions, pumped protons are dissipated away (presumably through H^+ channel). Therefore, SR membrane has no significant membrane potential, and Ca^{2+}-ATPase is in reality a Ca^{2+} pump. SERCA1a can also transport Mn^{2+} but at a slower rate with unknown stoichiometry. H^+-countertransport (and dissipation) is necessary partly for stabilizing empty Ca^{2+}-binding sites in the E2 states and for changing the affinity of the Ca^{2+}-binding sites.

The SERCA pump itself is not regulated by phosphorylation. As long as Ca^{2+} and ATP are present, the pump runs continuously. In cardiac muscle, however, there are regulatory proteins phospholamban (52 amino acid residues) and sarcolipin (31 residues). They are related short transmembrane peptides and regulated by phosphorylation (MacLennan and Kranias 2003). PMCA is regulated by calmodulin and protein kinases. Their binding sites are located in



Calcium ATPases, Fig. 1 A simplified reaction scheme according to the E1/E2 model. Only forward direction is shown

the cytoplasmic extension after the last transmembrane helix (Brini and Carafoli 2009).

Energetics

The free energy required for transferring 2 mol of Ca^{2+} against a 15,000-fold concentration gradient requires 12.6 kcal, even when no membrane potential exists. This number clearly exceeds the standard free energy of ATP (−7.3 kcal/mol). The amount of free energy required is obtained, in muscle cells, by reducing the concentration of ADP by converting it to ATP with creatine kinase. In fact, the whole reaction cycle can be reversed and ATP can be synthesized under certain conditions (Inesi 1985). In particular, the ATPase in the E1P state (but not in the E2P state) readily synthesizes ATP, as the standard free energy liberated by hydrolysis of aspartylphosphate (11.7 kcal/mol) is substantially higher than that of ATP. Therefore, E1P and E2P are also called ADP-sensitive and -insensitive phosphorylated forms, respectively. For PMCA, because of the membrane potential, transfer of only one Ca^{2+} per ATP hydrolyzed is possible.

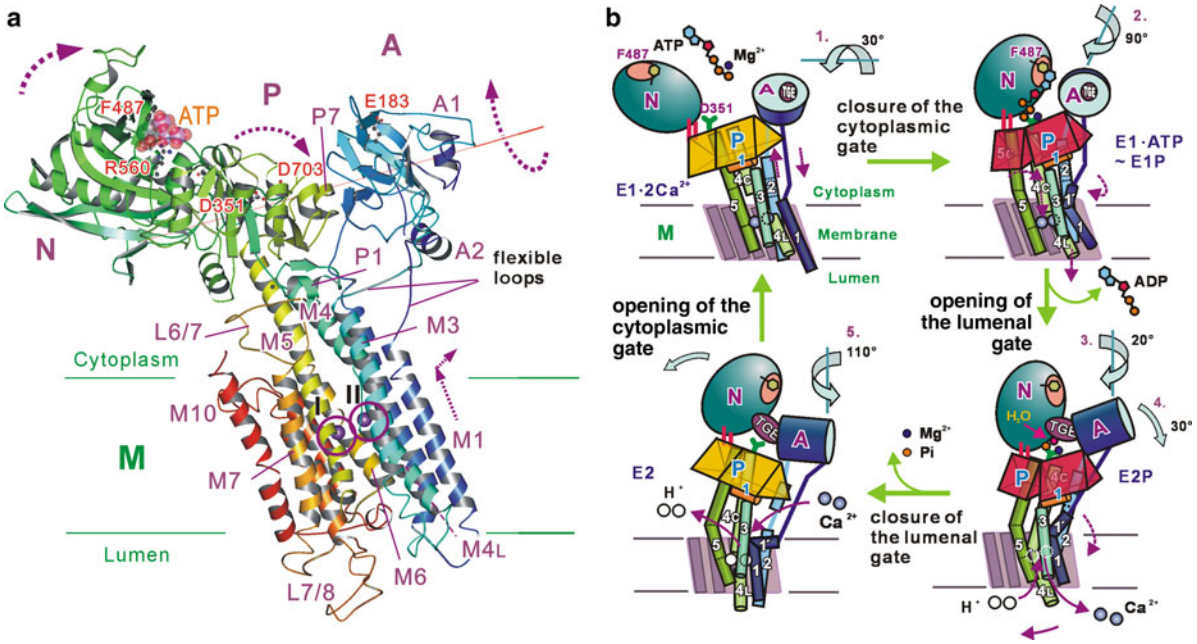
Inhibitors

There are three well-known inhibitors of high affinity, namely, thapsigargin (TG), a sesquiterpene lactone from a plant, cyclopiazonic acid, an indole tetramic acid fungal toxin, and 2,5-di-*tert*-butyl-1,4-dihyhydroxybenzene (BHQ). Of these three, TG has the highest affinity with a subnanomolar dissociation constant (K_d). All of them fix the enzyme in the E2 state. No strong inhibitor is known to stabilize the ATPase in the E1 states. The binding sites of BHQ and cyclopiazonic acid are located on the cytoplasmic surface of the transmembrane region and partially overlap; TG binds between the M3 and M7 transmembrane helices.

Protein Production and Purification

The most common source of SERCA is rabbit hind leg white muscle, in which only SERCA1a is present. Approximately 500 mg of SR membrane ("light" SR fraction devoid of T-tubule containing Ca^{2+}-release channels) can be obtained from 150 g of muscle by differential centrifugation. This preparation contains usually 30 mg/ml proteins, ~60% of which is SERCA1a, and can be stored for a few months at −80°C with 0.3 M sucrose. SERCA1a can be affinity purified with Reactive Red 120 after solubilization with 2% octaethyleneglycol dodecylether ($C_{12}E_8$) and hydrolyzes ~20 ATP molecules/sec at 25°C (in 123 mM KCl, 6.15 mM $MgCl_2$, 0.12 mM $CaCl_2$, 2 mM ATP, 0.1% $C_{12}E_8$, 61.5 mM MOPS, pH 7.0).

Recombinant SERCA can be expressed in HEK293, COS1 and COS7. Large-scale productions have been achieved using adenovirus vectors, yielding the expression level of SERCA1a as high as 20% of total microsomal proteins. For a large-scale production, an yeast (*Saccharomyces cerevisiae*) system has also been used and yielded crystals of mutants.



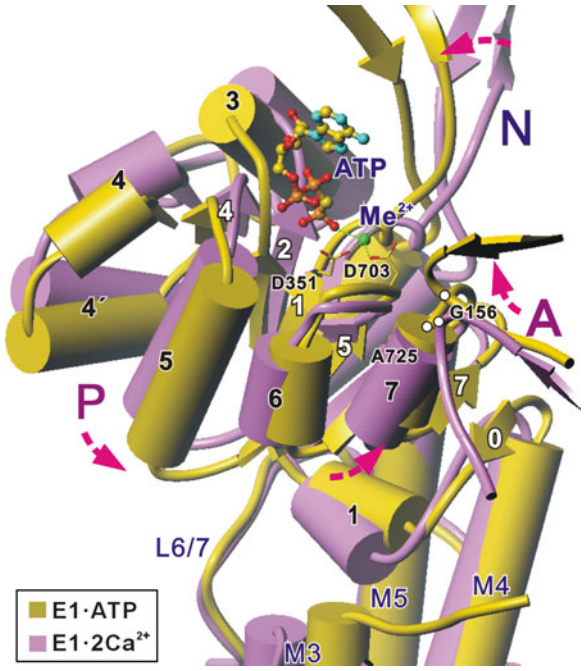
Calcium ATPases, Fig. 2 Architecture of Ca^{2+}-ATPase and its ion pumping mechanism. (**a**) A ribbon representation of Ca^{2+}-ATPase in the E1·2Ca^{2+} state, viewed parallel to the membrane plane. Colors change gradually from the amino terminus (*blue*) to the carboxy terminus (*red*). Two *purple spheres* (numbered and circled) represent bound Ca^{2+}. Three cytoplasmic domains (A, N, and P), some of the α -helices in the A-domain (A1–A2), P-domain (P1 and P7), and those in the transmembrane domain (M1–M10) are indicated. Docked ATP is shown in transparent *space fill*. Several key residues – E183 (A, activation of attacking water), F487 and R560 (N, ATP binding), D351 (P, phosphorylation site), and D703 (magnesium binding) are shown in *ball*-and-*stick*. Axis of rotation (or tilt) of the A-domain is indicated with *thin orange line*. PDB accession code is 1SU4 (E1·2Ca^{2+}). (**b**) A cartoon illustrating the structural changes of Ca^{2+}-ATPase during the reaction cycle, based on the crystal structures in nine different states

Architecture of the Molecule

Ca^{2+}-ATPase is a tall (∼150 Å high) integral membrane protein, comprising three large cytoplasmic domains designated as A (actuator), N (nucleotide binding), and P (phosphorylation), 10 (M1–M10) transmembrane α-helices and short (except for L7/8 that connects M7 and M8) lumenal loops (Fig. 2a) (Toyoshima 2008). The M4 and M5 helices are very long (∼60 Å), extending from the lumenal surface to the top of the P-domain. The cytoplasmic extensions of the transmembrane helices may appear to form a "stalk (S)" segment. The distance between the transmembrane Ca^{2+}-binding sites and the phosphorylation site is >50 Å. Since 12 out of 13 Trp residues reside in the transmembrane region, intrinsic fluorescence from Trp is widely used to monitor the movements of transmembrane helices. Limited proleolysis with proteinase K and trypsin provides useful information on the arrangement of cytoplasmic domains.

Structure of the A-domain: The A-domain is the smallest (∼160 residues) of the three cytoplasmic domains and acts as the "actuator" of the gates that control the binding and release of Ca^{2+}. It is connected to the M1 and M3 helices with flexible links and more directly to the M2 helix with a swivel (Fig. 2). The A-domain contains the ^{183}TGES loop, one of the signature sequences of the P-type ATPase, which plays a critical role in activating the water molecule that attacks the aspartylphosphate (Fig. 2b).

Structure of the P-domain: The P-domain is the catalytic core domain and contains the phosphorylated residue Asp351, Mg^{2+}-binding residue Asp703 (Fig. 3), and other critical residues that classify Ca^{2+}-ATPase as a member of the haloacid dehalogenase superfamily (Burroughs et al. 2006). The P-domain has a Rossmann fold, commonly found in nucleotide-binding proteins, consisting of a parallel β-sheet and associated α-helices. A key feature is that the cytoplasmic extension of M5 is integrated into the P-domain as one of the associated

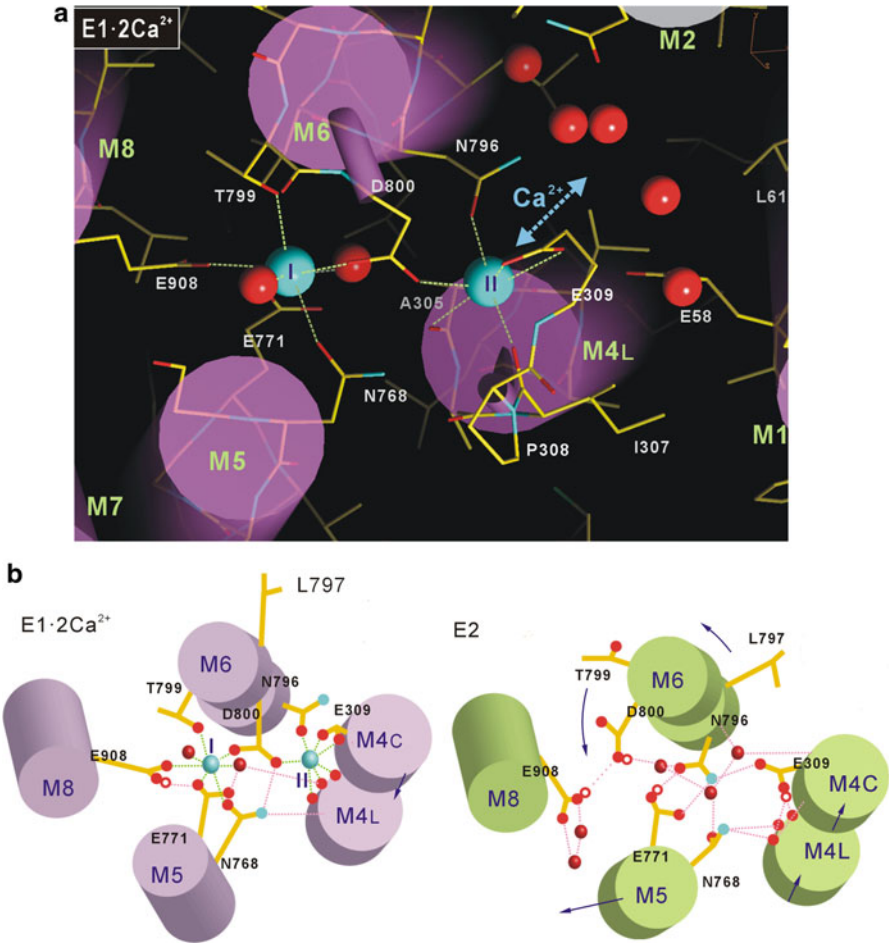


Calcium ATPases, Fig. 3 Structural changes caused by the binding of ATP and Mg^{2+} to the P-domain. The bound metal (Me^{2+}, small *green sphere*) is most likely Ca^{2+} rather than Mg^{2+} in the crystal structure. Note that the P-domain is bent (*arrows* in *red broken lines*) by coordination of the metal by the γ-phosphate, D351, and D703 (shown in stick model) and that the A-domain tilts because of the inclination of the P7 helix

helices, and the cytoplasmic end of M4 is clamped to M5 by a short antiparallel β-strand; the M3 helix is connected to the P-domain by critical hydrogen bonds and also moved by the P1 helix that runs along the bottom of the P-domain (Fig. 3). Therefore, structural events that occur in the P-domain are readily transmitted to the transmembrane domain. The central β-sheet consists of two parts (strands 1–4 and 5–7), which allow bending of the P-domain when phosphate and Mg^{2+} bind (arrows in Fig. 3). In this sense, the P-domain has an integrated hinge that alters the orientation of the P-domain with respect to the M5 helix and also the inclination of the N-domain with respect to the P-domain depending on the phosphorylation (Fig. 3). The Mg^{2+} coordinated by Asp351 and Asp703 is essential for phosphoryl transfer. However, almost any divalent cations can occupy this site and interferes with the reaction. This is the reason why high concentration of Ca^{2+} is inhibitory. There is a K^+ (or Na^+)-binding site at the bottom of the P-domain. This monovalent ion accelerates the hydrolysis of aspartylphosphate and stabilizes the E2 state.

Structure of the N-domain: The N-domain is the largest (~240 residues) of the three cytoplasmic domains and the least conserved domain in P-type ATPases. The N-domain is a long insertion between the two parts that constitute the P-domain and connected to them with two strands having a β-sheet like hydrogen bonding (Fig. 3). This is a primary hinge and allows a 60° change in inclination to allow phosphoryl transfer from ATP. The N-domain contains the binding site for ATP (Fig. 2). The side chain of Phe487 stacks with the adenine ring and Arg560 fixes the β-phosphate. Lys515, a critical residue located at the depth of the binding cavity, can be labeled specifically at alkaline pH with FITC, which is used for many spectroscopic studies.

Organization of the transmembrane domain: SERCA1a has 10 (M1–M10) transmembrane α-helices (Fig. 2), two of which (M4 and M6) are partly unwound throughout the reaction cycle. M1–M2 form a rigid V-shaped structure and follow the movements of the A-domain, and thereby play many roles in opening and closing the transmembrane gates. They show very large movements in both within and perpendicular (up to two turns of α-helix) to the membrane. M1, connected to the N-terminal half of the A-domain, consists of two parts and form a kinked helix to accommodate different positions and orientations of the A-domain. The N-terminal part (M1′) is amphipathic and lie on the membrane surface when M1 is kinked. This kink is important in making a pivot for the movements of M3 and M4. The length of the linker that connects the A-domain and M1′ is critical. M2 is a long contiguous helix from E1 to E2P, but becomes disrupted in transition to E2·Pi. M3–M4 also form a helix pair and show both lateral and vertical movements. M5 is the spine of the molecule but can bend at two Glys. The lumenal part (M5L) stays unchanged. M6 and M7 are located far apart and connected by a loop of ~20 residues (L6/7; Fig. 2a). This loop, running along the bottom of the P-domain and connected to M5 with critical hydrogen bonds, is rigid and serves as a limiter for movements of M5 and the socket of M3. M7–M10 in SERCA1a appear to be an anchor to the membrane and do not undergo a large rearrangement or conformational changes. They presumably have specialized functions in each subfamily



Calcium ATPases, Fig. 4 Structure of the transmembrane Ca^{2+}-binding sites. (**a**) atomic model in the E1·2Ca^{2+} state. (**b**) Cartoons illustrating the binding sites in E1·2Ca^{2+} and E2 viewed approximately normal to the membrane. Two Ca^{2+} appear as *cyan spheres* and water molecules as *red spheres*. Note that site II Ca^{2+} is exchangeable by conformation change of the E309 side chain in E1·2Ca^{2+} (*double-headed arrow* in **a**). The *arrows* in (**b**) indicate the movements of the helices in the transition E2 → E1·2Ca^{2+}. *Red circles* represent protonation of the oxygen atoms. *Dotted lines* indicate hydrogen bonds (*pink*) and coordination of Ca^{2+} (*light green*)

and are in fact lacking in type I P-type ATPases (heavy metal pumps). The amino acid sequence is well conserved for M4–M6 but not for M8 even within the members of closely related P-type ATPases, such as Na^+, K^+-, and H^+, K^+-ATPases.

Details of the Ca^{2+}-Binding Sites

The two Ca^{2+}-binding sites (I and II) are located side by side near the cytoplasmic surface of the lipid bilayer (Fig. 4), with the site II ~3 Å closer to the surface (Fig. 2a). Yet, the binding of two Ca^{2+} is sequential and cooperative. The binding sites have K_ds of 1.7 and 0.18 μM and the Hill coefficient of 1.7–1.8 (Inesi 1985). They show a strong pH dependence (pK_a = 6.4). The Glu309Gln mutant shows K_d of 0.23 μM (Hill coefficient: 0.94) and pK_a of 7.8.

Site I, the binding site for the first Ca^{2+}, is located at the center of the transmembrane domain in a space surrounded by the M5, M6, and M8 helices, and formed by the side chain oxygen atoms and two water molecules (Fig. 4). M8 is located rather distally and the contribution of Glu908 is not essential in that Gln can substitute Glu908 to a large extent. Electrostatic calculation shows that the carboxyl group of Glu908 is protonated throughout the reaction cycle.

Site II is formed "on" the end of the lumenal half of the M4 helix (M4L) with the contribution of four side chain and three main chain oxygen atoms (Fig. 4). For providing main chain oxygen atoms, the M4 helix is partly unwound (between Ile307-Gly310) and Glu309, the gating residue, caps the bound Ca^{2+}. This arrangement of oxygen atoms is reminiscent of the EF-hand motif (see "EF-Hand Proteins").

Synopsis of Ion Pumping

Since the first crystal structure of SERCA1a in E1·2Ca^{2+} published in 2000, more than 20 crystal structures for nine different states that roughly cover the entire reaction cycle have been deposited in the Protein Data Bank (Toyoshima 2008). Rapid advancement was made by the use of metal fluorides adducts (BeF_3^- for the ground state, AlF_4^- for the transition state, and MgF_4^{2-} for the product state) as stable phosphate analogs. Here presented is a brief scenario of ion pumping by SERCA1a. More detailed account is found in (Toyoshima 2008). Movies illustrating these movements and aligned coordinates of the crystal structures can be downloaded from the author's Web site (http://www.iam.u-tokyo.ac.jp/StrBiol/).

E1 → E1·2Ca^{2+}: binding of two Ca^{2+}. In the absence of Ca^{2+} and at pH 7, most of SERCA1a is in the E1 state, in which Ca^{2+}-binding sites have high affinity and the cytoplasmic headpiece is open. The first Ca^{2+} will enter the binding cavity through improperly formed site II (otherwise, it will be trapped there) and binds to site I. This will rotate M6 and position Asp800 properly. The M5 helix will straighten (Fig. 1b) and alter the arrangement of oxygen atoms in site II to form a higher affinity binding site. Finally the carboxyl of Glu309 side chain will cap site II Ca^{2+}, and the binding signal is transmitted to the phosphorylation site some 50 Å away. Because there is enough space around Glu309, the cytoplasmic gate remains unlocked, and site II Ca^{2+} is exchangeable with those in the cytoplasm (Fig. 4a).

E1·2Ca^{2+} → E1P: occlusion of bound Ca^{2+}. ATP cross-links the P- and N-domains, so that the γ-phosphate of ATP and a Mg^{2+} bind to the P-domain to bend it in two directions (Fig. 3). This bending of the P-domain tilts the A-domain sitting on the P7 helix by ~30° (1 in Fig. 2b), and thereby places strain on the link between the A-domain and the M3 helix. This strain appears to be the driving force for the A-domain rotation in the next step. At the same time, the M1 helix is pulled up (small arrows in broken lines; Fig. 2a) to fix the side chain conformation of Glu309 by occupying the space around it. Thus, the cytoplasmic gate is locked and two Ca^{2+} are occluded in the transmembrane binding sites.

E1P → E2P: release of Ca^{2+} into the lumen of SR. Phosphoryl transfer to Asp351 allows the dissociation of ADP, which triggers the opening of the N- and P-domain interface. The A-domain rotates 90° (2 in Fig. 2b) and brings the ^{181}TGES loop of the A-domain deep into the gap between the N- and P-domains above the aspartylphosphate so that it occupies the space where ADP was in E1P·ADP to prevent rebinding of ADP. At the same time, it shields the aspartylphosphate from bulk water. The A-domain rotation causes a 30° change in inclination of the P-domain toward M1, which in turn causes a drastic rearrangement of the transmembrane helices M1–M6, including a large (~5.5 Å) downward movement of M4, sharp bending of M5 toward M1 (Fig. 2b), and rotation of M6 (Fig. 4b), which destroy the Ca^{2+}-binding sites. The V-shaped structure formed by the M1 and M2 helices pushes against M4L, opening the lumenal gate and releasing the bound Ca^{2+} into the lumen (Fig. 2b). This will allow protons and water molecules to enter and stabilize the empty Ca^{2+}-binding sites.

E2P → E2: hydrolysis of aspartylphosphate and closing of the lumenal gate. The A-domain rotates further by 25° around a different axis (3 in Fig. 2b). This rotation places further strain on the M2 helix, which, as a result, partly unwinds and releases the V-shaped structure formed by the M1 and M2 helices so that it takes a ~5 Å lower position toward the lumenal side. This movement imposes more upright position on M4L and closes the lumenal gate. At the same time, the rotation of the A-domain introduces one water molecule in the phosphorylation site. Glu183 in the TGES loop activates the water molecule to attack aspartylphosphate. Then, the resultant inorganic phosphate and Mg^{2+} are released and the P-domain becomes relaxed (4 in Fig. 2b). This in turn releases the M1 and M2 helices to lock the lumenal gate and places the ATPase into the E2 state.

E2 → E1: release of protons and change in affinity of the Ca^{2+}-binding sites. The E2 state, or more rigorously, E2·nH^+ (n = 2 or 3) state is unstable at pH 7, and protons are released spontaneously into the cytoplasm to confer high affinity on the Ca^{2+}-binding sites. ATP can bind to the ATPase in the E2 state and accelerate this transition presumably by opening the cytoplasmic headpiece. One Mg^{2+} may bind to the Ca^{2+}-binding sites with mM K_d and accelerate the reaction cycle presumably by achieving most of structural changes that occur on the binding of first Ca^{2+}. Thus, the ground state under physiological conditions is E1·Mg^{2+}. There is confusion on this point in the literature.

Calcium in Biological Systems

Robert H. Kretsinger
Department of Biology, University of Virginia, Charlottesville, VA, USA

Synonyms

Calcium as a secondary messenger; Calmodulin; Cytosolic signaling; EF-hand proteins; Myosin light chains; Troponin C

Definition

The variation in the concentration of free Ca^{2+} ion within the cytosol over time is a form of information. This information can be transduced into a change in protein conformation and/or enzyme activity by interaction with a calcium-modulated protein(s).

Overview

Calcium is unique in biological systems. Ca^{2+} is the only metal cation demonstrated to function as a secondary messenger in the cytosol of eukaryotes. The information in this pulse of Ca^{2+} ions (Berridge 2006) is transduced into a change of conformation of a calcium-modulated protein(s). Many of these calcium-modulated proteins contain two to twelve tandem EF-hand domains. Others contain one or two C2 domains or four annexin domains. Numerous calcium channels and calcium pumps in the membranes of the cell and its various organelles, especially the endoplasmic reticulum, are involved in tuning the calcium concentration in the cytosol (Permyakov and Kretsinger 2010).

This standard model requires several refinements. Some EF-hand proteins are involved in temporal buffering of waves or pulses of calcium in the cytosol; others appear to be involved in facilitated diffusion. Many extracellular proteins bind calcium; it is essential for their stabilities and functions. The concentration of free Ca^{2+} ions is usually held constant in the extracellular fluid, or plasma, of multicellular organisms. However, there is some evidence that $[Ca^{2+}]_{out}$ may vary in a controlled manner over restricted volumes and/or brief times. Calcium may be involved in extracellular signaling (Hofer 2005); these target proteins are considered to be calcium modulated. Some prokaryotes have calcium-binding proteins; however, there is no evidence of calcium functioning as a second messenger (Permyakov and Kretsinger 2009).

Over 30 distinct biominerals have been identified; most contain calcium (Lowenstam and Weiner 1989). These calcium carbonates and phosphates contain proteins that are inferred to be essential in determining their rates of formation and domain structures as well as the mechanical properties of shells, teeth, and bones. Many diseases are associated with mutations and/or malfunctions of these diverse calcium-binding proteins including pumps and channels.

Calcium Coordination

Many of these unique properties of calcium in biology can be related to its basic chemistry. Calcium (Latin calc, "lime") is the fifth most abundant element and the third most abundant metal in the earth's crust. The stable ion Ca^{2+} has the electron configuration of argon – $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6$ – plus two additional protons; it is less reactive than the alkaline metals. Calcium has four stable isotopes (^{40}Ca, ^{42}Ca, ^{43}Ca, and ^{44}Ca), plus two more isotopes (^{46}Ca and ^{48}Ca) that have such long half-lives that for all practical purposes, they can be considered stable. It also has a radioactive isotope ^{41}Ca, which has a half-life of 103,000 years. Ninety-seven percent of naturally occurring calcium is ^{40}Ca.

Seawater contains approximately 400 ppm calcium, nearly all free Ca^{2+} ion (~10 mM). Calcium makes up 3.5% of the earth's crust and occurs almost solely in inorganic compounds. It is obtained from carbonate minerals like chalk, limestone, dolomite, and marble. Six metals are present in the human body in high concentrations: calcium (1,700 g per 70 kg of body mass), potassium (250 g), sodium (70 g), magnesium (42 g), iron (5 g), and zinc (3 g). Other metals are present less than 1 g per 70 kg of body mass (Permyakov and Kretsinger 2010).

Fifteen metals are essential for at least some organisms. They are considered in two groups: nontransition (Na, K, Mg, Ca, Zn, Cd) and transition elements (V, Cr, Mn, Fe, Co, Ni, Cu, Mo, W). Atoms of alkali elements, sodium and potassium, possess one *s*-electron in the outer shell besides the electron structure of rare gas atoms; therefore, they are characterized by low ionization potentials (5.138 and 4.339 eV, respectively). Their ions have relatively large radii (1.02 and 1.38 Å). The ionization potential of the calcium atom ($1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6\ 4s^2$) for the first electron is 6.1132 eV; the ionization potential for the second electron is 11.871 eV. In normal geological and biological conditions, the Ca^{1+} ion does not exist. The completely filled octets of the Mg^{2+}, Ca^{2+}, and Sr^{2+} ions ($2s^2\ 2p^6$, $3s^2\ 3p^6$, and $4s^2\ 4p^6$, respectively) have no preferences with respect to the direction of bond formation and can be modeled by spheres with increasing radii (0.72, 0.99 and 1.35 Å) and decreasing charge density. The similar sizes of the ions of calcium and of the lanthanides (0.99 and 1.06–0.85 Å) allow the lanthanides to replace calcium in many binding sites; this is useful for spectroscopic studies. The alkali and alkaline earth metals have very weak tendencies to form covalent bonds.

The transition elements involved in biological processes – V, Cr, Mn, Fe, Co, Ni, Cu, Mo, W – have

incompletely filled *d*-orbitals; Cu is actually $4s^1\ 3d^{10}$. They, including copper, are characterized by variable valences and formation of colored complexes and paramagnetic substances due to unpaired electrons. The transition elements are often involved in redox reactions.

Zinc and cadmium are not transition elements since they have no empty *d*-orbitals. Zn^{2+} ions are different from the other non-transition metal ions. While the radius of Zn^{2+} ion (0.74 Å) is close to the radius of the Mg^{2+} ion (0.72 Å), its ionization potentials are higher than those of calcium and magnesium. The high values of zinc ionization potentials (9.394 and 17.964 eV) are reflected in its stronger tendency to form covalent bonds. It is bound by many proteins.

Metal cations in aqueous solution are surrounded by water molecules oriented by the electric field of the ion; this creates charge–dipole interactions. The smaller the radius of an ion, the greater the charge density and the stronger is its interaction with the dipole moment of water. Some ions possess a rather rigid and stable first hydration shell that can have tetrahedral (Li^+) or octahedral (Mg^{2+}, Co^{2+}, Ni^{2+}) geometry. The Zn^{2+} ion can have both tetrahedral and octahedral coordination in the first hydration shell. The Mg^{2+} ion, with its +2 charge and small radius, tightly orders six water molecules in an octahedral arrangement in the first hydration shell. The second, and perhaps third, layers of water are also organized by the charge of the ion and contribute to the overall hydration free energy of -455 kcal mol^{-1}. The K^+ ion is larger and has only a +1 charge; as a result, eight or nine water molecules pack around the ion in a less well-ordered manner; the hydration energy is -80 kcal mol^{-1}. Because the Mg^{2+} ion interacts strongly with six water molecules in $[Mg(H_2O)_6]^{2+}$, larger anions do not readily replace the water to give precipitates. The larger Ca^{2+} ion binds more strongly to those larger anions relative to water; hence, these anions displace water from calcium more readily. Large anions, CO_3^{2-} and PO_4^{3-}, precipitate with calcium at lower metal ion concentrations than with magnesium. As a consequence, calcium has a lower concentration in sea water ($\sim$10 mM for $[Ca^{2+}]$ versus $\sim$50 mM for $[Mg^{2+}]$). One can find deposits, both geochemical and biochemical, of $CaCO_3$, $CaSO_4$, and $Ca_3(PO_4)_2$, but not of the corresponding magnesium salts except mixed in the calcium salts, for example, dolomite ($CaMg(CO_3)_2$). Calcium oxalate is insoluble; its crystals are found in plant tissue, but magnesium oxalate is soluble. Moreover, calcium tends to precipitate many polyanions, such as DNA, RNA, and some acidic proteins (Lowenstam and Weiner 1989; Mann 2001).

Calcium and monovalent metal cations, except Li^+, have a wide variety of geometries of the first hydration shell. The number of water molecules associated with the cation and the distance between them and the central ion vary and increase with increasing ion size. Because the six oxygens of hexa-aquo-magnesium are in optimal van der Waals contact and leave slowly, magnesium association rate constant, $k_{on}(Mg)$, for proteins is relatively low. In contrast, the waters of hepta-aquo-calcium have more lateral mobility; thus, $k_{on}(Ca)$ is much faster; this accounts for most of the difference in affinity of calcium-binding proteins for calcium versus magnesium. The Ca^{2+} ion is heptahydrate and has a diffusion coefficient of 1.335 10^{-9} m^2 s^{-1} in water at 25°C and a water exchange rate of 10^8–10^9 s^{-1}.

The favored coordination for the Mg^{2+} ion is sixfold octahedral. Ca^{2+} shows a greater diversity of coordination numbers, with seven- and eightfold coordination the most common in crystal structures of small organic molecules complexed with calcium. Bond distances between the Ca^{2+} ion and its ligands vary more than do those of Mg^{2+}. The radius of the coordination sphere is significantly larger for calcium than for magnesium ions: bond distances to oxygen donor atoms typically range from 2.0 to 2.1 Å for Mg^{2+} and 2.2 to 2.5 Å for Ca^{2+}. Compared to Mg^{2+} ions, Ca^{2+} forms looser complexes of higher and variable coordination number, without directionality, and with more variable bond lengths (Permyakov and Kretsinger 2010).

Calcium-Modulated Proteins

Those calcium-binding proteins in the cytosol or bound to membranes facing the cytosol are inferred to be calcium modulated. That is, when the cell is quiescent, the concentration of the free Ca^{2+} ion is less than 10^{-7} M (pCa $>$ 7) and the calcium-modulated protein is in the apo- or magnesi-form. Following stimulus, the concentration of calcium rises (pCa $<$ 5.5), and the protein binds calcium (Whitiker 2010). The attendant change in structure is involved in the transduction of the information of a pulse or wave of

Ca^{2+} ions to an ultimate target enzyme or structure. Most of these calcium-modulated proteins contain from two to twelve copies of the EF-hand domain (Nakayama et al. 2000). There are other proteins in the cytosol that bind calcium and also appear to be modulated by calcium; these include proteins that contain one or several C2 domains, such as protein kinases C or synaptotagmin, the annexins, as well as calcium pumps and channels.

Many of the functional characteristics of calcium and of calcium-modulated proteins can be rationalized from the geometry of calcium coordination. In proteins, the Ca^{2+} ion (atomic radius 0.99 Å) is usually coordinated by seven oxygen atoms in an approximate pentagonal bipyramidal conformation at average Ca-O distance 2.3 ± 0.2 Å; the oxygen atoms have some lateral flexibility. The Mg^{2+} ion (atomic radius 0.65 Å) is usually bound by six oxygen atoms at the vertices of an octahedron with Mg-O distance 2.0 Å; these oxygens are in tight van der Waals contact with one another. Although many small molecules bind magnesium with greater affinity than they bind calcium, most intra- and extracellular proteins bind calcium with much greater affinity than they bind magnesium.

The dissociation constant is the ratio of the off rate to the on rate: $K_d\ (M) = k_{off}\ (s^{-1})/k_{on}\ (M^{-1}\ s^{-1})$. The rate-limiting dehydration of $Ca(H_2O)_7{}^{2+}$ is fast, $\sim 10^{8.0}\ s^{-1}$, while that of $Mg(H_2O)_6{}^{2+}$ is slow, $10^{4.6}\ s^{-1}$. This difference reflects the loose pentagonal bipyramidal versus the tight octahedral packing of the oxygen ligands. The cation must be (partially) dehydrated before it can bind to the protein. These rates are important for modeling the flux of Ca^{2+} ions through the cytosol and the attendant binding of proteins. The increase in affinity of most proteins for calcium relative to magnesium derives primarily from this difference in k_{on} (Permyakov and Kretsinger 2010).

Calcium-Binding Proteins

Certainly, calcium-modulated proteins bind calcium; the term "calcium-binding proteins" may be short hand for those that are not demonstrated to be calcium modulated and/or are not intrinsic membrane proteins. Calcium may be essential to maintain the structure, stability, and functions of these calcium-binding proteins. However, they are not directly involved in information transduction pathways. The apo-forms of calcium-modulated proteins usually have well-defined structures. They undergo a change in conformation upon binding calcium as an essential step in information transduction, as illustrated for the N-terminal EF-lobe of calmodulin (Fig. 1). In contrast, the apo-forms of (non-calcium-modulated) calcium-binding proteins are often disordered and are not usually encountered under physiological conditions.

Biomineralization

Cells, especially bacteria and protists, can alter the ion concentrations in their immediate environment, thereby inducing precipitation of (usually) amorphous biominerals, so-called "*b*iologically *i*nduced *m*ineralization" (Mann 2001).

Biomineralization can occur intracellularly in vesicles derived from the Golgi apparatus or endoplasmic reticulum. These membrane-enclosed vesicles, for instance, those containing amorphous calcium phosphate in bone, may be retained within the cell. Or, following exocytosis, or polarized budding of the cell membrane, the vesicles, so-called exosomes, may fuse and/or dissolve to release their minerals into the extracellular environment, for example, mollusk shells or chiton teeth. Packets of amorphous calcium phosphate attached to collagen fibrils are the precursors of plates of hydroxyapatite attached to theses fibrils.

Animals can create an extracellular space (partially) enclosed by cells and/or an impermeant matrix. They change its composition by ion pumps in the cell or vesicle membranes. And they synthesize and/or secrete polysaccharides and proteins in(to) this space – "*b*iologically *c*ontrolled *m*ineralization." The resultant minerals are (usually) amorphous precipitates. These usually, but not always, undergo one or several transitions to the lowest free energy crystal form. The resultant crystals may be randomly oriented, in terms of their crystallographic axes, or aligned relative to the organic matrix. In either case, they will have incorporated some of the protein or polysaccharide into the macroscopic crystals observed in the matured or maturing organism. These organics may be incorporated into the macroscopic crystal in fault lines between smaller, perfect crystal domains. Or, the organic(s) may form a distinct layer with its fiber axes aligned and thereby directing the orientation of the

mineral crystallites. This implies some sort of (quasi) epitaxis, a subject of much speculation but limited experimental evidence.

The overall shapes of these crystallites usually differ from those of their inorganic counterparts. A plausible mechanism, a sort of anti-epitaxis, posits that certain inhibitory proteins, often containing γ-carboxyglutamic acid, selectively bind to specific faces, thereby inhibiting growth in that direction but permitting it in other directions (Mann 2001). The details of these calcium–proteins interactions in the solid state are poorly understood.

Summary

The chapters in this volume focus on the soluble calcium-binding and calcium-modulated proteins because more is known of their structures and modes of actions. They provide a reference or comparison for the intrinsic membrane proteins and those associated with biominerals.

Definition of the Subject

Calcium is involved in almost every cellular activity. As a second messenger it is a critical component of the signaling network. It, furthermore, links mitochondrial energy production by oxidative phosphorylation to the actual energy demand. As complex animals left the oceanic calcium-rich environment to adopt terrestrial life they carried with them a huge calcium reservoir in their bones that guarantees the supply of the hundred times smaller amount of calcium vital for cell survival by maintaining calcium homeostasis. In contrast, too much calcium in the cell under pathologic condition or physical cell lesion presents a death signal (cardiac infarction, brain stroke). The human genome contains over 200 genes coding for calcium binding proteins (primarily EF-hand proteins). Their functions and relations to disease are discussed. The final remarks refer to the genetic makeup which may affect many of the regulatory proteins responsible for calcium homeostasis. Since longevity has significantly increased in recent times medicine is confronted with late-onset diseases caused by genetic defects dating from ancient times, hundreds of thousands to millions of years ago.

Scope of This Brief Essay on Calcium in Health and Disease

How and why has Nature come to rely on calcium as a ubiquitous dynamic signaling (free Ca^{2+} ions) as well as a structural (in organic and inorganic complexes) component. Calcium is the most abundant mineral in the body, bones and teeth, accounting for >99% of the total of around 1 kg (Williams and Fausto da Silva 2006). For Ca^{2+} to act as intracellular messenger receptor proteins have evolved that recognize the Ca^{2+} signal (Berridge 2005; Bradshaw and Dennis 2009; Haiech et al. 2009, 2011). These calcium sensors contain highly specific Ca^{2+} binding sites, so-called EF-hands (a characteristic helix-loop-helix structure with one Ca^{2+} binding to the loop), which will be described in detail in several other contributions in this Encyclopedia. Suffice it to mention that starting with the first Ca^{2+} sensing protein, troponin-C in striated muscles, followed by brain calmodulin in the 1960s, over 66 subfamilies with Ca^{2+} binding EF-proteins stemming from over 200 human genes have been described so far (Schaub and Heizmann 2008; Nakayama et al. 2000; Heizmann et al. 2002; Krebs and Michalak 2007; Leclerc and Heizmann 2011). Many of these proteins proved to be related to various diseases and a selection of them have been compiled in Table 2 toward the end of the article. If not tightly controlled Ca^{2+} is a highly cytotoxic substance. Any drastic Ca^{2+} overload in a living cell leads to its death. The routes of the cellular Ca^{2+} death converge in the mitochondria where they will bring the energy production to a halt (Carafoli and Brini 2008). The mitochondrial structures on which the Ca^{2+} load imprints its kiss of death will briefly be discussed. Several aspects of calcium in health and disease will be highlighted by selected examples rather than treated in general terms. Above all, however, only detailed knowledge of the normal functioning of Ca^{2+} physiology allows one to better understand disease pathways. Because of space limitation, only few overviews and books could be cited

from where the primary literature can be retrieved. However, references specifically pertaining to the clinical relevance of individual EF-hand proteins for various diseases as listed in Table 2, are also incorporated in the reference list.

Is Calcium More Toxic than Botulinum Toxin?

The answer is not as easy as it may look. True, the toxin (a disulfide-linked dimer of two polypeptides of 50 and 100 kDa) produced by the anaerobic, Gram-positive bacterium *Clostridium botulinum* (in Latin botulus means "sausage") is the most acutely toxic substance known. Ninety to 200 ng of botulinum toxin applied intravenously or by inhalation suffices to kill an adult person, and 4 kg would be more than enough to eliminate the entire human population of the world. The heavy chain of the toxin targets the poison to the nerve axon terminals (Brunger et al. 2008). The light chain of the toxin is a proteinase attacking some of the fusion proteins (SNARE proteins) in the neuromuscular junction, thereby preventing it from anchoring nerve vesicles to the presynaptic membrane, thus inhibiting release of acetylcholine. By interference with the nerve impulses it causes flaccid muscle paralysis. Fortunately, however, one seldom encounters this lethal toxin, and if canned meat is under suspicion, heating destroys the toxin. It is nevertheless feared as a potential bioterror weapon.

How does the cytotoxicity of Ca^{2+} compare to botulinum toxin? Ca^{2+} as ubiquitous intracellular second messenger presents a vital signaling component involved in virtually all cell activities including regulation of metabolic enzymes, membrane-linked processes (excitation-contraction, -secretion, and -transcription coupling, nerve impulse transmission), hormonal regulations, control of contractile and motile systems, cell cycle, fertilization, and vision. In cardiomyocytes the cytoplasmic Ca^{2+} concentration is very low at rest $\sim 10^{-7}$ M which is almost 20,000-fold lower than in the extracellular space (Table 1). The Ca^{2+} signal for a heart beat (heart muscle contraction) transiently increases the very low cytoplasmic Ca^{2+} concentration about 100-fold to 10^{-5} M. This signal results from Ca^{2+} entry into the cell through the voltage-gated L-type Ca^{2+}-channel (LCC) upon surface membrane depolarization (Fig. 1), and subsequently further Ca^{2+} is released from the intracellular sarcoplasmatic reticulum (SR) via the ryanodine Ca^{2+} release channel (RYR). After a fraction of a second the activator Ca^{2+} will be removed again by the Ca^{2+}-pumps and the Na^+/Ca^{2+}-exchanger (NCX) for muscle relaxation (more detailed description in Sect. Regulation of Cardiac Contraction by Calcium Signaling). Such highly precise regulation of cytoplasmic Ca^{2+} requires extremely fast (operating in the millisecond time range) mechanisms to shift Ca^{2+} between extracellular and intracellular compartments involving various pumps and channels (Fig. 1). For instance, a voluntary skeletal muscle that goes from rest into mechanical activity increases its energy requirement 2,000-fold within a fraction of a second. The signaling Ca^{2+} for contraction at the same time must also assure the necessary metabolic activation for sufficient ATP production. Should anything go off course with the Ca^{2+} control, in particular, too much Ca^{2+} in the cytoplasm would severely damage if not kill the cell. Since all cells of the body are bathedin this highly toxic environment containing $\sim$2 mM Ca^{2+} it is most likely that an excess of Ca^{2+} may enter the cytoplasm following any cell lesion. Any cell death results from Ca^{2+} overload in the cytoplasm including myocardial infarction, brain stroke, degenerative nerve cell diseases, inflammatory cell death, ischemia-reperfusion injury etc.

Thus, in contrast to botulinum toxin, our body cells are constantly exposed to a massive burden of deadly toxic Ca^{2+}. Each living cell must have developed robust devices to rid it from excessive Ca^{2+}. Early in the sixteenth century the Swiss-born Philippus Aureolus Theophrastus Bombastus von Hohenheim, called Paracelsus, introduced some rationale in the patient treatment, in particular, he stated: "the dose

Calcium in Health and Disease, Table 1 Approximate extracellular and intracellular ion concentrations of a cardiomyocyte

Ion	Extracellular concentration (mmol/L)	Intracellular concentration (mmol/L)	Ratio of extracellular to intracellular ion concentrations
Na^+	145	15	10
K^+	4	150	0.03 (40-fold difference)
Cl^-	120	5–30	4–25
Mg^{2+}	1	1	1
Ca^{2+}	2	0.0001 (cytoplasm)	20,000

L = voltage-gated L-type Ca^{2+}-channel (LCC); NCX = Na^+/Ca^{2+}-exchanger; RYR = ryanodine receptor, Ca^{2+} release channel of the SR; IP3R = inositol trisphosphate receptor, Ca^{2+} release channel of the SR; KATP = ATP-dependent K^+-channel. The resulting imbalances of ion distribution across the cell surface membrane are given in Table 1. Collectively, the various ion gradients give rise to the membrane resting potential of around −80 mV (positive outside and negative inside). For further explanations see text

makes the poison." This statement holds true until today: any medicine with an impact becomes poisonous when overdosed. It also applies to both Ca^{2+} and botulinum toxin. Minute amounts of this latter toxin injected into specific muscles will weaken them for a period of several months and is used to prevent formation of wrinkles by paralyzing facial muscles. In fact, it is the most common cosmetic operation today. On the other hand, in view of the large amount of calcium in the bones and the complicated hormonal control of its partition over different pools it is almost impossible to influence the body calcium content. Only the small and dynamic intracellular fraction may be affected by the so-called calcium channel blockers that bind to LCC and reduce extracellular Ca^{2+} entry during the action potential. As the dihydropyridine drugs presenting the major class of calcium channel blockers bind to LCC, these channels are also known as dihydropyridine receptors (DHPRs). The ion gradients between extra- and intracellular compartments of a cardiomyocyte are provided by energy (ATP) consuming ion pumps in functional interaction with ion channels and exchangers (see Fig. 1 and Table 1).

Bodily Calcium Balance

Calcium is the fifth most abundant element in the human body. It is an essential element that is available only through dietary sources. Its metabolism depends on (i) intestinal absorption, (ii) renal reabsorption, and (iii) bone turnover. These processes are in turn regulated by a set of interacting hormones including parathyroid hormone (PTH), 1,25-dihydroxyvitamin-D (1,25D), ionized calcium itself, and their corresponding receptors in the gut, kidney, and bone. Up to 50% of bone is made up of the inorganic calcium hydroxyapatite (known as bone mineral) interwoven with the collagen fiber network providing structural strength. The non-bone calcium (10–15 g in an adult) representing <1% of total body calcium is in constant and rapid exchange among the various calcium pools. Serum calcium ranges from 2.2 to 2.6 mM in healthy subjects. It comprises free Ca^{2+} ions (~51%), protein bound complexes (~40%) mainly with albumin and globulin, and ionic complexes (~9%) mainly Ca^{2+}-phosphate, Ca^{2+}-carbonate, and Ca^{2+}-oxalate. Only free Ca^{2+} ions are in equilibrium between the different calcium pools.

To avoid calcium toxicity, the concentration of serum ionized Ca^{2+} is most tightly maintained within a physiological range of 1.10–1.35 mM. This concentration range extends to the extracellular fluid compartment (EFC), which provides the backup for delivery to and reuptake of Ca^{2+} from the cells. Serum Ca^{2+} homeostasis is regulated by a rapid negative feedback hormonal pathway. A fall of serum Ca^{2+} inactivates the Ca^{2+}-receptor (CaR) in the parathyroid cells and increases PTH secretion, which restores serum Ca^{2+} by activating the parathyroid receptor (PTHR) in bone, to increase Ca^{2+} resorption, and in kidney, to increase tubular Ca^{2+} reabsorption. In kidney, the increased PTH secretion augments its Ca^{2+} restorative effect by increasing secretion of 1,25D which through the vitamin-D receptor (VDR) in the gut, increases active Ca^{2+} absorption and increases Ca^{2+} resorption in bone. Calcitonin produced by the parafollicular C-cells in the thyroid gland inhibits the activity of osteoclasts which digest bone matrix, thereby, releasing Ca^{2+} and phosphorus into the blood. In the kidney, calcitonin inhibits tubular reabsorption of both Ca^{2+} and phosphorus promoting their loss in the urine. The contribution of calcitonin in serum Ca^{2+} regulation varies from species to species and is almost negligible in humans.

During youth the calcium-bone balance is positive for bone formation (formation > resorption), in young adults it is neutral (formation = resorption), while with advancing age it becomes negative (formation < resorption). The threatening occurrence of osteoporosis at higher age is often therapeutically encountered by higher calcium intake combined with biphosphonate drugs. However, the efficiency of this treatment is questionable as almost the entire excess calcium offered over the normal daily nutritional intake is excreted via kidney, feces, and sweat. What the experts agree on is that this treatment activates bone metabolic turnover. The bone structure is, however, remodeling throughout life, renewing the entire skeletal tissue on average every 10–12 years. In order to fend off osteoporosis it is important to combine calcium supply with the correct amount of vitamin-D. In addition, estradiol levels may have to be redressed in women with osteoporosis. In elderly patients (>70 years of age) with cardiovascular risks calcium supplementation should be limited to the dietary reference intake of around 1,200 mg in order to avoid ectopic calcification of the vascular system.

In summary, the tight regulation of Ca^{2+} in serum and EFC is a prerequisite for its safe use as intracellular signaling component. About 1 g of calcium is in the plasma and EFC, while all tissue cells together comprise 6–8 g of calcium mostly stored in intracellular vesicles such as sarcoplasmatic (SR) and endoplasmatic (ER) reticulum (Fig. 1). This dynamic calcium-system is safely backed up by the massive 1 kg calcium-store in the bones. Approximately 400 Ma ago, the ancestors of the bony fish (osteichthyes) and cartilaginous fish (chondrichthyes) diverged in the Silurian period. The structural strength of a calcified skeleton was critical for complex animals at the end of the Devonian period when they left the calcium-rich ocean to resume life on land after plants had already conquered dry land. So the calcium-rich bones made up for the loss of calcium in the oceanic environment supporting the calcium-dependent regulation of cells and nervous system.

Calcium as Intracellular Second Messenger

How can calcium function as highly specific intracellular signal transmitter? Divalent cations such as Ca^{2+} and Mg^{2+} can form more stable and more specific complexes with organic substances like proteins than the other abundant monovalent cations Na^+ and K^+. They do, however, not form covalent bonds in biology. Energy usage in all living cells relies on phosphoryl bond breakdown and Ca^{2+} more readily than Mg^{2+} forms insoluble salts with the originating inorganic phosphate and pyrophosphate; this limits its solubility to around 10^{-3} M. This lower solubility of calcium salts required Ca^{2+} to be ejected from the cytoplasm while Mg^{2+} could be kept in the cells in millimolar concentrations where it serves as cofactor in enzyme reactions involving the MgATP complex. Consequently, all living cells have developed robust devices to rid the intracellular space from Ca^{2+} by energy consuming ion pumps and ion channels (Fig. 1). As mentioned, Ca^{2+} in the EFC and in the cells (outside the bony skeleton) amounts to 10–15 g while the total bodily Mg^{2+} content is about 25 g. One third of the Mg^{2+} is in the cells (~9 g, corresponding to a concentration of ~18 mM^{-1}) of which only a small fraction is ionized (~ 1 mM^{-1}) with almost the same concentration inside and outside of the cells (Table 1). Calcium as member of the 4th row in the periodic table of elements

(4 electron shells) has a more complex electron configuration than magnesium (in the 3rd row of the periodic table with 3 electron shells) allowing for greater flexibility of Ca^{2+} in coordination with protein ligands (usually with 6–8, but up to 12 coordination points are possible). In contrast, Mg^{2+} (ionic radius = 0.64 Å) is much smaller than Ca^{2+} (ionic radius = 0.99 Å) and requires a strictly fixed geometry with 6 coordinating oxygen atoms in binding with proteins. Importantly, ligand binding by Ca^{2+} to the protein sensor sites is ~1,000 times faster than with Mg^{2+}. What kind of animal life would that be with Mg^{2+} as signal transmitter operating at a 1,000-fold slower time scale? Slow thinking and slow moving, a concert pianist could not play a trill with 10 key strokes per second. Finally, the enormous Ca^{2+} gradient between cell inside and outside presents a large electrochemical potential that can be used to create signaling Ca^{2+} spikes by letting Ca^{2+} ions quickly enter via the LCC in the cell membrane.

Canonical EF-Hand Calcium Sensor Proteins

In the 1960s, troponin-C (TNC, ~18 kDa mass), which is involved in regulation of contraction in striated muscle (skeletal and heart muscle), was the first characterized intracellular Ca^{2+} sensor protein, being joined soon after by parvalbumin (PARV, 12 kDa) isolated from fish and frog muscles and calmodulin (CAM, ~16.8 kDa) obtained from the brain. TNC is firmly incorporated in the actin filament structure of striated muscle and in cooperation with troponin-I (TNI, ~24 kDa), troponin-T (TNT, ~36 kDa), and tropomyosin (TM, 28.5 kDa) presents the Ca^{2+}-dependent switch for muscle activity. There are two TNC isoforms, cardiac TNC (cTNC, exclusively expressed in cardiac and slow contracting aerobic muscle fibers) and fast skeletal muscle sTNC, which are the products of two different genes, TNNC1 (cTNC) and TNNC2 (sTNC). Mutations in all troponin components as well as in tropomyosin, collectively known as striated muscle regulatory proteins, have been found that may cause different forms of hereditary heart disease including hypertrophic (HCM), dilated (DCM), restrictive (RCM), and non-compaction cardiomyopathies. Most of these hereditary cadiomyopathies are either caused or accompanied by changes in Ca^{2+} signaling quality, i.e., increased or decreased Ca^{2+}-sensitivity of the contractile machinery.

CAM is a ubiquitous cytoplasmic Ca^{2+}-sensor that by interaction with over 100 different proteins regulates the activity of a myriad of soluble and structural components in different cell compartments. CAM is the prototypical intracellular Ca^{2+}-sensor containing four canonical Ca^{2+} binding EF-hands. It contains two EF-hands in the N-terminal and two EF-hands in the C-terminal portions of the dumbbell-shaped molecule. It is assumed that the compact structure of CAM with four EF-hands may have arisen in prokaryotes by two subsequent gene duplications from a single EF-hand precursor protein. This prokaryote Ca^{2+} binding CAM seems to have been so successful that it was carried over into the eukaryotic lineage where it was preserved in the kingdoms of protista, fungi, plantae, and animalia. CAM is one of the most conserved proteins with 100% amino acid (AA) sequence identity among all vertebrates. It consists of 149 AA including the N-terminal methionine which may be removed in the mature protein. Around 500 Ma ago the genome of all vertebrates contained three separate CAM genes. Mammalians including humans still contain three different genes, all coding for the same AA sequence. Why are there three genes for the same protein? It seems that the 5′- and 3′- untranslated regions (UTR) may vary to some degree between the three genes possibly permitting different protein expression levels at discrete cellular sites during differentiation and in highly specialized cell types such as neurons or striated muscle cells. No structural mutations have been reported so far for CAM exons indicating they probably would not be compatible with life. On the other hand, several point mutations in the introns flanking exons 3 and 4, whose significance remains unknown, have been described.

The evolutionary relation based on sequences indicates that CAM and cTNC together with sTNC, myosin essential light chain (ELC), myosin regulatory light chain (RLC), and parvalbumin (PARV) belong to the so-called CTER family of EF-hand proteins. CTER stands for CAM, TNC, ELC, and RLC. All these proteins contain 4 EF-hand motifs with the exception of PARV which has lost one of them in the distant past. In addition, some of the EF-hands in these proteins have also lost the Ca^{2+} binding capacity due to evolutionary sub-functionalization. CAM does not only bind to targets when it is saturated with Ca^{2+}, but it can

also be firmly associated with some proteins in its apo-form (no Ca^{2+} bound) where it may function as a Ca^{2+}-sensor subunit in a heteromeric protein complex. This is the case with proteins relevant for Ca^{2+} regulation such as RYR, the pore forming subunit of the LCC, the inositol 1,4,5-trisphosphate (IP3) -operated Ca^{2+} release channel (IP3R = IP3 receptor) of the SR or ER, and phosphorylase kinase. In other Ca^{2+} regulated proteins a single EF-hand motif is found integrated in the primary structure as, for instance, in calcineurin-B, dystrophin, calpain proteases, vertebrate phosphodiesterases and in RYR.

The S100 Protein Family

The first S100 protein was isolated from brain also in the 60s of the last century, which is now known as S100B. It is a small (~10.7 kDa) acidic protein soluble in 100% saturated ammonium sulfate solution and hence named "S100." The S100 proteins are, compared to CAM, phylogenetically late-comers exclusively expressed in vertebrates, fishes, amphibians, reptiles, birds, and mammalians. They represent the largest subgroup within the superfamily of Ca^{2+} binding EF-hand proteins. At least 20 S100 protein coding genes have been located in the human genome 16 of which are clustered in a region of chromosome 1q21. This region is prone to molecular rearrangement linking S100 proteins and cancer. The S100 proteins derived from the 1q21 gene cluster are designated as S100A followed by Arabic numbers (S100A1, S100A2, S100A3 etc.). In contrast, proteins from other chromosomal regions just bear a letter (S100B, S100C, S100D etc.).

The S100 proteins (molecular weight 9–13 kDa) contain two Ca^{2+} binding motifs, one classical C-terminal EF-hand (as the four EF-hands in CAM with 12 AA in the Ca^{2+} binding loop) and one S100-specific N-terminal "pseudo EF-hand" (with 14 AA in the binding loop). Moreover, the Ca^{2+} binding loop in the S100 pseudo EF-hands varies considerably between the different proteins allowing for functional differentiation. Usually two S100 proteins form a functional dimer with the two protein monomers running side-by-side in opposite direction (antiparallel), though also heterodimers and few multimers can be found. Upon Ca^{2+} binding the C-terminal EF-hand undergoes a large conformational change resulting in the exposure of a hydrophobic surface responsible for target binding. The expression of the S100 members is often tissue and cell type specific. A unique feature of these proteins is that some members are secreted from cells upon stimulation. In the high extracellular Ca^{2+} concentration larger complexes are formed which act as pro-inflammatory signaling components through activation of RAGE (receptor for advanced glycation end-products) and Toll-like receptor-4 (Leclerc and Heizmann 2011).

Ca^{2+} binding to S100 proteins induces structural changes that allow interaction with target proteins and modulation of their activity. These protein-protein interactions also significantly affect the Ca^{2+} binding properties (affinity and kinetics). Furthermore, the regulatory properties of specific S100 proteins can be altered by various post-translational modifications including phosphorylation, nitrosylation, citrullination, carboxymethylation, glutathionylation, transamidation, or sumoylation.

In contrast to CAM and TNC, the S100 proteins are not directly involved in switching on and off key cell functions such as muscle contraction or nerve transmission, but rather operate as modulators. This is reflected in the relatively mild phenotypes in mice in response to overexpression or knockout of individual S100 proteins. Alternatively, functional redundancy may be operating among different S100 proteins. Nevertheless, specific S100 proteins are associated with serious diseases including cancer, autoimmune and inflammatory diseases, neurodegeneration, and cardiomyopathy. Due to their specific disease association several of the S100 proteins have proven their value as diagnostic and prognostic markers (see Sect. Calcium Binding Proteins in Disease).

Magnesium Acting as Modulator of Calcium Signaling

It is important that fast and selective binding of Ca^{2+} to its sensor protein occurs in the presence of ~1 mM Mg^{2+} (Table 1). That is 10,000 times higher than cytoplasmic Ca^{2+} at rest and still at least 100 times higher when the activator Ca^{2+} is at its peak. Thus Ca^{2+} signaling is possible only if Mg^{2+} has significantly lower affinities to the regulatory protein sites.

Beside different affinities also the binding kinetics play an important role. The two C-terminal EF-hands of cTNC and sTNC seem to confer stability to the protein in the filamentous structure and have a high Ca^{2+} affinity ($K_d \sim 10^{-8}$ M). However, in the presence of physiological concentrations of Mg^{2+} the apparent affinity for Ca^{2+} is lowered by two orders of magnitude. It may thus be assumed that these C-terminal "structural" sites may always be occupied be it by Ca^{2+} or by Mg^{2+} at rest as well as during activation. Only the N-terminal sites, two in sTNC and one in cTNC, are involved in regulation of contraction. These "regulatory" sites have an affinity for Ca^{2+} of $K_d \sim 10^{-6}$ M which is virtually not affected by Mg^{2+} because the affinity for Mg^{2+} is as low as $K_d \sim 10^{-2}$ M (10 mM Mg^{2+} would be required for 50% binding saturation even in the absence of Ca^{2+}). This situation ensures that in striated muscle (heart and skeletal) signaling depends solely on Ca^{2+} and is not disturbed by Mg^{2+}.

In CAM the affinity of the two N-terminal EF-hands for Ca^{2+} is about one order of magnitude lower ($K_d \sim 10^{-5}$ M) than that of the two C-terminal EF-hands ($K_d \sim 10^{-6}$ M). This allows CAM to sense Ca^{2+} transients in the cytoplasm over a relatively wide concentration range. For full activation of CAM, Ca^{2+} binds with positive cooperativity to all four CAM EF-hands comparable in a way to binding of oxygen to the hemoglobin tetramer. Beginning with the first Ca^{2+}, conformational changes are stepwise induced as the saturation of CAM with Ca^{2+} proceeds. At low cytoplasmic Ca^{2+} in the resting state, most of the CAM molecules will be in the apo-form (no bound divalent cation). The affinity for Mg^{2+} is again so much lower that it hardly interferes with the Ca^{2+} signal. However, during rest some sites of CAM may become occupied by Mg^{2+}. Since the binding kinetics of Mg^{2+} are so much slower than those of Ca^{2+}, the slow exchange rate at the sites occupied by Mg^{2+} could slightly delay the spread of the Ca^{2+}-CAM signal.

The question remains, however, can relatively small variations of Mg^{2+} levels affect intracellular Ca^{2+} signaling in a physiologically relevant manner? Hypermagnesemia is uncommon except in kidney insufficiency and may be counteracted by intravenous application of Ca^{2+} and loop diuretics. High blood Mg^{2+} antagonizes Ca^{2+} function by attenuating nerve transmission. The more common hypomagnesiemia reduces the Ca^{2+}antagonism of Mg^{2+} thus unmasking the effects of Ca^{2+}. It can be cured by Mg^{2+} supplementation. Low Mg^{2+} typically accompanies chronic diseases including hypertension, diabetes, cardiovascular disease, hyperthyreosis, diarrhea, and alcohol abuse. Its symptoms are increased excitability of nerves and muscle, paresthesia, muscle cramps, cardiac insufficiency and arrhythmias. In hypertension with hypomagnesemia administration of Mg^{2+} alone can lower the blood pressure significantly. Changes in intracellular Mg^{2+} obviously affect Ca^{2+} function in various signaling pathways at every point where Ca^{2+} is involved. This leads to significant cumulative effects on Ca^{2+} function particularly in the central nervous system (CNS), in muscles, and blood vessels.

Parvalbumin: A Delayed Calcium Buffer and Food Allergen

In contrast to the Ca^{2+} sensing signaling proteins, PARV has unique properties that render it an intracellular "delayed Ca^{2+} buffer." It contains three EF-hands of which the first N-terminal motif is incomplete, and therefore, unable to bind Ca^{2+} (Schaub and Heizmann 2008). The two functional EF-hands have a high affinity for Ca^{2+} ($K_d = 10^{-7}$–10^{-9} M) and a moderate affinity for Mg^{2+} ($K_d = 10^{-3}$–10^{-5} M). Ca^{2+} and Mg^{2+} compete for the same binding sites in PARV, therefore, the actual binding is determined by the relative concentrations of the two cations. Given the 10,000 times higher Mg^{2+} concentration (~1 mM) than that of Ca^{2+} at rest (0.0001 mM) PARV has bound Mg^{2+} in the resting myocyte. Ca^{2+} can bind to PARV only when Mg^{2+} is dissociated. The off-rate of Mg^{2+} from PARV measured in vitro is about 3 per second. Even if this off-rate should be considerably faster in the living cell, it still remains the rate-limiting step for Ca^{2+} binding to PARV. Muscle physiology has shown that PARV is present in fast twitching muscles of small mammalians and frogs at submillimolar concentrations. PARV is not found in slow contracting muscles nor in the hearts of larger animals. In contrast it is present in especially high concentrations in the muscles of fishes performing fast burst swimming with high amplitude undulations. PARV is designed to bind Ca^{2+} with a certain delay after Mg^{2+} has dissociated from the binding sites so that Ca^{2+} binding to PARV does not compete with the initial binding of Ca^{2+} to the regulatory sites of cTNC for triggering contraction.

In this way PARV accelerates relaxation in fast moving muscles by facilitating the removal of Ca^{2+} from cTNC and its reuptake into the SR. For these properties PARV has been successfully used in transgenic animal experiments to alleviate diastolic heart dysfunction, when cytoplasmic Ca^{2+} is not sufficiently removed between two heart beats.

Excitatory GABAergic (GABA = gamma-aminobutyric acid) neurons contain high concentrations of PARV in the soma, the axons as well as in the presynaptic terminals. For its Mg^{2+} and Ca^{2+} binding properties PARV accelerates the initial decay phase of the Ca^{2+} transients without affecting the Ca^{2+} peak height thus allowing fast firing rates. These characteristics have been shown to contribute to short-term synaptic plasticity.

Food allergy induced by gastrointestinal sensitization provokes the most common life-threatening IgE-mediated anaphylaxis. PARV with bound Ca^{2+} is remarkably resistant to heat and denaturing chemicals; this might contribute to its allergenic properties (Schaub and Heizmann 2008). It shares this allergenic potential with many other Ca^{2+} binding proteins isolated from pollen (grass, trees, and weeds), parasites, and fish. Interestingly, PARV with mutations in both EF-hands preventing Ca^{2+} binding results in almost complete loss of antigenicity.

Regulation of Cardiac Contraction by Calcium Signaling

Regulation of cardiac and skeletal muscle contraction is one of the best studied regulatory systems (Fig. 1). One reason may be that in this system Ca^{2+} induced alterations in protein-protein interactions directly translate into mechanical output by the sarcomeric contractile actomyosin machine. Contractile parameters reflect the complex regulatory finesses and can easily be measured. Figure 1 displays the topical repartition of the devices (ion channels and energy using ion pumps) that guide the Ca^{2+} signaling pathways in cardiac muscle. Ca^{2+} entering through the LCCs in response to the depolarizing action potential (AP) approaches the closely positioned RYR of the SR terminal cisternae where it induces a much larger Ca^{2+} release from the SR (Ca^{2+}-induced Ca^{2+} release = CICR, indicated in Fig. 1 by the bent arrow pointing to RYR). This Ca^{2+} serves at the same time its two major purposes (i) induction of contraction by binding to the N-terminal regulatory site in cTNC, and (ii) stimulation of ATP synthesis in the mitochondria. Akin to the close apposition of LCCs and terminal cisternae of the SR, also the mitochondria are located in proximity to the SR Ca^{2+} release channels so that Ca^{2+} from the SR directly attains the mitochondrial matrix through the Ca^{2+} uniporter of the mitochondrial inner membrane (MIM). Consequently, the Ca^{2+} concentration in the mitochondrial matrix (MM) closely follows the Ca^{2+} outflux from the SR. This allows for coordination of energy production and demand.

For termination of contraction Ca^{2+} is quickly sequestered from the cytoplasm into the SR by the high affinity Ca^{2+}-pump of the SR (SERCA) which operates against a steep gradient. In the SR calcium can reach as high a concentration as several mM, mostly bound to the SR calcium storage protein calsequestrin (CSQ) which is complexed to triadin, junctin, and the luminal side of the RYR. The sudden drop in cytoplasmic Ca^{2+} causes the activator Ca^{2+} to dissociate from the cTNC regulatory EF-hand inducing relaxation. While in larger animals, including humans, around 70% of the systolic Ca^{2+} is taken up by the SERCA, the remainder is extruded from the cell by the sarcolemmal NCX. The sarcolemmal Ca^{2+}-pump (PMCA; PMCA4 in cardiomyocytes) is located in the caveolae and hardly contributes to Ca^{2+} extrusion, but rather functions as a regulator of Ca^{2+} signal transmission to target molecules including nNOS (neural nitric oxide (NO) synthase), calcineurin (PP2B, Ser/Thr protein phosphatase) and others.

The Na^+/K^+-pump (NKA) plays a pivotal role by establishing and maintaining the Na^+ and K^+ gradients between in- and outside the cell (Fig. 1 and Table 1). The electrochemical potentials of Na^+ and K^+ are linked to each other by the pump, while the Na^+ gradient provides the driving potential for Ca^{2+} extrusion via the NCX uphill against the high Ca^{2+} concentration outside (the required energy for this uphill Ca^{2+} extrusion is thus provided indirectly by the Na^+/K^+-pump). The sarcolemma is impenetrable for the positively charged Na^+ ion while a series of different K^+-channels allow for K^+ escape down its gradient to the outside of the cell. In fact, the inside negative resting potential of −80 mV results primarily from the constant outflow of K^+ ions.

The resting potential is additionally modulated by the ATP-dependent K^+-channel (KATP channel) in the

sarcolemma (sarcKATP channel). This channel is a hetero-octamer consisting of four Kir6.2 subunits forming the pore and four sulfonylurea regulatory subunits (SUR; SURA2 in cardiomyocytes). Different metabolites and drugs can bind to the SUR subunits while nucleotides may bind to both types of subunits. Generally, binding of ATP closes the channel while ADP activates it. Since usually ATP is far in excess over ADP the channels are not very active. However, when the cells are under metabolic stress (for instance during ischemia or in acute heart failure) the cytoplasmic Ca^{2+} may increase because it is no more efficiently extruded from the cell due to energy shortage of the pumps for maintaining the ion gradients (Zaugg and Schaub 2003). In such situations the fall in the ATP/ADP ratio stimulates the sarcKATP channels through which K^+ ions escape strengthening the inside negative membrane potential. The larger the potential negativity (hyperpolarization) the shorter the AP and the lessCa^{2+} enters the cell, while at lower negativity (hypopolarization) more Ca^{2+} enters the cell during a longer AP. If during increased heart work the beat frequency and the number of APs also increases, more Ca^{2+} accumulates per time interval in the myocyte; this, in turn, translates into positive inotropism (stronger contractions). Since contractility and metabolic activity are coupled by Ca^{2+} the sarcKATP channels directly link cellular activity to the actual metabolic capacity. High activity of the sarcKATP channels under metabolic stress causes hyperpolarization (less Ca^{2+} enters the cell) which, as a protective mechanism, attenuates myocyte activity. The subunit composition of the sarcKATP channels varies from tissue to tissue according to function. KATP channels with varying subunit composition are also found in the cell nucleus and in the inner mitochondrial membrane.

Orchestration of Calcium Signaling in the Cardiomyocyte

The regulation of contraction and energy production in the cardiomyocyte is in reality even more complex than discussed above and depicted in Fig. 1. The cardiomyocyte is subject to a three-tiered control system, (i) immediate and fast feedback in response to mechanical load on a beat-to-beat basis (Frank-Starling relation depending on changes in Ca^{2+}-sensitivity of the contractile machinery), (ii) more sustained regulation involving transmitter and hormones as primary messengers triggering various intracellular signaling cascades, and (iii) long-term adaptation by changes in the gene expression profile. All three stages are critically dependent on location and time-specific deployment of Ca^{2+} (Schaub et al. 2006).

First, the ion pumps and the Ca^{2+} release channels of the SR have additional regulatory subunits which may be fixed in the protein complex or may reversibly interact with them. Second, most of the polypeptides involved in regulation can be reversibly modified, primarily by phosphorylation. Such covalent protein modification requires at least two enzyme systems, mostly different types of protein kinases for phosphorylation and protein phosphatases to reverse the phosphorylation effects. Many of these modifiers of the Ca^{2+} handling components are themselves dependent on Ca^{2+} for activity. Interestingly, a number of cardiac proteins involved in sarcomere regulation can be phosphorylated in their N-terminal region at Ser or Thr that are missing in their skeletal muscle counterparts; these include cTNI, phospholamban (PLN, the regulatory subunit of SERCA in the SR), SERCA2a (the cardiac-specific isoform of SERCA), cardiac myosin binding protein-C (cMyBPC), and cardiac titin. In the cases of cTNI, PLN, cMyBPC, and cardiac titin, these phosphorylatable sites reside on an additional peptide stretch contained in the primary sequence of the cardiac species. cTNI contains a 31 AA insert with two Ser's in addition to four more phosphorylatable Ser and Thr sites in the remainder of the protein. The six sites in cTNI can be reversibly phosphorylated by at least seven different protein kinases (PKA, PKC, PKG, Rho kinase, CaMKII, PAK1, and PAK3; some of these kinases are themselves Ca2+−dependent) partly overlapping and partly specific for particular sites. The different kinases are under control of different signaling cascades, but all affect the Ca^{2+} binding properties of cTNC by its interaction with the modified cTNI.

Third, adding to the complexity of intracellular Ca^{2+} handling almost all regulatory proteins come in different isoforms displaying different properties, which are specific for cardiac and other tissues. For instance, at least 11 isoforms of SERCA encoded by three separate genes have been discovered so far. Alternative splicing of the gene ATP2A2 produces three isoforms, SERCA2a, SERCA2b, and SERCA2c. SERCA2a is typical for cardiac and slow

muscle SR, SERCA2b is the major isoform expressed in the skin epidermis, and SERCA2c is a ubiquitous minor partner. Over 130 mutations in the ATP2A2 gene have been reported mostly affecting all three isoforms. However, mutations causing the rare Darier's skin disease reside in exon 21 which is specific for SERCA2b in the epidermis and not present in the other isoforms. Consequently, the mutated protein is associated with severe disruption of Ca^{2+} transport function in the skin but does not affect the heart.

The major players in cardiovascular regulation comprise the catecholamines, which stimulate the beta-adrenergic receptors as well as angiotensin and endothelin, which stimulate their respective receptor systems. All the receptors involved in these regulatory systems are G-protein-coupled receptors (comprising seven transmembrane segments, GPCRs) whose stimulation affects different signaling cascades resulting in an increase of cellular Ca^{2+}. Ca^{2+}-dependent, reversible phosphorylation of their intracellular C-terminal domain governs their activities, switch of G-protein coupling, and internalization.

Calcium as Regulator of Mitochondrial Energy Metabolism

Over 95% of a vertebrate's energy requirement is produced in the mitochondria by oxidative phosphorylation in the respiratory chain. The human heart generates over 30 kg ATP during a day. Eighty to ninety percent of the required ATP is met by the catabolism of free fatty acids (FFAs) via beta-oxidation. The entire ATP (concentration ~10 mM) pool of the heart is turned over within ~1 min at body rest (basal heart activity) and within less than ~10 s at maximum workload. Thus even a small mismatch between ATP production and utilization would rapidly lead to acute heart failure.

The heart is an omnivore, able to oxidize different substrates to support ATP synthesis: FFAs, glucose, lactate, and even AAs. The mitochondrial outer membrane (MOM) allows, via porins (voltage-dependent anion channel, VDAC, letting through molecules up to ~5,000 kD), free solute exchange between the cytoplasm and the mitochondrial intermembrane space (MIMS), but the MIM remains impenetrable. There are several active mitochondrial transport systems for substrate transfer to the matrix; these are Ca^{2+} regulated. As the energy production relies on the availability of the substrates, cytoplasmic Ca^{2+} could regulate mitochondrial metabolism without entering the matrix via the uniporter.

Nevertheless, direct regulation of mitochondrial metabolism by Ca^{2+} has been established. Under normal conditions glucose covers ~10% of the energy costs. This fraction can be increased several fold during high mechanical loads or during pathologic conditions. Even with maximal stimulation of glycolysis the FFA oxidation remains dominant. First, Ca^{2+} activates glycogen phosphorylase kinase in the cytoplasm; this subsequently phosphorylates and activates glycogen phosphorylase thus increasing the delivery of glucose for glycolysis yielding pyruvate. After energy consuming transport into the mitochondrial matrix pyruvate is decarboxylated and transformed to acetyl-CoA by the pyruvate dehydrogenase complex, which is then fed into the tricarboxylic acid cycle (TCAC). This enzyme complex comprises over 90 subunits with three functional activities: pyruvate dehydrogenase (PDH), dihydrolipoyl transacetylase, and dihydrolipoyl dehydrogenase. The activity of the PDH is dependent on Ca^{2+}, so are also isocitrate dehydrogenase and alpha-ketoglutarate dehydrogenase of the TCAC. The protons of NADH (nicotinamide adenine dinucleotide), which originate from these reactions, will be transferred to the respiratory chain. Finally, also the ATP synthase (FoF1, complex-V assembled from about 16 polypeptide subunits) is stimulated when Ca^{2+} is increased in the matrix probably by a post-translational modification not yet understood in detail, or alternatively, by association of FoF1 with the Ca^{2+}-sensor protein S100A1. The metabolic link to increased energy demand by cytoplasmic and mitochondrial Ca^{2+} is given by the following scheme:

$$\begin{aligned}&\text{Energy demand} \uparrow \rightarrow \text{cytoplasmic } Ca^{2+} \uparrow\\ &\rightarrow \text{mitochondrial } Ca^{2+} \uparrow\\ &\rightarrow \text{activities of dehydrogenases} \uparrow\\ &\rightarrow NADH/H^{+} \uparrow \rightarrow ATP \uparrow\\ &\rightarrow \text{energy supply} \uparrow\end{aligned}$$

In fact, oxidative phosphorylation is stimulated more rapidly by Ca^{2+} than by the dephosphorylated phosphoryl carriers creatine or ADP. Thus intramitochondrial

Ca^{2+} functions as metabolic mediator by matching energy supply to actual demand. What is the effect of excess Ca^{2+} in the cytosol and especially in the mitochondria?

Mitochondrial Calcium Death

When Ca^{2+} inundates a cell because of physical cell membrane lesion or under a pathologic condition this cell is doomed to die. The site which determines over life or death is the mitochondrion that cannot fend off being swamped by the high cytoplasmic Ca^{2+}. Besides stimulating most cell activities in vain, the excess cytoplasmic Ca^{2+} dissipates energy by producing heat. In the mitochondrion excess Ca^{2+} precipitates as Ca-phosphate; this brings the respiratory chain to a halt. Normally Ca^{2+} exits the mitochondrion via the Na^{+}/Ca^{2+}-exchanger. However, when the cytoplasmic Ca^{2+} is very high this exchange becomes insufficient. Under such strenuous conditions when the respiratory chain can no longer sustain the proton gradient across the MIM (with a 150–180 mV potential inside negative) the FoF1 ATP synthase starts operating in reverse, that is it hydrolyzes ATP, as it does when isolated in vitro. Consumption of ATP by the FoF1 ATPase contributes to maintaining the membrane potential at suboptimal levels by pumping protons out of the matrix in order to gain time for potential recovery of the cell. During this period the adenine nucleotide translocase (ANT, ~33 kDa) also operates in reverse by letting ATP produced by anaerobic glycolysis in the cytoplasm flow into the matrix of the mitochondrion. Ca^{2+} overload, depletion of ATP and oxidative stress (reactive oxygen species, ROS) resulting from uncoupling of the respiratory chain may lead to opening of a non-specific pore in the MIM, known as the mitochondrial permeability transition pore (mPTP). Which proteins are integral constituents of this pore is still debated, but the ANT and the mitochondrial phosphate carrier (PiC, ~40 kDa) appear to be involved in the pore formation with cyclophilin-D (CyP-D, a matrix peptidyl-prolyl *cis-trans* isomerase, ~19 kDa) as regulator. This pore has a diameter of 1.2–1.5 nm and allows solutes passing <1,500 Da. With this free exchange of solutes between mitochondrial matrix and cell cytoplasm the residual proton gradient finally collapses and the cell death processis initiated.

There are three types of cell death pathways: apoptosis, autophagy, and necrosis. Much attention has been paid to apoptosis and autophagy because of their genetically determined or "programmed" pathways that mediate both these processes. They occur under specified conditions during development, maintenance and repair of tissues in response to extracellular or intracellular signals. Necrosis presents a more general death reaction elicited by too much Ca^{2+} in the cytoplasm and the mitochondria. The Ca^{2+}-dependent cysteine proteinases, calpains, in the cytoplasm significantly contribute to the destruction of the cell. The caspase (cysteine proteinases) cascade activation in apoptosis may be triggered by either extracellular inducers via Fas ligand and death receptor, or intrinsic inducers (stress, DNA damage, chemotherapy, irradiation). The intrinsic inducers lead to mitochondrial damage resulting in the release of pro-apoptotic proteins from the Blc2 family as well as the pro-apoptotic cytochrome-c. Both extrinsic and intrinsic apoptotic pathways merge on the Ca^{2+}-activated effector caspase3. Furthermore, characteristic pro-apoptotic proteins have been shown also to be involved in necrotic cell death. In cardiac infarction, brain stroke, atherosclerotic and other pathologic lesions excess Ca^{2+} is the decisive factor which drives the living matter to death by necrosis.

Calcium Binding Proteins in Disease

A selection of human EF-hand proteins associated with various diseases is given in Table 2. The field has exploded during the present decade; the processes are extremely complex with many of the S100 proteins specifically involved in particular diseases. To help the reader finding the primary literature references are given at the bottom of Table 2. The different specificities reflect sub-functionalization within the S100 protein family and may allow for potentially new therapeutic approaches. As mentioned in Sect. The S100 Protein Family, these proteins modify the Ca^{2+} signals and may thus not be as critical for survival as TNC and CAM. Instead, derangement of individual S100 proteins (under- or overexpression, non-lethal mutations) within certain limits may be compatible with life, though disease may develop. Many of these diseases associated with neurodegenerative processes, cardiomyopathy, or mood disorders occur later in life.

FH 8	Fasciola hepatica	Fraga et al. (2010)
Troponin (mutations)	Cardiomyopathy	Pinto et al. (2009)
Nesfatin/nucleobindins	Anti-obesity treatment	Shimuzu et al. (2009)

This presumably reflects cumulative perturbations each time the organism approaches stress situations until it transgresses into overt disease.

Cardiac troponin components (cTNI and cTNT) present two established biomarkers (Table 2). cTNI and cTNT together with cTNC form the Ca^{2+} binding muscle troponin complex. Several isoforms of cTNT are expressed in heart and skeletal muscle during development, while cTNI exists only in the heart. The new highly sensitive automated cTNI and cTNT tests (using polyclonal antibodies) are the "gold standard" for cardiac infarct detection with a cutoff limit at ~0.014 ng/ml in the blood. Only a hundred dead myocytes can give detectable increases in cTNI and cTNT. Two hours after onset of pain symptoms the cTN-tests already read significantly higher than in healthy controls. Serial determinations with 2–6 h intervals allow one to estimate infarct size and prognosis for the future. The cTNT or cTNI test is superior to all other clinically available biomarkers including myoglobin, MB fraction of creatine kinase (CK-MB), myeloperoxidase, and heart fatty acid binding protein. The ECG (electrocardiogram) itself is often insufficient to diagnose acute myocardial infarction since

ST-segment elevation in the ECG may occur under other conditions as well.

Gene therapy with several Ca^{2+}-dependent proteins to rescue experimental models of heart failure has been performed with mice and rats. In human severe heart failure systolic dysfunction is accompanied by downregulation of SERCA2a. Less Ca^{2+} is available in the SR and an increase of heart rate cannot compensate for the lower Ca^{2+} content. Transgenic expression of SERCA2a improves cardiac contraction in a mouse heart failure model. In isolated cardiomyocytes from rats with cardiac insufficiency transfection of S100A1 restores contractile parameters. Cardiac targeted transgenic expression of PARV in mice improves relaxation thus improving diastolic dysfunction (Sect. Parvalbumin a Delayed Calcium Buffer and Food Allergen). Although these examples provide proof of principle for gene therapy with Ca^{2+} handling proteins to restore Ca^{2+} homeostasis or to delay disease onset. It is, however, not known at present how many gene copies will be incorporated into the host genome nor where these copies will be inserted with regard to genomic regulation. A steady expression at a defined level in the target cells without affecting the endogenous gene activity profile would be required. These conditions are far from being realized in the near future.

Final Remarks

Disturbance of Ca^{2+} homeostasis can be lethal. There are many Ca^{2+} binding and Ca^{2+} regulating proteins in the cell that are interrelated in complex signaling networks; these provide a robust framework for cell function. However, under significant pathological stress or even with physical cell lesions the control over the Ca^{2+} homeostasis may get out of hand. Ca^{2+} then accumulates in the cell and invades the mitochondria, the gate to death. As Ca^{2+} is involved in almost all physiological cell functions, so it plays a key role in most, if not all, diseases. A much larger proportion of diseases than one might be inclined to believe, ultimately depends on the individual genetic makeup. The most common DNA sequence deviations are single nucleotide polymorphisms (SNPs). About 15–20 million SNPs are unevenly spread over the entire human genome, on an average one in every 100–200 nucleotides. Added to these are several thousand structural variants, for example, shorter and longer deletions, insertion, inversions, copy number variants, and segmental duplications. The various Ca^{2+}-related protein genes are estimated to harbor several thousand sequence variants giving rise to major and minor functional alterations (gain-of-function or loss-of-function). The vast majority of these variants were established thousands to millions of years ago. Most of the lethal defects have been eliminated; while those variants compatible with life have survived and become fixed in the extant genomes.

Why then do fatal diseases still develop during aging in the modern human populations? In the industrialized countries life span has almost doubled from ~40 to ~80 within little more than 100 years. This is mainly due to the introduction of improved hygiene and nutrition, as well as the prevention and treatment of infectious diseases. Despite these benefits, the longer life is burdened with ailments including chronic degenerative disease, cancer, cardiovascular disease, and neuropathy. This may be due to the accumulation of mutations for late onset diseases that have not been subjected to evolutionary pressure. Natural selection does not select for healthy octagenarians, but only for survival through the reproductive and child rearing phase in order to assure species preservation. Today's medicine is thus confronted with an elderly and disease-prone population that may be referred to as "evolutionary" or "Darwinian" medicine.

Calcium ion; Cardiac excitation/contraction coupling; Cardiac hypertrophy; Relaxation of cardiac muscle

Definition

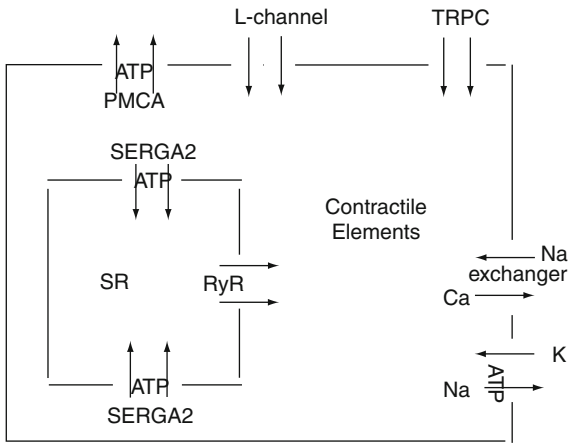
Ca^{2+} signaling refers to coupling of membrane excitation to contractile activation of heart muscle. Mechanisms permitting cyclic rise and reduction of Ca^{2+} concentration within cardiac muscle cells are required for optimal heart beating. Alterations of these mechanisms are followed by deficient contraction and relaxation.

Introduction

Ca^{2+} signaling serves as a common mechanism to couple membrane excitation to intracellular functions in most biological tissues (Clapham 2007). This mechanism is based on: (a) a high gradient between extracellular (or intracellular stores) Ca^{2+} concentration (mM) and intracellular (cytosolic) Ca^{2+} concentration (0.1 μM); (b) passive fluxes of signaling Ca^{2+} through selective channels from extracellular fluids (or intracellular stores) into the cytosol; (c) the presence of intracellular proteins, such as calmodulin and troponin, mediating activation of specific enzymes and/or functions upon Ca^{2+} binding; and (d) active transport of Ca^{2+} from the cytosol to extracellular fluids (or intracellular stores) to reduce the cytosolic Ca^{2+} concentration and terminate the Ca^{2+} signal.

Ca^{2+} Signaling in Cardiac Muscle

In cardiac muscle, variations of cytosolic Ca^{2+} are involved in several signaling functions including activation of transcription and contraction (Bers 2008).



Calcium in Heart Function and Diseases, Fig. 1 *Diagram of Ca^{2+} movements that couple membrane excitation to contraction and induce subsequent relaxation in cardiac myocytes. Arrows* indicate direction of ion movements. Initial influx of trigger Ca^{2+} occurs through the voltage-dependent L-channel upon membrane depolarization. This initial Ca^{2+} influx then triggers release of a larger amount of Ca^{2+} from the sarcoplasmic reticulum (SR) through the ryanodine receptor channel (RyR). This Ca^{2+} is sufficient to raise the cytosolic Ca^{2+} concentration to the μM level and to induce contraction of myofilaments. Following repolarization of the membrane, the excess cytosolic Ca^{2+} is actively transported back into the lumen of the sarcoplasmic reticulum (SR) by SERCA2. Furthermore, a smaller amount of cytosolic Ca^{2+} is extruded from the cell by the plasma membrane ATPase (PMCA) and the Na^+/Ca^{2+} exchanger. The cytosolic Na^+ concentration is kept low by active extrusion through the Na^+/K^+ ATPase. Under certain circumstance, Ca^{2+} influx may occur though the transient receptor potential channel (TRPC)

Variation of cytosolic Ca^{2+} may occur as transient and spatially diffuse events triggered by electrical depolarization of the plasma membrane or waves and "sparks" confined to limited subcellular areas. Initiation and decay of signals is dependent on various proteins that render possible passive Ca^{2+} fluxes down a gradient, active Ca^{2+} transport against a gradient, and Ca^{2+}/Na^+ exchange sustained by respective gradients (Fig. 1).

The sequence of Ca^{2+} passive fluxes and Ca^{2+} active transport involved in contractile activation and subsequent relaxation in cardiac myocytes is shown in the diagram of Fig. 1. Initially, influx of low quantities of extracellular Ca^{2+} occurs through voltage-gated L-type Ca^{2+} channels that reside on the plasma membrane. The L-type channels are normally closed at resting membrane potential but are activated (i.e., opened) at depolarized membrane potentials. The functional

importance of this channel has led to the development of pharmacological "Ca^{2+} blockers," which are currently used in treatment of cardiovascular diseases. Influx of extracellular Ca^{2+} may also occur through transient receptor potential channels (TRPC), whose importance was recognized in cardiac myocytes subjected to experimental hypertrophy. In turn, a prominent contribution to the rise of cytosolic Ca^{2+} is attributed to release from internal stores of sarcoplasmic reticulum (SR), which is elicited by the initial entry of extracellular Ca^{2+} through the L-type channels. Ca^{2+} release from the sarcoplasmic reticulum occurs through the ryanodine channel, which is the major mediator of "calcium-induced calcium release" (CICR) in myocytes.

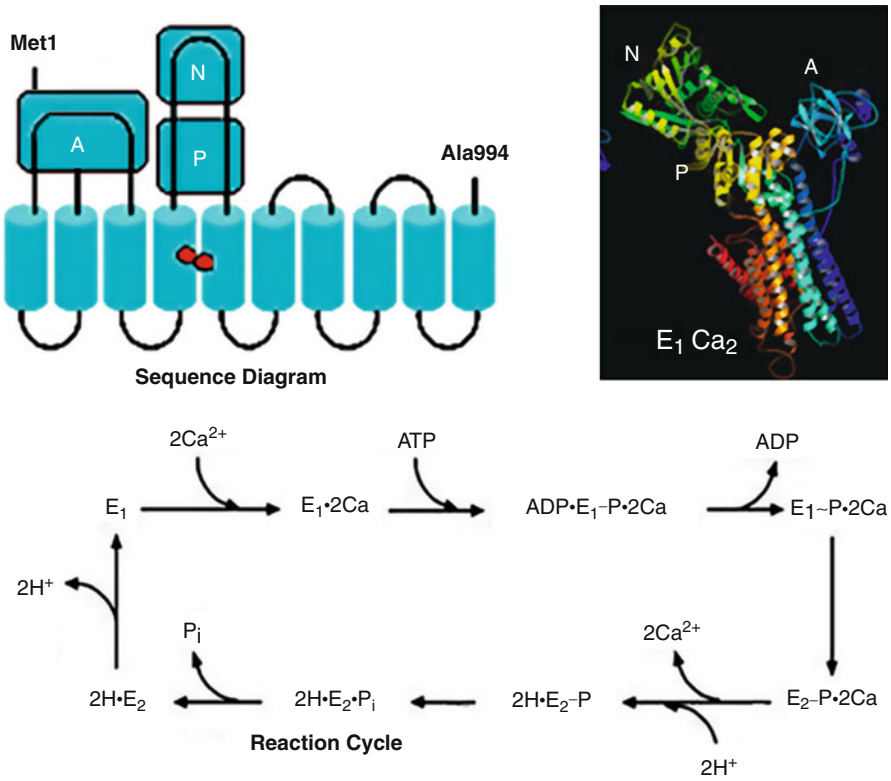
When a Ca^{2+} signal reaches its peak, decay is due in part to return of cytosolic Ca^{2+} to the extracellular fluids, mediated by the plasma membrane Ca^{2+} ATPase (PMCA) which utilizes ATP for active transport of Ca^{2+} and by the Na^+/Ca^{2+} exchanger which allows efflux of cytosolic by utilization of the Na^+ gradient originally produced by the Na^+ pump across the plasma membrane. On the other hand, the major contribution to signal decay is due to return of cytosolic Ca^{2+} to intracellular stores, which is accomplished through active transport by the sarcoplasmic reticulum Ca^{2+} ATPase. In fact, the Ca^{2+} transport ATPase (SERCA2) of cardiac sarcoplasmic reticulum plays an important role as it fills intracellular stores with Ca^{2+} to be released to initiate contractile activation and, in turn, sequesters cytosolic Ca^{2+} to allow relaxation. It is noteworthy that SERCA2 protein is present in cardiac muscle at much higher stoichiometric levels than the PMCA or the Na^+/Ca^{2+} exchanger.

The Ca^{2+} Transport ATPase of Sarcoplasmic Reticulum

Vesicular fragments of sarcoplasmic reticulum (SR) membrane originally prepared from skeletal and cardiac muscle were referred to as "relaxing factor" since they prevented "superprecipitation" (i.e., contraction analog) of native actomyosin (containing myosin, actin, and the troponin complex) upon addition of ATP. It was soon established that this effect was produced by ATP-dependent sequestration of Ca^{2+} by the vesicles from the reaction medium. In fact, the same relaxing effect could be produced simply by Ca^{2+} chelation with EGTA added to the medium. ATP-dependent sequestration of Ca^{2+} by the SR vesicles is operated by the Ca^{2+}-activated sarco-/endoplasmic reticulum ATPase (SERCA) which is the prominent protein component of the SR membrane. The SERCA protein is encoded by three highly conserved genes (SERCA1, 2, and 3) localized on different chromosomes and undergoes alternative splicing following transcription (Periasamy and Kalyanasundaram 2007). The cardiac SR ATPase (SERCA2a) is encoded by the (human nomenclature) ATP2A2 gene, which also yields the SERCA2b isoform found in the endoplasmic reticulum of most cells. The SERCA2 gene (ATP2A2) encodes a transcript that can be alternatively spliced into three different isoforms of the SERCA protein: SERCA2a expressed predominantly in cardiac and slow twitch skeletal muscle; SERCA2b expressed in all tissues at low level including muscle and nonmuscle cells; and SERCA2c detected in epithelial, mesenchymal, and hematopoietic cell lines, primary human monocytes, and recently even in cardiac muscle.

Mechanism of ATP Utilization and Coupled Ca^{2+} Transport

The SERCA enzyme is a prototype ion-motive ATPase of the P-type family. The SERCA1 isoform, but also the SERCA2 isoform, has been studied in detail, demonstrating that the catalytic and transport cycle includes Ca^{2+} binding, ATP utilization by formation of a phosphorylated enzyme intermediate, translocation of bound Ca^{2+} across the SR membrane against a concentration gradient, and final hydrolytic cleavage of Pi from the phosphoenzyme intermediate (Inesi et al. 1990; Toyoshima and Inesi 2004). The amino acid sequence (Fig. 2) comprises ten transmembrane, mostly helical segments, where the fourth, fifth, sixth, and eighth segments contribute residues to the binding of two Ca^{2+} (TMBS) that are required for enzyme activation and undergo active transport. The SERCA headpiece includes an N domain with the ATP binding site, a P domain with the aspartyl residue undergoing phosphorylation as a catalytic intermediate, and an A domain containing the conserved TGE motif required for catalytic assistance of the final hydrolytic reaction. A high-resolution three-dimensional structure has been obtained (Fig. 2) under conditions

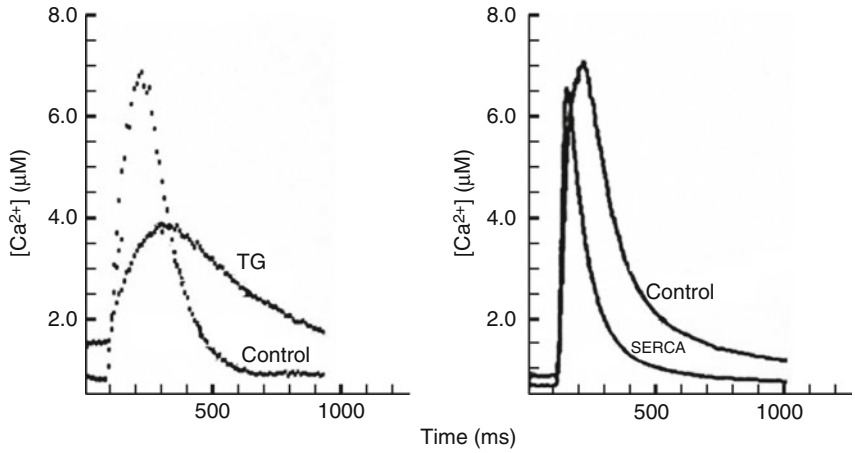


Calcium in Heart Function and Diseases, Fig. 2 *Two-dimensional SERCA sequence diagram, crystal structure of the $E_1{\cdot}Ca_2$ state (Protein Data Bank code 1su4), and sequential reactions comprising an ATPase catalytic and Ca^{2+} transport cycle*. The sequence diagram shows ten transmembrane segments, with two *red dots* indicating two Ca^{2+}-bound. It also indicates the sequence distribution into N (ATP binding), P (phosphorylation), and A (catalytic actuator), which are then assembled in the cytosolic headpiece of the protein, as shown in the crystal structure. The membrane-bound segments containing the Ca^{2+} binding sites are then clustered in the assembled structure. Note that in the catalytic cycle diagram, two Ca^{2+} are exchanged for two H^+ (at pH 7), and the enzyme undergoes sequential reactions including phosphorylation and conformational changes. Ca^{2+} binding, phosphorylation, isomeric transition of the phosphoenzyme, and H^+ dissociation are all involved in triggering conformational changes as the cycle proceeds in the forward direction

corresponding to various steps of the reaction cycle, demonstrating that the ATPase protein undergoes a series of long-range conformational changes as the catalytic and transport cycle proceeds with sequential reactions. Diverse conformational states correspond to the enzyme with high affinity and outward orientation of the Ca^{2+} sites with respect to the lumen of SR (E1), the enzyme following binding of two Ca^{2+} ($E_1{\cdot}Ca_2$), the initial phosphoenzyme intermediate obtained by utilization of ATP ($E_1{\cdot}Ca_2$-P), the phosphoenzyme intermediate after a conformational change producing lower affinity and lumenal orientation of the calcium sites ($E_2{\cdot}Ca_2$-P), the phosphoenzyme after luminal dissociation of (E_2-P), and the enzyme following hydrolytic cleavage of Pi that still retains low affinity and lumenal orientation of the calcium sites (E_2). At neutral pH, binding and dissociation of two Ca^{2+} is accompanied by exchange with two H^+ that derive from acidic chains of residues participating in binding (Fig. 2). It is apparent that, overall, the free energy of ATP is utilized to reduce the Ca^{2+} binding affinity of SERCA. In fact, if the free energy required for a catalytic and transport cycle is considered to be

$$\Delta G = nRT \ln\left(K_a^{\mathrm{CaE-P}}/K_a^{\mathrm{CaE}}\right)$$

where $n =$ two calcium ions transported per cycle, and the equilibrium constants correspond to the association constants of the enzyme for Ca^{2+} in the ground state



Calcium in Heart Function and Diseases, Fig. 3 *Effects of thapsigargin (TG) and heterologous SERCA expression (SERA) on cytosolic Ca^{2+} transients of cardiac myocytes subjected to electrical field stimulation*. Myocytes treated with TG (10 nM) or overexpressing exogenous SERCA following gene transfer by adenovirus vectors are compared with control myocytes. Note the reduction in peak height and decay rate following TG treatment and the increased decay rate following SERA overexpression (Adapted from Prasad and Inesi 2009; and Cavagna et al. 2000)

and following activation by ATP. The derived value corresponds approximately to the standard free energy deriving from hydrolytic cleavage of the terminal phosphate of ATP (Inesi et al. 1990).

The Sarcoplasmic Reticulum ATPase in Cardiac Muscle

From the cell physiology point of view, the important role played by SERCA in Ca^{2+} signaling is well apparent in primary cultures of cardiac myocytes, as they provide a rather simple system to study complementary features of SERCA transport activity and cytosolic Ca^{2+} signaling. In fact, myocytes subjected to electric stimuli develop cytosolic Ca^{2+} transients that include a rapid rise followed by a slower decay. The rapid Ca^{2+} rise does not show significant dependence on temperature, as expected of passive flux through a channel. On the contrary, the rate of decay exhibits strong temperature dependence, similar to that exhibited by the transport activity of isolated SR vesicles. This behavior is consistent with passive flux through a channel giving rise to the Ca^{2+} transient and dependence of the transient decay on active transport by the SERCA enzyme. The dependence of Ca^{2+} signaling on transport by SERCA can be demonstrated by inhibiting its catalytic and transport activity with thapsigargin (TG), a plant-derived sesquiterpene lactone which (when used at nanomolar concentrations) inhibits specifically SERCA activity without effecting cell growth or other cell characteristics. In cardiac myocytes subjected to electrical stimuli, it can then be shown that severe alterations of Ca^{2+} signaling are produced following specific inhibition of SERCA2 transport activity with TG (Fig. 3) or SERCA2 gene silencing with short interference RNA. In more complex models of cardiac muscle, severe alterations of Ca^{2+} signaling as well as contractile function have been demonstrated following specific inhibition of SERCA2 transport activity with TG, or reduction of expression by a SERCA2 gene null mutation. On the other hand, increased expression of endogenous SERCA, or expression of heterologous SERCA in addition to endogenous SERCA, allows faster decay of Ca^{2+} signals (Fig. 3).

A specific feature of SERCA2 in cardiac muscle is its regulation by phospholamban (MacLennan and Kranias 2003). Phospholamban is a small protein that interacts with the transmembrane and stalk regions of the SERCA protein. The functional effect resulting from this interaction is a displacement of the ATPase activation curve to a higher Ca^{2+} concentration range, therefore yielding lower activity at relevant cytosolic Ca^{2+} concentrations. This effect is overcome by phospholamban phosphorylation following adrenergic activation of protein kinase, thereby providing a mechanism for increased cardiac contraction and

more efficient relaxation upon sympathetic discharge. Numerous and elegant studies with transgenic animals have shown that phospholamban is a key determinant of cardiac function and dysfunction. In addition, specific mutations in the human phospholamban gene may result in severe cardiomyopathies.

Defects of Ca^{2+} Signaling in Diseases of Cardiac Muscle

A most important point to consider regarding the involvement of Ca^{2+} ATPase in cardiac diseases is SERCA2 downregulation in cardiac hypertrophy, leading to deficient Ca^{2+} signaling and failure (Prasad and Inesi 2010). It is apparent that downregulation occurs since SERCA2 is not included in the transcriptional program leading to hypertrophy of cardiac muscle. Even though the mechanism of SERCA2 downregulation in hypertrophy is not yet clear, altered regulation of transcription and expression is undoubtedly an important factor. In addition to SERCA, other Ca^{2+}-handling proteins such as Na^+/Ca^{2+} exchanger and the TRPC proteins may be involved. Calcineurin, a Ca^{2+}/calmodulin-activated phosphatase and transcriptional activator that plays an important role in heart development and remodeling, is likely to be involved in adaptive responses to alterations of cytosolic Ca^{2+} homeostasis. However, the consequences of its activation are likely to be interwoven with additional mechanisms of transcriptional regulation that may enhance or counteract the overall effect, directing it to expression of specific proteins and excluding others. Presently, clarification of adaptive mechanisms for up- and downregulation of endogenous SERCA and other Ca^{2+}-handling proteins is a most promising endeavor in order to gain understanding and hopefully improving treatment of cardiac hypertrophy and failure.

The evidence indicating that defective expression, function, and regulation of Ca^{2+} cycling proteins is a significant factor in the pathogenesis of cardiac hypertrophy and failure has led to attempts to relieve related shortcomings by overexpression through introduction of exogenous cDNA, targeting calcium cycling proteins in heart failure through gene transfer (Del Monte and Hajjar 2003). On the other hand, development of pharmacological agents aimed at specific transcriptional pathways would be most helpful, in order to control the expression levels of calcium signaling proteins and the hypertrophy program. The present knowledge on activators and inhibitors of various enzyme involved in transcription is likely to provide a guide for evaluation of chemical structures and synthesis of new compounds. The advantage of pharmacological agents, as compared to exogenous gene transfer, is related to their easier administration and wider population targeting.

Definition

Calcium contained or stored within neurons or extracellular calcium readily available for neurons to utilize for receptor binding, influx through channels, flux through transporters or pumps or for intracellular second messenger signaling is calcium in the nervous system.

Ca^{2+} and Ca^{2+} Signaling

The calcium ion (Ca^{2+}) is a ubiquitous ion and second messenger found in all living organisms. Ca^{2+} facilitates cellular responses to external and internal stimuli and is critical for normal cellular function and survival. It regulates the activity of a large number of enzymes involved in a variety of physiological processes. In neurons, Ca^{2+} controls many cellular processes such as synaptic plasticity, neurotransmitter release, gene expression, differentiation, and cell fate. Ca^{2+} signals activate specific cellular processes at different rates. For example, some processes such as synaptic vesicle release occurs within microseconds after Ca^{2+} signals, while neuronal gene expression can be activated hours after Ca^{2+} signals occur (reviewed by Berridge et al. 2003).

Ca^{2+} concentration gradients must be maintained within neurons to allow Ca^{2+} to be an effective second messenger. The extracellular space and the lumen of intracellular organelles such as the endoplasmic reticulum (ER), nuclear envelope (NE), and the mitochondrial matrix contain high concentrations of Ca^{2+} (low millimolar concentrations) and thus function as Ca^{2+} stores. The cytoplasm of the cell contains low Ca^{2+} concentration (high nanomolar concentrations) relative to Ca^{2+} maintained in stores thereby providing an adequate driving force for Ca^{2+} flux. In neurons, excessive accumulation of intracellular Ca^{2+} can initiate apoptosis. Ca^{2+} released from intracellular stores into the cytosol is quickly taken back up into stores or extruded out of the cell by Ca^{2+} pumps that consume energy in the form of ATP or by ion exchangers that are regulated by ion concentration gradients. Mitochondria take up Ca^{2+} from the cytosol through the Ca^{2+} uniporter located in the inner mitochondrial membrane into the mitochondrial matrix. Uptake of Ca^{2+} into the mitochondria increases mitochondrial metabolism and energy generation. Excessive Ca^{2+} uptake, however, can lead to the opening of the mitochondrial permeability transition pore facilitating apoptosis (reviewed by Rimessi et al. 2008).

While active transport keeps the concentration of Ca^{2+} in the cytoplasm low, a variety of Ca^{2+} channels generate an increase in cytoplasmic Ca^{2+} through influx of Ca^{2+} from the extracellular space or through release of Ca^{2+} from intracellular stores. In neurons, the main types of Ca^{2+} channels include voltage-gated Ca^{2+} channels (VGCCs), ligand-gated Ca^{2+} channels (LGCCs), and intracellular Ca^{2+} channels (ICCs) that might have functional characteristics similar to VGCCs and LGCCs. These channel types are activated by different stimuli and control different neuronal processes. In the neuronal postsynapse, Ca^{2+} influx occurs primarily via either glutamate receptors, VGCCs, or ICCs (reviewed by Higley and Sabatini 2008). In many neuronal types in the brain, NMDA receptors and VGCCs elicit a significant portion of Ca^{2+} influx.

Ca^{2+} Channels in the Nervous System

VGCCs are widely expressed in the nervous system and they are activated by membrane depolarization leading to influx of Ca^{2+} into the cell from the extracellular space. There are two types of VGCCs: high-voltage-activated (Ca_v1 and Ca_v2) and low voltage-activated (Ca_v3) VGCCs (reviewed in Duncan et al. 2010). The involvement of VGCCs in synaptic transmission, neuronal development, and gene expression is well documented. VGCC activity is influenced by subunit composition, phosphorylation, G-protein signaling and changes in channel subunit expression,

splicing, or targeting (Koulen et al. 2005a; Martín-Montañez et al. 2010, reviewed in Duncan et al. 2010).

Ligand-gated Ca^{2+} channels are activated by a variety of small molecules and neurotransmitters to facilitate Ca^{2+} influx into neurons. One well-characterized example is the *N*-methyl-D-aspartate (NMDA) receptor which is activated by the excitatory neurotransmitter, L-glutamate. The NMDA receptor exhibits widespread expression in the brain and plays a crucial role in long-term potentiation (LTP) and synaptic plasticity (reviewed in Duncan et al. 2010). The NMDA receptor is regulated, in part, by magnesium (Mg^{2+}), accessory proteins, and subunit phosphorylation. Other ionotropic glutamate receptors, kainate and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors, as well as some serotonin, acetylcholine, and purinergic receptors, are nonselective cation channels that conduct mainly sodium (Na^{+}) and depolarize the plasma membrane. Membrane depolarization by AMPA receptor activation relieves the Mg^{2+} block of NMDA receptors allowing them to open and conduct Ca^{2+} upon glutamate binding (reviewed in Duncan et al. 2010). Additionally, the LGCCs above can depolarize the plasma membrane thereby activating VGCCs.

Nicotinic acetylcholine receptors (nAchRs) are LGCCs widely expressed in the nervous system and are activated by the neurotransmitter, acetylcholine. Nicotinic AChRs are involved in neuronal development, synaptic plasticity, and gene expression (reviewed in McKay et al. 2007). One particular nAchR, composed of α7 subunits, is much more selective for Ca^{2+} than other nAChRs. Ca^{2+}-conducting nAChRs can activate intracellular Ca^{2+} channels such as ryanodine receptors (RyRs) via Ca^{2+}-induced Ca^{2+} release (CICR) (McKay et al. 2007).

Transient receptor potential (TRP) channels are nonselective cation channels and consist of a diverse family of receptors containing multiple subgroups (reviewed by Berridge et al. 2003). The TRP channel family is activated by a very wide range on endogenous agonists. TRP channels typically exhibit low conductances and can function over more prolonged periods of time without overwhelming the cell with Ca^{2+} (Berridge et al. 2003). TRPC plays a role in capacitive Ca^{2+} entry to refill intracellular Ca^{2+} stores (Berridge et al. 2003). TRPC channels are linked to IP_3Rs via Homer proteins stimulating opening of channels (Duncan et al. 2005).

In addition to the plasma membrane LGCCs and VGCCs, neurons also express intracellular Ca^{2+} channels (ICCs) predominantly localized to intracellular membranes such as the endoplasmic reticulum (ER) (Stevens et al. 2008). The ICCs are activated to release Ca^{2+} by second messengers such as inositol 1, 4, 5-trisphosphate (IP_3). IP_3 receptors (IP_3Rs) and RyRs are the major ICCs releasing Ca^{2+} from intracellular stores and they are widely expressed in the nervous system (Koulen et al. 2005a, b, 2008; Mafe et al. 2006; Duncan et al. 2007). Some TRP proteins of the polycystin family are also ICCs and contribute to CICR (Koulen et al. 2002; 2005c). Ca^{2+} release from and reuptake into intracellular stores control cytoplasmic Ca^{2+} concentrations as well as the spatial and temporal characteristics of cytoplasmic Ca^{2+} signals. IP_3Rs and RyRs are essential for a variety of cellular processes influenced by Ca^{2+} such as cell proliferation, development, gene expression, and neurotransmitter release.

Neurons utilize distinct signaling cascades to elicit different physiological responses from Ca^{2+} (reviewed in Berridge et al. 2003, Berridge 2006). For example, some G-protein-coupled receptors (GPCRs) that couple to the IP_3 signaling cascade elicit rapid Ca^{2+} transients, whereas others elicit Ca^{2+} responses that arise slowly but continue over a longer duration (reviewed in Berridge et al. 2003). In addition, activation of the metabotropic glutamate receptor (mGluR) mGluR1 generates single Ca^{2+} transients, while mGluR5 produces Ca^{2+} oscillations (Berridge et al. 2003).

RyRs are activated by the same ion that they conduct – Ca^{2+}. They are CICR channels as they augment Ca^{2+} signals generated from other sources (Hayrapetyan et al. 2008; Rybalchenko et al. 2008). In neurons, VGCCs emit Ca^{2+} which, in turn, activates RyRs releasing additional Ca^{2+} via CICR (Berridge et al. 2003).

RyR accessory proteins also regulate RyR activity. Homer proteins bind RyR1 thereby increasing channel open probability and Ca^{2+} release rate (reviewed in Duncan et al. 2005). Homer dimerization is important for relevant regulation of RyR1 activity (Duncan et al. 2005). The short dominant-negative form of Homer, Homer 1a, competes with the long Homer 1c form for RyR1 binding (Hwang et al. 2003, reviewed in Duncan et al. 2005). Homer 1c reduces RyR2 activity by reducing channel open probability and Homer 1a decreases this inhibition (Westhoff et al. 2003, reviewed in

Duncan et al. 2005). In addition, Homer-1 has been shown to interact with polycystin-1 in hippocampal neurons, suggesting that Homer proteins are important functional regulators of ICCs and other ion channels (Stokely et al. 2006).

In addition to Ca^{2+} channels, Ca^{2+}-binding proteins including Ca^{2+} buffers and Ca^{2+} sensors also regulate processes critical for proper neuronal function (reviewed in Amici et al. 2009). Ca^{2+} sensors such as calmodulin (CaM), hippocalcin, and neuronal Ca^{2+} sensor-1 (NCS-1) play a major role in regulating synaptic plasticity in neurons (Amici et al. 2009). In addition, Ca^{2+} buffers such as calbindin D-28, calretinin, and parvalbumin influence the spatial and temporal characteristics of a Ca^{2+} response (reviewed in Berridge et al. 2003).

Ca^{2+} and Neurotransmission

Neurotransmitter release is controlled by cytosolic Ca^{2+}. Ca^{2+} influx into synaptic terminal leads to vesicle release and priming of new synaptic vesicles (reviewed in Berridge et al. 2003). Ca^{2+}-mediated synaptic transmission occurs through various sources of Ca^{2+} including NMDA receptors and VGCCs (Berridge et al. 2003). Activation of VGCCs at synaptic terminal depolarizes the membrane and relieves the Mg^{2+} block of NMDA receptors thus allowing Ca^{2+} influx upon glutamate binding. This phenomenon is known as coincidence detection as the activation of NMDA receptors sometimes requires sufficient membrane depolarization (Berridge et al. 2003).

Action potentials along the neuronal axon generate synchronous release of neurotransmitter followed by asynchronous release which occurs at much lower rates (Neher and Sakaba 2008). Synchronous release occurs via brief Ca^{2+} microdomains that develop and quickly subside near VGCCs (Neher and Sakaba 2008). In many of the synapses studied, vesicle releases rate are affected by a narrow local Ca^{2+} concentration range (Neher and Sakaba 2008). In some synapses, short-term depression during prolonged activity is, in part, due to exhaustion of the pool of "readily releasable" vesicles (Neher and Sakaba 2008). The Ca^{2+} concentration required for vesicle recruitment is lower than that of the Ca^{2+} concentration required for vesicle release (Neher and Sakaba 2008).

Ca^{2+} release from IP_3Rs and RyRs regulates neuronal and astrocyte exocytosis (reviewed in Berridge 2006). For example, astrocytes utilize Ca^{2+} release from IP_3Rs to initiate exocytosis of glutamate-containing vesicles (Berridge 2006). Peptides released from terminals of hypothalamic neurons also require localized Ca^{2+} release from RyRs (Berridge 2006).

In the hippocampus, spontaneous transmitter release from mossy fiber boutons generates miniature excitatory postsynaptic currents (mEPSCs) in hippocampal CA3 neurons. The mEPSC frequency is normally low during periods of relative inactivity but increases considerably after stimulation of presynaptic nAChRs introducing Ca^{2+} into the cell (Berridge 2006). This Ca^{2+} influx does not initiate transmitter release, but it enhances Ca^{2+} release from RyRs to elicit spontaneous Ca^{2+} sparks that initiate exocytosis (Berridge 2006).

Ca^{2+} and Neuronal Differentiation and Development

Ca^{2+} signaling regulates the neuronal migration, differentiation, and development in the central nervous system. Neuronal precursor cells in the brain migrate from the ventricular zone (VZ) to future cortical areas during early development. Ca^{2+} regulates neuronal motility, axonal elongation and guidance, and dendritic development (reviewed in Gomez and Zheng 2006). VGCCs are a key player in regulating neuronal motility. For example, activation of N-type VGCCs influences the migration of cerebellar granule cells (reviewed in Gomez and Zheng 2006). Directional cues are, in part, mediated by intracellular Ca^{2+} gradients. The Ca^{2+} concentration within cellular microdomains, particularly near the leading neuritic processes, underlies the translocation of neuronal soma (reviewed in Gomez and Zheng 2006).

In addition, the Ca^{2+} concentration gradient range can control growth cone repulsion or attraction (reviewed in Gomez and Zheng 2006). Extension of growth cones is mediated by an optimal Ca^{2+} concentration range, and the frequency of Ca^{2+} waves influences the rate of axonal elongation (reviewed in Gomez and Zheng 2006).

The Ca^{2+}-dependent kinase, Ca^{2+}/calmodulin-dependent protein kinase (CaMK) II isoform is involved in axonal extension and guidance

(reviewed in Gomez and Zheng 2006). The α-CaMKII isoform requires relatively large Ca^{2+} transients to influence axonal branching, while the β-CaMK II isoform requires lower Ca^{2+} concentration to regulate neurite extension (reviewed in Gomez and Zheng 2006). Additionally, Ca^{2+} can regulate the cGMP/cGMP-dependent kinase (PKG) as well as the Rho GTPase pathways of neurite growth and extension (reviewed in Gomez and Zheng 2006). The Ca^{2+}-dependent phosphatase, calcineurin, controls neurite extension differentially depending upon the nature of the Ca^{2+} signals (reviewed in Gomez and Zheng 2006).

Numerous neuronal functions, such as synapse development, are controlled by spatially restricted Ca^{2+} transients (reviewed in Berridge 2006). Spatially restricted Ca^{2+} signals arise in each stage of synapse development and these Ca^{2+} transients perform essential functions in the establishment and turnover of synapses (reviewed in Michaelsen and Lohmann 2010). The initial stage of synapse formation is the establishment of a contact between axons and dendrites, which is normally initiated by dendritic filipodia (Michaelsen and Lohmann 2010). Creation of these synaptic contacts generates spatiotemporally regulated Ca^{2+} transients in dendrites which, in turn, regulate this interaction (Michaelsen and Lohmann 2010). These contact-generated Ca^{2+} responses likely start in the filopodium, and spread into the dendritic shaft, where they terminate rapidly (Michaelsen and Lohmann 2010).

In developing hippocampal neurons, a rise in spontaneous Ca^{2+} signaling is associated with a reduction in filopodial motility (Michaelsen and Lohmann 2010). Elevating intracellular Ca^{2+} concentrations reduces filopodial motility, while inhibiting spontaneous dendritic Ca^{2+} responses initiates filopodial growth (Michaelsen and Lohmann 2010). Likewise, axon-dendrite contacts showing strong contact-generated dendritic Ca^{2+} signals become stabilized while dendrites exhibiting insignificant Ca^{2+} signaling become unstable (Michaelsen and Lohmann 2010).

To accomplish restricted Ca^{2+} signals in dendrites of aspiny interneurons, Ca^{2+} entry must be spatially confined and efficiently eliminated via buffering or extrusion (Michaelsen and Lohmann 2010). Synaptic Ca^{2+} transients are spatially restricted to microdomains in aspiny interneurons due in large part to the presence of Ca^{2+}-permeable AMPARs which exhibit rapid inactivation kinetics, thus limiting the overall Ca^{2+} influx (reviewed in Berridge 2006; Michaelsen and Lohmann 2010). In addition, synaptic clustering of these Ca^{2+}-permeable AMPARs thereby generate more spatially restricted Ca^{2+} transients compared to VGCCs. These Ca^{2+}-permeable AMPARs are transiently expressed in immature, developing pyramidal cells, but are generally absent later in development when spines mature (Michaelsen and Lohmann 2010).

In aspiny neurons, endogenous Ca^{2+} buffers also help to confine synaptic Ca^{2+} responses allowing for highly localized Ca^{2+} transients (Michaelsen and Lohmann 2010). Aspiny interneurons abundantly express the Ca^{2+}-binding protein parvalbumin, while young pyramidal neurons transiently express calbindin or calretinin providing adequate intracellular Ca^{2+}-buffering capability (Michaelsen and Lohmann 2010).

The confinement of Ca^{2+} transients within individual synapses may be critical for certain forms of synaptic plasticity throughout this stage of development. Young hippocampal neurons can undergo LTP prior to the formation of dendritic spines (Michaelsen and Lohmann 2010). Mature neurons require CaMKII activation through elevations in synaptic Ca^{2+} to generate LTP. Unlike in mature neurons, LTP in immature neurons requires cAMP-dependent protein kinase A instead of CaMKII (Michaelsen and Lohmann 2010).

In later developmental stages, spines appear on pyramidal neuron dendrites. Spine formation is regulated by CaMKs, including CaMKI, CaMKII, and CaMKIV, indicating that localized Ca^{2+} signals may elicit growth of individual spines (Michaelsen and Lohmann 2010). Activation of the CaMKIα isoform initiates axonal growth, while CaMKIγ activation supports dendritic outgrowth (Neal et al. 2010).

Ca^{2+} signaling from intracellular stores can regulate dendritic branching. For example, overexpression of the long Homer-1 isoform, Homer-1 L, in cerebellar Purkinje neurons results in elevated IP_3R-mediated Ca^{2+} signaling that leads to the reduction of dendritic branching (Tanaka et al. 2006).

Ca^{2+} and Neuronal Gene Expression

Postsynaptic Ca^{2+} influx generates signaling events ultimately leading to the alteration or regulation of the expression of genes involved in dendritic development and synaptic plasticity (Greer and Greenberg 2008).

Differential gene expression through Ca^{2+} signals largely depends upon which Ca^{2+} channels generate the Ca^{2+} response (Duncan et al. 2007; Greer and Greenberg 2008).

The L-type VGCCs exhibit specific biophysical properties leading to high Ca^{2+} conductance with a relatively long duration, which is necessary for increases in nuclear Ca^{2+} and likely critical for changes in gene expression (Greer and Greenberg 2008). Furthermore, the somatic localization of L-type VGCCs places the receptors in close proximity to the nucleus compared to other channels exhibiting synaptic localization thereby allowing them to generate nuclear Ca^{2+} signals important for changes in gene expression (Greer and Greenberg 2008). In addition, the expression of differentially distributed IP_3R subtypes within subcellular compartments, such as the nuclear envelope, can generate nuclear Ca^{2+} transients which likely control processes important in nuclear function such as gene expression (Duncan et al. 2007).

The Ca^{2+}-binding protein, calmodulin (CaM), is a major mediator of Ca^{2+}-induced signals. CaM can activate CamKII, which can activate the transcription factors CREB and NeuroD in the nucleus (Greer and Greenberg 2008). In addition, the MEF2 transcription factor is activated by calcineurin (Greer and Greenberg 2008).

NFkB- and NFAT-mediated gene transcription can be initiated by fast Ca^{2+} oscillations while slower oscillations stimulate NFkB (Mellström et al. 2008). This effect demonstrates how Ca^{2+} can discretely activate transcription factors. The transcription factor CREB is important in neuronal function and Ca^{2+} influx through synaptic NMDA receptors or VGCCs can activate CREB to initiate BDNF gene expression (Mellström et al. 2008). Interestingly, activation of extrasynaptic NMDA receptors counteracts this CREB-mediated activation of BDNF expression (Mellström et al. 2008). Furthermore, different Ca^{2+} signaling machinery in neurons underlies different phases of neuroprotection. Synaptic Ca^{2+} influx through NMDA receptors leads to Akt activation and short-term neuronal survival (Mellström et al. 2008). On the other hand, sustained neuroprotection involves CREB activation followed by nuclear Ca^{2+}/calmodulin activity (Mellström et al. 2008).

Some CamKII and CaMKIV forms are predominantly nuclear. Mice not expressing CaMKIV are defective in hippocampal LTP and LTD in Purkinje neurons of the cerebellum, both attributable to CREB phosphorylation status (Mellström et al. 2008).

Ca^{2+} and Neurodegeneration

In a variety of neurodegenerative diseases, normal neuronal function and viability is influenced by intracellular Ca^{2+} signaling. Excessive increases in intracellular Ca^{2+} can initiate apoptosis or necrosis depending upon the concentration, location, and duration of released Ca^{2+}. Accordingly, strategies for regulating intracellular Ca^{2+} concentrations and Ca^{2+} signaling may be useful therapeutic interventions against neurodegenerative diseases (Duncan et al. 2010; Hwang et al. 2009; Rybalchenko et al. 2009).

Age-related changes in neuronal Ca^{2+} regulation include increased intracellular Ca^{2+} concentrations, increased Ca^{2+} influx through VGCCs, and impaired mitochondrial Ca^{2+} buffering together with dysregulated intracellular Ca^{2+} stores (Duncan et al. 2010). Oxidative stress, which occurs in numerous neurodegenerative diseases, can significantly alter intracellular Ca^{2+} signaling (Kaja et al. 2010).

Excessive NMDA receptor activation by glutamate causes massive Ca^{2+} influx leading to subsequent excitotoxicity and neuronal death (Duncan et al. 2010). In retinal ganglion cells, glutamate administration stimulates NMDA receptors leading to delayed Ca^{2+} dysregulation preceeding neuronal death (reviewed in Duncan et al. 2010). Brain tissue obtained from Alzheimer's disease (AD) patients exhibits significant changes in the expression of neuronal Ca^{2+} signaling proteins (Reviewed in Duncan et al. 2010). Furthermore, NMDA receptor activation or glutamate receptor expression contributes to AD pathophysiology in experimental models (reviewed in Duncan et al. 2010). For example, Aβ reduces NMDA receptor activity and cell surface expression levels (Duncan et al. 2010).

In animal models of AD, mutations in PS1 and PS2 lead to changes in IP_3R function resulting in increased Ca^{2+} release from ER stores and decreased neuronal viability (reviewed in Duncan et al. 2010). Interestingly, IP_3 concentrations in brains of patients with AD are diminished (Duncan et al. 2010). Mutant PS-1 and triple transgenic (PS-1/PS-2/APP) mice exhibit elevated RyR levels, increased Ca^{2+} release from RyRs, and increased vulnerability to Aβ (Duncan et al. 2010).

Furthermore, exposure of cultured neurons to Aβ elevates RyR3 expression and activity resulting in neuronal death (Duncan et al. 2010). In accordance, AD patients exhibit alterations in RyR expression and ryanodine binding in affected brain regions (Duncan et al. 2010).

Recently, the role of PS1 and PS2 on intracellular Ca^{2+} signaling has been examined at the molecular level. Application of an 82 amino acid PS1 fragment to the cytoplasmic side of RyR increases single channel RyR current and open probability (Rybalchenko et al. 2008). Similarly, application of an 87 amino acid PS2 fragment significantly increases RyR single channel activity without affecting Ca^{2+} sensitivity of the receptor (Hayrapetyan et al. 2008). These effects of PS1 and PS2 may represent a role for presenilins in regulating RyR activity and Ca^{2+} homeostasis in general.

Acknowledgments Partial support by Grants EY014227 and EY022774 from NIH/NEI; RR027093 and RR022570 from NIH/NCRR; and AG010485, AG022550, and AG027956 from NIH/NIA as well as by a Research to Prevent Blindness Challenge Grant and by the Felix and Carmen Sabates Missouri Endowed Chair in Vision Research (P.K.) is gratefully acknowledged.

Calcium ions in eyesight; Calcium regulation of phototransduction and light adaptation

Definition

Phototransduction refers to the process of converting light into electrical signals underlying the neural activity of the retina. Photoreceptors, the site of transduction in both invertebrate and vertebrate vision, can modulate their cellular responses as a function of light intensity and background illumination in order to cope with the wide range of lighting in the environment. These adaptation and transduction mechanisms rely on calcium signaling. A variety of ocular pathologies, including different forms of retinal degeneration and the aberrant growth of retinal precursors or other cell types in the eye, often are due to mutations in gene products regulating calcium. The discovery of these events is now providing opportunities for intervention in the treatment of very disparate diseases of the eye.

Calcium in Vertebrate Photoreceptors

Vertebrate photoreceptor cells can detect the absorption of a single photon of light and continue to respond in a near linear fashion over four to six log units of light intensity before the response saturates. The intracellular concentration of calcium and the "toolbox" of ▶ calcium-binding proteins found in the photoreceptor cell contribute to this process, modulating the range of light intensity to which the cell can respond (Nakatani et al. 2002). Photoreceptor cells also are capable of adjusting their responses to compensate for changes in

background illumination. This sort of adaptation allows one to see in a darkened theater and then to drive a car upon exiting from a matinee on a sunny day. While the intricacies of the molecular mechanisms underlying these events are not fully understood, the role of calcium and its targets has been partially elucidated. Of further significance, the binding proteins that mediate the effects of calcium also have been implicated in a variety of ocular diseases.

Phototransduction

Vertebrate photoreceptor cells are comprised of an inner and an outer segment. The inner segment contains the organelles characteristic of a eukaryotic cell and maintains synaptic contact with the next layer of retinal neurons. A thin modified cilium connects the inner segment to the highly specialized outer segment. Of the two types of photoreceptor cells, rods and cones, found in the vertebrate retina, rods are better studied, but the basics of phototransduction are believed to be the same in cones (Yau and Hardie 2009). The rod outer segment is comprised of a plasma membrane enclosing a separate stack of flattened saccules referred to as disks (Fig. 1a). Approximately 1,000–2,000 of these disks per rod outer segment house the roughly 10^7–10^9 visual pigment molecules, rhodopsin. Rhodopsin consists of a chromophore, the 11-*cis* aldehyde of vitamin A (11-*cis* retinal) bound in the dark to the protein opsin, an intrinsic membrane protein. Cone cells use the same chromophore but differ in their types of opsin, resulting in different spectral properties underlying the detection of color. The direct effect of light is to cause the isomerization of 11-*cis* retinal to its all-*trans* configuration. In vertebrate photoreceptor cells this results in the dissociation of retinal from opsin and its subsequent recycling through the pigmented cells lying adjacent to the outer segments. Isomerization also initiates the phototransduction enzymatic cascade (Fig. 1b).

Rhodopsin is perhaps the best characterized member of the large family of G-protein coupled receptors (GPCRs). Following photoisomerization of the chromophore, rhodopsin binds a G-protein, referred to in the earlier literature as transducin (G_t). Once G_t binds to photoactivated rhodopsin, GTP is exchanged for GDP causing the alpha submit ($G_{t\alpha}$) of the heterotrimeric G-protein to dissociate. $G_{t\alpha}$ subsequently interacts with the inhibitory gamma subunits of the disk-associated cGMP-phosphodiesterase (PDE), resulting in PDE activation.

cGMP acts as the internal transmitter mediating between the absorption of light by rhodopsin in the disk membranes and the change in conductance of the outer segment plasma membrane. Cation channels in the outer segment plasma membrane are directly gated by cGMP. These channels remain open in the dark when cGMP levels are high. Activation of PDE and its subsequent hydrolysis of cGMP cause these cation channels to close. A hyperpolarization of the photoreceptor cell ensues, ultimately leading to a decrease in the release of synaptic transmitter and conveyance of the light signal to the next order of retinal neurons.

To inactivate these light events and reset the system, several counter measures must be instigated. First, rhodopsin is phosphorylated by a specific kinase (GRK1), causing the binding of an additional protein, arrestin. These two events, phosphorylation and the binding of arrestin, block the activation of further G-proteins by photoactivated rhodopsin. Next, GTP is hydrolyzed to GDP by the intrinsic GTPase activity of $G_{t\alpha}$. The fidelity of this process is aided by a GTPase-activating protein (GAP) complex. Following the hydrolysis of GTP, the PDE- $G_{t\alpha}$ complex dissociates; PDE then binds once again with its inhibitory subunits and $G_{t\alpha}$ with its beta and gamma subunits. These steps ensure that no further cGMP is hydrolyzed. Guanylate cyclase (GC) in the outer segment then converts GTP to cGMP and the cation channels in the plasma membrane reopen. Newly delivered 11-*cis* retinal binds to opsin, arrestin uncouples, rhodopsin is dephosphorylated, and the system is essentially reset to receive the next photon.

While sodium ions comprise the majority of the cations conducted through the cGMP-gated channels of the outer segment plasma membrane, calcium ions make up roughly 15% of the current. Therefore, in the dark when the cGMP-gated channels are open, the intracellular concentration of calcium is high, approximately 500–700 nM. Calcium is then returned to the extracellular milieu by its extrusion from the outer segment through the activity of plasma membrane Na^+/Ca^{2+}-K^+ exchangers. The rate of the exchanger is unaffected by light, so the closure of the cGMP-gated channels upon illumination decreases the amount of calcium entering the cell, and the intracellular concentration of calcium drops as the exchanger continues to operate. This decline in

intracellular calcium upon light exposure in turn activates GC, mediated by specific calcium-binding proteins referred to as GCAPs (guanylate cyclase–activating proteins). GCAPS are 23 kDa members of the ▶ EF-hand superfamily of calcium-binding proteins. Three mammalian isoforms of GCAPs (GCAP1-3) have been identified in the retina, each containing four EF-hand motifs, but only EF-hands 2–4 are capable of binding calcium. GCAPs, in their calcium-bound form, inhibit GC activity. Therefore, when calcium levels are highest in the dark GC activity is marginal owing to the inhibitory effect of calcium-bound GCAP. As calcium levels fall upon illumination, GCAP in its unbound form is no longer inhibitory and GC synthesizes cGMP to return the cell to its dark-adapted state. In this manner, calcium acts as a counter measure to light, thus allowing the photoreceptor cell to extend its responsive range of light intensity. In knock-out mice lacking GCAP, rod cells have a diminished capacity to return to dark-adapted conditions following light stimulation, thus supporting the contention that calcium-regulated GC activity mediated by GCAP is necessary for adaptation.

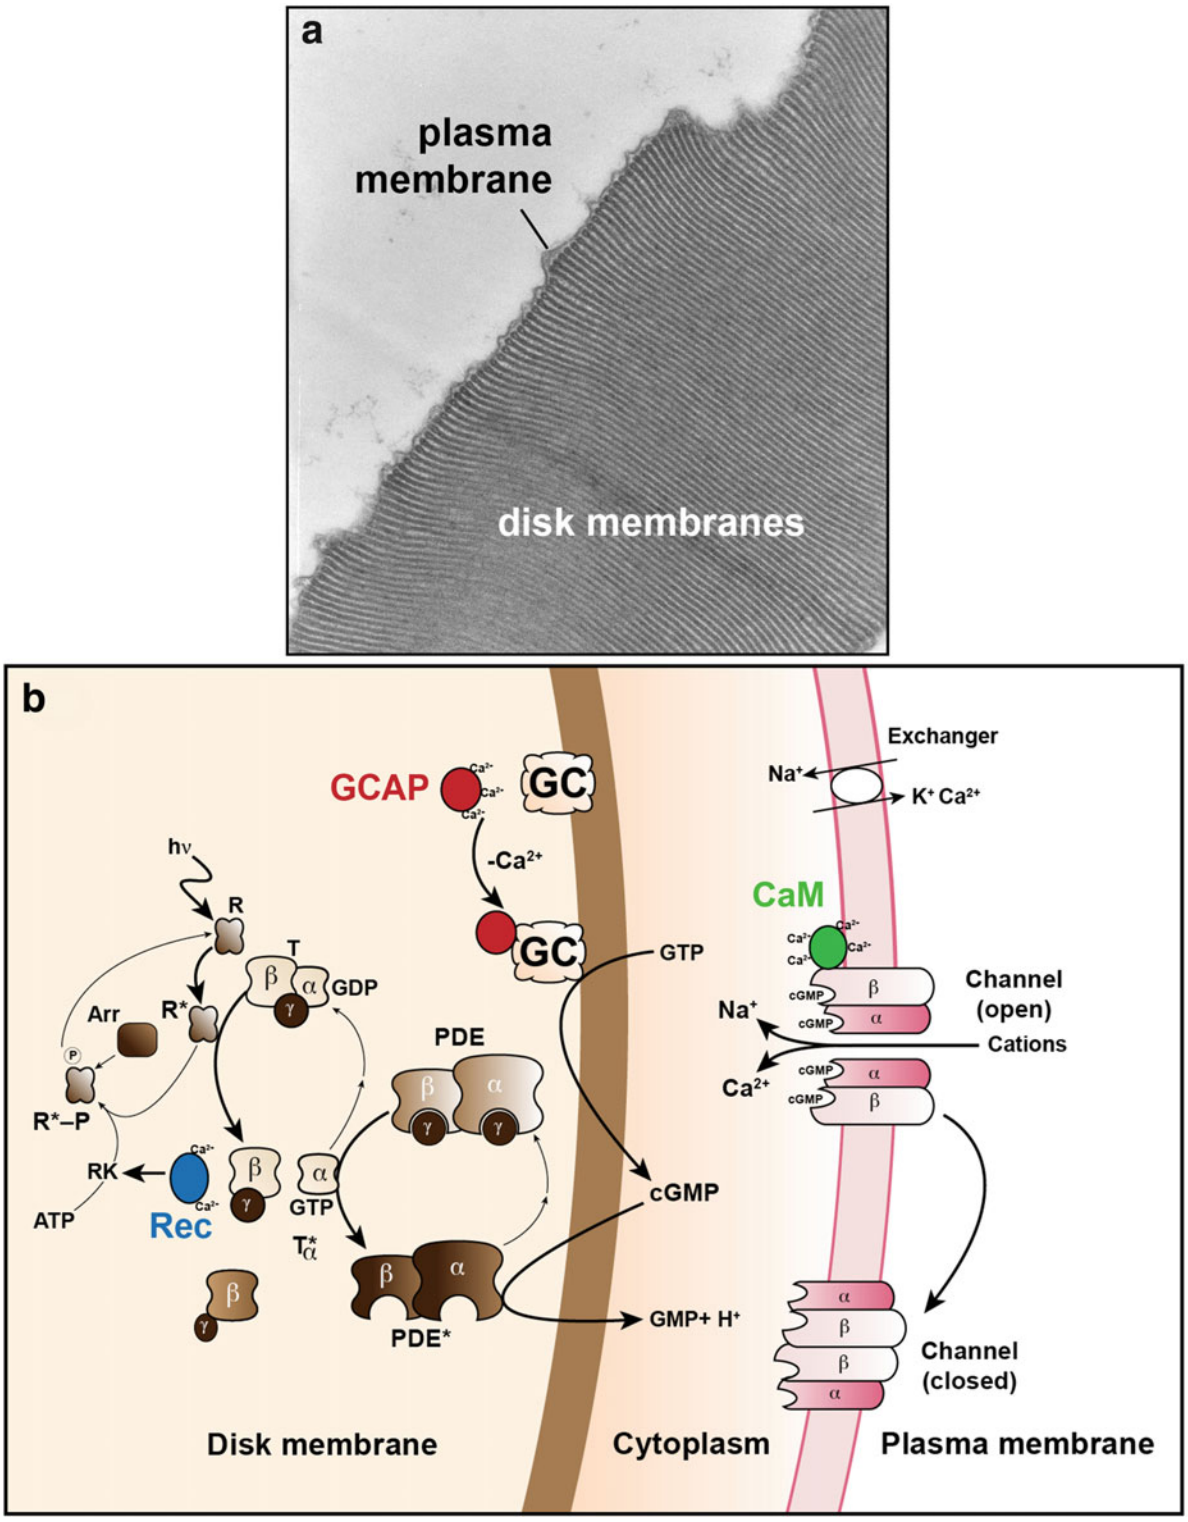
The decline in calcium concentration following photoactivation has at least two additional consequences for adaptation. GRK1 activity is thought to be regulated by another EF-hand calcium-binding protein, which is relatively specific for photoreceptor cells. It is known by several names in the literature: recoverin, S-modulin, and visinin. This protein also contains four EF-hand motifs. Like calmodulin, EF1 and EF2 in recoverin interact to form one domain, while EF3 and EF4 form a second domain. However, recoverin overall takes a globular shape with the two domains in close proximity, connected through a short U-shape linker, rather than the long central helix providing the classic dumbbell shape of calmodulin. In dim light, calcium-bound recoverin purportedly interacts with GRK1, slowing rhodopsin phosphorylation and the subsequent binding of arrestin. As the light intensity increases and calcium levels in the photoreceptor cell decline, the interaction with recoverin diminishes, allowing GRK1 to phosphorylate rhodopsin and arrestin to bind, thus reducing the lifetime of photoactivated rhodopsin. Again, calcium acts as a counter measure to light, in this instance by negatively regulating the activity of GRK1 through recoverin.

Finally, the affinity of the cGMP-gated channel is modulated by the calcium concentration. In the dark when calcium levels in the outer segment are elevated, the affinity of the plasma membrane cation channels for cGMP is lower. This is thought to be due to the negative interaction of calmodulin or a similar EF-hand calcium-binding protein with the channel. As the intracellular concentration of calcium declines upon illumination, the modulatory affect of calmodulin also decreases and the affinity of the channel to cGMP increases. This allows channels to reopen, thus accelerating the return to the dark-adapted state.

In summary, the light-dependent decline in intracellular calcium can affect the synthesis of cGMP through the action of GCAPs, regulate the lifetime of photoactivated rhodopsin by recoverin, and alter the sensitivity of the cation channel through calmodulin or a comparable calcium-binding protein. These processes then contribute to the photoreceptor's ability to adapt to different levels of illumination in the host's environment, a key feature of vision.

Ocular Pathologies in Humans

(a) Degenerative Cone Diseases – Patients afflicted with autosomal dominant cone dystrophies experience impaired central and color vision. Mutations underlying these dystrophies are heterogeneous but often involve genes expressed in photoreceptor cells. Some involve phototransduction-specific genes encoding, for example, visual pigment proteins, while others affect gene products expressed at the other end of the cell at the synaptic processes. The most extensively studied genes contributing to cone dystrophies, however, are associated with cGMP synthesis involving GC and GCAP1 (Jiang and Baehr 2010). GC mutations often involve its dimerization domain, while mutations in GCAP1 primarily involve residues flanking the EF-hands or residues within the EF-hand calcium-binding loops. GCAP1(Y99C) involves the replacement of a hydrophobic tyrosine residue with cysteine flanking EF-hand 3. This alters both the structure and the calcium binding of EF-hand 3. EF-hand 3 is critical in transforming GCAP1 from an activator to an inhibitor upon binding calcium. In contrast to a flanking residue, GCAP1(N104K) contains a mutation within the loop region of EF3 causing a significant reduction in the binding affinity for calcium. This renders the GCAP1 mutant



Calcium in Vision, Fig. 1 (continued)

unable to inhibit GC even at elevated levels of calcium. Since calcium-bound GCAP1 is necessary to inhibit GC, both mutations are predicted to result in elevated levels of cGMP and a greater frequency of open cation channels, thus allowing more persistent entrance of calcium into the photoreceptor outer segment. Calcium is a potent apoptotic signal, perhaps underlying the ensuing degeneration of the cone photoreceptors.

Similar to Y99C, a mutation in a flanking hydrophobic residue at EF-hand 4, GCAP1(I143NT), also has been identified in a patient population afflicted with cone dystrophy. The mutation results in the reorientation of the N-terminal helix, lowering the affinity for calcium binding at EF4. GCAP1(E155G) changes an invariant glutamate residue at position 12 of EF4, essential for calcium binding. Again, these mutations are expected to result in elevated GC activity in dark-adapted cone cells and aberrant levels of cGMP and channel conductance.

(b) Cancer-Associated Retinal Degenerations – Paraneoplastic syndromes encompass a spectrum of neurodegenerative diseases associated with the early onset of cancer in a portion of the body distinct from the degenerative site in the nervous system. These remote effects of cancer are thought to be mediated by an autoimmune reaction. *C*ancer-*A*ssociated *R*etinopathy (CAR) is one such disease, whereby a tumor, often a small cell carcinoma of the lung, initiates the loss of photoreceptor cells in the retina. The calcium-binding protein recoverin is directly involved in this effect (Ohguro and Nakazawa 2002).

Recoverin has been shown to be expressed in some primary tumors. Since recoverin is normally found in the eye, an immune privileged site, its presence in the tumor leads to an immune response in the patient. Both antibodies and activated T cells specific for recoverin have been found in CAR patients. The autoantibodies react to several different regions of the recoverin sequence, but an immunodominant region was identified around residues 64–70. When anti-recoverin antibodies are generated in animals, the same regions of recoverin are antigenic and residues 64–70 remain dominant. This region of recoverin corresponds to the first α-helix of EF-hand 2, consisting primarily of hydrophobic amino acids that normally would not be expected to be so antigenic. Recoverin is normally expressed at high levels in both rod and cone cells, localized throughout the cells, from the tips of their outer segments to their synaptic processes. Recoverin also has been found in a subset of bipolar and non-retinal cells but is considered essentially photoreceptor-specific. In rodents inoculated with recoverin, the resultant antibodies are taken up by the photoreceptor cells and then activate an apoptotic process leading to the degeneration of both rod and cone cells. A peptide corresponding to residues 64–70 also induces photoreceptor degeneration. Therefore, this unsuspecting region of recoverin is both immunodominant and immunopathogenic. (A second pathogenic site in recoverin corresponding to residues 136–167 also has been identified). Importantly, inoculation with recoverin or its immunopathogenic regions recapitulates what happens in humans with CAR, whereby widespread photoreceptor degeneration is observed. The remaining retinal layers are intact, but without photoreceptor cells to transduce light into the electrical activity of the nervous system the afflicted individuals are left visually impaired or blind depending upon the extent of photoreceptor cell damage. Patients are often treated with immunosuppressants such as prednisone in an attempt to

Calcium in Vision, Fig. 1 Phototransduction in the vertebrate rod photoreceptor cell. The vertebrate rod outer segment contains a stacked series of double-membranous disks surrounded by a plasma membrane, as seen in this electron micrograph. (**a**) Disk membranes are densely packed with the visual pigment molecule, rhodopsin, to optimize photon capture. Other components of the phototransduction enzymatic cascade involved in the regulation of cytoplasmic cGMP are associated with the cytoplasmic surface of the disks. (**b**) Channels in the plasma membrane are modulated by cGMP and thereby the entrance of sodium and calcium ions. Sodium ions determine to the larger extent the membrane potential and the subsequent signaling of synaptic transmitter release, while calcium ions regulate adaptation through a series of calcium-binding proteins (see text). Abbreviations: *hv* light, *R* rhodopsin, *R** photoactivated rhodopsin, *RK* rhodopsin kinase, *R*-P* phosphorylated rhodopsin, *Arr* arrestin, *T* transducin, *PDE* phosphodiesterase, *GC* guanylate cyclase, *GCAP* guanylate cyclase–activating protein, *Rec* recoverin, *CaM* calmodulin

dampen the immunological response to recoverin's aberrant expression in tumor cells. Potentially more relevant, the visual symptoms often precede the detection of cancer, so once autoantibodies to recoverin are detected in the patient's serum, that individual can be moved from the ophthalmology setting to an oncology clinic where the tumor can be treated. If the tumor at these early stages can be eradicated then the antigen, recoverin, is no longer a source for the autoimmune-mediated loss of photoreceptor cells. Therefore, the combined suppression of existing anti-recoverin antibodies and the elimination of the source of recoverin offer the best hope for salvaging vision.

While many diseases are thought to be mediated by autoimmunity, they often remain invalidated. CAR is one of the best examples of autoimmunity, since the antigen, recoverin, has been found in tumor cells of patients afflicted with the visual disorder, the immune response leads to specific anti-recoverin antibodies and specific activated T cells, the antigen is normally localized in photoreceptor cells, the site of degeneration, and the disease can be recapitulated in animal models using recoverin.

(c) Uveal Melanoma – The primary malignancy of the eye originates in the pigmented structures of the iris, choroid, and ciliary body, collectively referred to as the uvea. Each of these structures contains melanocytes that can become transformed into melanomas. One of the genes expressed at much lower levels in melanomas compared to their normal cell counterparts is ALG-2, *A*poptosis *L*inked *G*ene-2 or PCD6, *P*rogrammed *C*ell *D*eath Protein 6. ALG-2 is pro-apoptotic. Transient transfection studies to reduce the expression of ALG-2 protected cells from apoptosis. In contrast, its overexpression renders cells more susceptible to apoptotic stimuli. The conclusion from such experiments is that lowering the expression of ALG-2 might interfere with normal execution pathways associated with programmed cell death. It therefore might be advantageous to melanoma cells, as well as other cancer cell types, to downregulate ALG-2 and thereby improve their survival status.

ALG-2 forms dimers in cells independent of calcium concentration; however, calcium is essential for its interaction with such targets as Alix/AIP. ALG-2 is a member of the ▶ penta-EF-hand calcium-binding protein family, and mutations in either EF-hands 1 or 3 eliminate binding to Alix/AIP. Mutations in EF-hand 5 reduce but do not abrogate binding. These three EF-hands correspond to the two high affinity and one low affinity calcium-binding domains in ALG-2. It is thought that ALG-2 might function in the ER stress response. The downregulation of ALG-2 therefore could protect cancer cells by short-circuiting the connection between elevated levels of calcium associated with ER stress and the subsequent activation of cell death pathways.

Interestingly, calcium could play a significant role in the eventual treatment of uveal melanoma, as well as other types of cancer and neurodegenerative diseases (van Ginkel et al. 2008). Certain nontoxic natural products, for example, resveratrol, EGCG, and quercetin, display antiproliferative, anti-angiogenic, and pro-apoptotic features during the treatment of uveal melanoma and other cancers. These compounds are especially important since they can differentiate between tumor cells and normal cells to a greater extent than conventional chemotherapeutics. They activate the ER stress pathway as well as the intrinsic or mitochondrial apoptotic pathway in tumor cells. They also can inhibit endothelial cell migration and tube formation involved in new blood vessel formation – a requirement for tumor growth. In both tumor and endothelial cells, but not most normal cells, these nontoxic compounds induce calcium signals. The endoplasmic reticulum (ER) appears to be the initial source of calcium, whereby resveratrol and the other compounds cause a rapid rise in cytoplasmic calcium by releasing ER stores, likely through the activation of the IP_3 receptor and/or partial inhibition of SERCA, the pump necessary for sequestering calcium in the ER. Following the first rise in cytoplasmic calcium, mitochondria respond by taking up calcium, contributing to their depolarization and a calcium-induced calcium release, constituting a second, longer increase in cytoplasmic calcium. The rise in cytoplasmic calcium is then linked to many events, including the activation of the intrinsic apoptotic pathway ultimately involving caspase-3. The elevated levels of calcium also

activate the calpains, a second family of cysteine proteases. Targets of calpain then include plasma membrane calcium pumps and exchangers, resulting in longer-term disruption of calcium homeostasis and tumor cell death.

Summary

The fundamentals of the phototransduction enzymatic cascade have been deciphered, and numerous gene mutations in components of the pathway leading to visual impairment and blindness have been identified. Since the retina is the most accessible portion of the central nervous system, lessons from its study may extend to the brain and other tissues. Not surprisingly, the retina has provided invaluable information about the normal physiology and pathology of calcium and calcium-binding proteins. This entry has focused on the calcium-binding proteins most readily associated with diseases of the human eye. Their further study represents an opportunity to bridge structural biology and key cellular pathways with aberrations leading to human disease, as well as new therapies based on the intricacies of calcium signaling. In addition, there is a host of other calcium-binding proteins that already have been identified in the retina, such as calretinin, the centrins, and certain ▶ neuronal calcium sensor proteins. These additional calcium-binding proteins await further examination to more definitively identify their function and possible connection with ocular pathologies.

Calcium in Invertebrate Photoreceptors

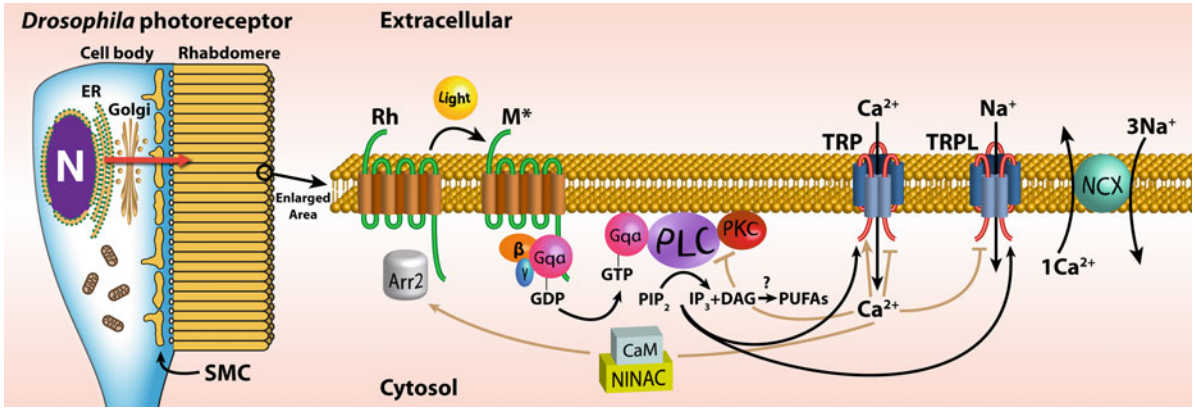
Phototransduction

The Drosophila compound eye is comprised of ~800 individual eye units called ommatidia. Each ommatidium contains eight photoreceptor cells. The R1-6 photoreceptor cells extend the length of the retina and express the major rhodopsin in the eye, Rh1 (rhodopsin1), which absorbs maximally in the blue-green region of the spectrum (λ_{max} 480 nm). Rh1, encoded by the *ninaE* gene, displays 22% amino acid identity with human rhodopsin. The R7 photoreceptor cells are located distally and express two ultraviolet-sensitive, Rh3 and Rh4, opsins. The R8 photoreceptors are proximal and express Rh5 (blue) and Rh6 (green) opsins. Like vertebrate cone photoreceptors, R7 and R8 cells function in color vision, while the R1-6 photoreceptor cells are specialized for several functions including brightness detection, orientation behavior, and motion detection (Vogt and Desplan 2007).

Each photoreceptor cell contains a photoreceptive rhabdomere, which is comprised of numerous tightly packed microvilli that contain the rhodopsin photopigments and the other components of phototransduction (Fig. 2). The rhabdomeres are functionally equivalent to the outer segments of the rod and cone photoreceptor cells in the vertebrate retina (Colley 2010; Fain et al. 2010; Yau and Hardie 2009).

Drosophila visual transduction is the fastest known G-protein-coupled signaling cascade. *Drosophila* Rh1 initiates the phototransduction cascade by interacting with a heterotrimeric Gq protein, which, in turn, activates phospholipase C (PLC-β) encoded by the *norpA* gene. Interestingly, PLC- β in *Drosophila* is closely related to PLC- β4 expressed in the vertebrate retina. In *Drosophila*, activation of PLC leads to the opening of two cation-selective, tetrameric, transient receptor channels (TRP and TRPL), resulting in a dramatic rise in intracellular Ca^{2+}. The photoreceptors depolarize and intracellular Ca^{2+} rises from resting, 100 nM levels, to tens of micromolar to as high as 1 mM in the microvilli. The downstream mechanisms for how PLC activity opens the TRP and TRPL channels remain elusive. Unlike other rhabdomeric photoreceptor cells, the IP_3-receptor is not involved, and hence, it is thought that either lipids generated via PLC activity or that PLC induced changes to the physical properties of the membrane bilayer may gate the channels. These lipid candidates include, DAG and/or downstream metabolites of DAG lipase, such PUFAs (polyunsaturated fatty acids), as well as a reduction in PIP_2 (Fig. 2). Indeed, PIP_2 has been recently shown to display both inhibitory and excitatory effects on TRP channels (Fain et al. 2010; Katz and Minke 2009; Wang and Montell 2007; Yau and Hardie 2009).

Following influx via the TRP channels, Ca^{2+} is removed from the rhabdomeres by extrusion from the cell via the sodium/Ca^{2+} exchanger (CalX), as is also the case in vertebrate rod photoreceptors. Ca^{2+} is also removed by diffusion into the cell body, where Ca^{2+} rises from approximately 100 nM resting levels to approximately 10 μM. These high levels of Ca^{2+} in the cell body are thought to be removed by



Calcium in Vision, Fig. 2 Phototransduction in *Drosophila*. Absorption of light by rhodopsin (Rh) converts it to active thermostable metarhodopsin (M*), which in turn stimulates the heterotrimeric Gq protein by GDP-GTP exchange. Activated Gqα-GTP is liberated from G_γ and G_β and stimulates PLC-β (phospholipase C). PLC hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG). DAG-kinase activity may subsequently produce polyunsaturated fatty acids (PUFAs). The two TRP and TRPL channels open due to events downstream of PLC, that are not yet known, and the photoreceptor cells depolarize. The light response is dominated by TRP, and TRP is chiefly Ca^{2+} permeable. Ca^{2+} influx acts sequentially for both positive and negative regulation of phototransduction (indicated by *brown lines* with *arrowheads* or *bars*, respectively). Initially, Ca^{2+} influx enhances TRP channel activation, but as Ca^{2+} rises to millimolar concentrations, Ca^{2+} inactivates both channels, and is thought to be the main mechanism of light adaptation. Rhodopsin inactivation by arrestin (Arr2) is Ca^{2+} dependent and requires calmodulin (CaM) and myosin III (NINAC). Ca^{2+} also terminates the light response by inactivating PLC via protein kinase C (PKC) (Yau and Hardie 2009). *Left*, diagram of the photoreceptor cell showing the nucleus (*N*), endoplasmic reticulum (*ER*), Golgi (*G*), submicrovillar cisternae (*SMC*), and rhabdomere with numerous tightly packed micovilli

sequestration via the sacro-endoplasmic reticulum ▶ Ca^{2+} ATPase (SERCA) and by buffering via Ca^{2+}-binding proteins, such as ▶ calnexin (Colley 2010; Fain et al. 2010; Katz and Minke 2009; Yau and Hardie 2009).

In *Drosophila* photoreceptor cells, Ca^{2+} is critical for excitation as well as for the termination of the light response. There are several proteins involved in Ca^{2+}-mediated termination including protein kinase C (PKC), calmodulin (CaM), and NINAC (myosin III) (Fig. 2). Failure in termination of the light response and loss of precise control of spatial and temporal profiles of Ca^{2+} are devastating to cells and can lead to cell death and retinal degeneration (Fain et al. 2010; Katz and Minke 2009; Wang and Montell 2007; Yau and Hardie 2009).

Retinal Degeneration in Drosophila

It is widely accepted that retinal degeneration can be caused by mutations in almost every constituent of the photoreceptor cells. These mutations fall into two classes. One class encompasses mutations leading to unregulated activities of phototransduction, including Ca^{2+} toxicity. These are termed light dependent. The second class involves defects in rhodopsin maturation and does not involve light activation of phototransduction. These are termed light independent (Colley 2010; Wang and Montell 2007).

Proper Ca^{2+} removal or sequestration is vital to photoreceptor cells. Ca^{2+} extrusion from photoreceptors via the ▶ Na^+/Ca^{2+} exchanger is critical to photoreceptor cell survival. Indeed, loss of the *Drosophila* Na^+/Ca^{2+} exchanger, CalX in the *calx* mutants causes high levels of sustained Ca^{2+} leading to retinal degeneration. In addition, overexpression of Calx is able to prevent the retinal degeneration resulting from constitutive activity of the TRP channels and Ca^{2+} overload. Therefore, Calx, indeed, plays a critical role in Ca^{2+} extrusion and cell viability (Wang and Montell 2007).

TRP channel function is critical to photoreceptor cell survival. Photoreceptor cells that lack TRP undergo light-dependent retinal degeneration. They are unable to sustain a steady-state current and are defective in Ca^{2+} influx. The mechanism for light-dependent retinal degeneration in *trp* null mutants is thought to result from the failure in a combination of the Ca^{2+} and PKC-dependent

inhibition of PLC. This leads to the unregulated stimulation of PLC and subsequent depletion of microvillar PIP_2. Therefore, a lack of TRP protein causes a light-dependent retinal degeneration because of unregulated light-stimulated activities of PLC (Wang and Montell 2007; Yau and Hardie 2009).

In some cases, mutations in rhodopsin itself, or in other cases, mutations in the *arrestin* gene, lead to light-dependent retinal degeneration. Arrestin functions to deactivate rhodopsin; therefore, loss in arrestin leads to unregulated rhodopsin and uncontrolled light-stimulated activities of phototransduction. Additionally, it is thought that loss of arrestin leads to decreased endocytosis of Rh1 and all of these defects lead to retinal degeneration (Colley 2010).

Since the initial 1983 report that mutations in rhodopsin lead to retinal degeneration in *Drosophila*, in excess of 100 mutations in human rhodopsin have been identified in autosomal dominant Retinitis Pigmentosa (adRP). A large number of these mutations lead to misfolded rhodopsin that is incorrectly transported through the secretory pathway. However, the mechanism by which the mutant rhodopsins act dominantly to cause retinal degeneration was not known. Studies in *Drosophila*, in 1995, on dominant rhodopsin mutations revealed that the retinal degeneration is caused by interference in the maturation of normal rhodopsin by the mutant forms of rhodopsin. These studies in *Drosophila* provided a mechanistic explanation for the cause of certain forms of adRP (Colley 2010).

Rhodopsin is synthesized on membrane-bound ribosomes and undergoes translocation, posttranslational modifications, folding, and quality control in the endoplasmic reticulum (ER). In the face of these intricate and error-prone processes, the photoreceptor cells have evolved systems of molecular chaperones to promote the proper processing of newly synthesized rhodopsin. To become functionally active, rhodopsin must be correctly folded and is required to precisely traverse the secretory pathway to the rhabdomeres for its role in phototransduction. The mechanisms for regulating rhodopsin maturation including folding, chaperone interaction, glycosylation, chromophore attachment, and transport are crucial for photoreceptor cell survival as defects in these processes lead to retinal degeneration in both flies as well as in humans. These types of retinal degenerations are generally in the light-independent class (Colley 2010).

In *Drosophila*, as in humans, rhodopsin undergoes N-linked glycosylation during biosynthesis, and in flies, elimination of the glycosylation site (N20I) results in the retention of rhodopsin in the secretory pathway and retinal degeneration. In addition, like in humans, *Drosophila* rhodopsin must attain its vitamin-A-derived chromophore at a lysine residue in the seventh transmembrane domain. Defects in chromophore production in the *Drosophila* mutants *ninaB*, *ninaD*, *ninaG*, and *santa maria*, cause a defect in Rh1 transport to the rhabdomere, causing a severe reduction in Rh1 and retinal pathology (Colley 2010; Wang and Montell 2007).

In Drosophila, the successful transport of Rh1 from the ER to the rhabdomere requires the cyclophilin, NinaA. Cyclophilins are peptidyl-prolyl *cis–trans* isomerases and are thought to play a role in protein folding during biosynthesis. Consistent with a function in protein folding, NinaA resides in the ER. NinaA is also detected in transport vesicles together with Rh1 and forms a specific and stable complex with Rh1, consistent with a broad role for NinaA as a chaperone in the secretory pathway. Mutations in NinaA lead to severe retinal pathology in flies. Similarly, in mammals, a cyclophilin-like protein (RanBP2/Nup358) plays a role in protein biogenesis (Colley 2010).

In photoreceptor cells, successful maturation of rhodopsin and regulation of Ca^{2+} are essential for cell function and viability. There is a growing list of proteins that serve multifunctional roles. One example is calnexin, which serves as both a molecular chaperone for Rh1 and as a regulator of Ca^{2+} that enters photoreceptor cells during phototransduction. Mutations in *Drosophila calnexin* lead to severe defects in Rh1 maturation as well as defects in the control of cytosolic Ca^{2+} levels following activation of the light-sensitive TRP channels. As a result, the photoreceptor cells undergo a light-enhanced retinal degeneration that is due to the combined detrimental effects of defective Rh1 maturation and Ca^{2+} regulation (Colley 2010).

Summary

In *Drosophila* photoreceptor cells, the precise regulation of spatial and temporal profiles of Ca^{2+} is essential for cell function and prolonged elevation of Ca^{2+} can be toxic, leading to retinal degeneration. Hence, proper Ca^{2+} removal or sequestration following a transient rise in cytoplasmic Ca^{2+} during phototransduction is

vital to photoreceptor cells. In addition to Ca^{2+} regulation, successful folding, maturation, and transport of rhodopsin and the other components of phototransduction is key to photoreceptor cell survival. Failure in Rh1 maturation and Ca^{2+} regulation leads to retinal degeneration in both *Drosophila* and vertebrates. Despite its perceived simplicity, *Drosophila* is surprisingly complex and contains a genetic makeup that is remarkably similar to humans. Therefore, mechanisms of Ca^{2+} regulation, rhodopsin maturation, and retinal degeneration identified in *Drosophila* will undoubtedly continue to provide insights that are clinically relevant to hereditary human retinal degeneration diseases.

Synonyms

Association/binding constant; Dication/divalent metal cation; Metal-binding site/pocket/cavity/cleft; Monocation/monovalent metal cation; Non-physiological/non-biogenic/"Alien" metal cation; Physiological/biogenic metal cation

Background/Definitions

Metal selectivity of a ▶ Ca^{2+}-binding site is an outcome of the competition between the bulk solvent and the protein ligands for the "native" Ca^{2+} and a "rival" cation M^{q+} (M = Na, K, Mg, Ln, etc.; q = 1, 2, 3) and can be assessed by the free energy of the $M^{q+} \rightarrow Ca^{2+}$ exchange reaction:

$$(M^{q+}-aq) + (Ca^{2+}-protein) \rightarrow (M^{q+}-protein) + (Ca^{2+}-aq) \quad (1)$$

In Equation (1), ($M^{q+}/Ca^{2+}-aq$) represents a hydrated metal cation outside the metal-binding cavity, and ($M^{q+}/Ca^{2+}-protein$) represents a metal cation bound in the protein cavity/ion channel pore. Equation (1) can be considered as the difference between two reactions describing the binding of the individual metal ions to the apoprotein, i.e.,

$$(M^{q+}-aq) + protein \rightarrow (M^{q+}-protein) \quad (2)$$

$$(Ca^{2+}-aq) + protein \rightarrow (Ca^{2+}-protein) \quad (3)$$

The association constant, $K_a(M^{q+})$ or $K_a(Ca^{2+})$, characterizing the affinity of the binding site for M^{q+} or Ca^{2+}, is given by

$$K_a(M^{q+}) = [M^{q+}-protein]/([M^{q+}-aq] \cdot [protein]) \quad (4)$$

$$K_a(Ca^{2+}) = [Ca^{2+}-protein]/([Ca^{2+}-aq] \cdot [protein]) \quad (5)$$

Since the reaction free energy is related to the association constant via

$$\Delta G = -RT \ln K_a, \quad (6)$$

where R is the gas constant and T, the temperature, the free energy for the $M^{q+} \rightarrow Ca^{2+}$ exchange reaction (1) can be expressed as

$$\begin{aligned}\Delta G(M^{q+} \rightarrow Ca^{2+}) &= -RT\,[\ln K_a(M^{q+}) - \ln K_a(Ca^{2+})] \\ &= -2.303\,RT\,\log\,[K_a(M^{q+})/ \\ &\quad K_a(Ca^{2+})]\end{aligned} \quad (7)$$

Competition Between Ca^{2+} and Physiological Metal Cations for Ca-Binding Sites

Proteins Containing EF-Hand Motifs

▶ The EF-hand motif is found in a large group of Ca^{2+} signaling and buffering/transport proteins such as ▶ calmodulin, ▶ troponin C, ▶ parvalbumin, recoverin, ▶ calcineurin, ▶ calbindin D, and ▶ S100 protein. The canonical ▶ EF-hand motif consists of a 12-residue Ca^{2+}-binding loop flanked by two helices creating a signature helix–loop–helix motif (Gifford et al. 2007). The aspartate/glutamate (Asp/Glu) carboxylates and asparagine/glutamine (Asn/Gln) backbone carbonyls from the loop coordinate to Ca^{2+}, which often retains a bound water molecule, in pentagonal bipyramidal geometry (Fig. 1a). This seven-coordinate geometry is contributed by the carboxylate-binding mode of the conserved Glu at the last position of the EF-hand binding loop (Glu-12), which binds Ca^{2+} bidentately via both carboxylate oxygens, whereas the other Asp/Glu residues bind Ca^{2+} monodentately via one of the carboxylate oxygens.

The EF-hand binding site is characterized by an exceptional selectivity for Ca^{2+}. It is designed to bind preferentially the "native" Ca^{2+} against the background of up to 10^5 times higher concentrations of the competing cytosolic Mg^{2+} (by a factor of 10^3–10^4) and Na^+/K^+ (by a factor of 10^6, see Table 1). The finely tuned structural and electrostatic properties of the binding cavity make Ca^{2+} the cation of choice for the EF-hand proteins (Drake et al. 1996): (1) Interactions among the metal ligands rigidify the Ca-binding loop and constrain the metal cavity to an optimal size for Ca^{2+} that disfavors larger cations. (2) The relatively rigid EF-hand cavity provides an optimal level of negative charge density that favors dications over monocations. (3) The EF-hand binding site's pentagonal bipyramidal geometry and relatively large size prevent the smaller Mg^{2+}, which strongly prefers octahedral geometry, from binding.

Under physiological conditions, however, the competition between Ca^{2+} and Mg^{2+} for the EF-hand binding site depends not only on the EF-hand protein properties but also on the cytosolic Ca^{2+} and Mg^{2+} concentrations. In the *resting* cell, the concentration of Ca^{2+} (10^{-7}–10^{-8} M) is three- to fivefold lower than that of Mg^{2+} (10^{-3}–10^{-4} M) and does not favor Ca^{2+} binding. In this *resting* state, Mg^{2+} occupies (at least partially) the EF-hand binding sites and stabilizes the resting EF-hand domains. However, Mg^{2+} binding to EF-hand sites does not trigger the extensive conformational changes characteristic of the Ca^{2+}-activated proteins and, thus, no signaling response occurs (Gifford et al. 2007). Interestingly, Glu-12 is *mono*dentately rather than *bi*dentately bound to *hexa*coordinated Mg^{2+} (Fig. 1b), yielding a physiologically silent protein. In an *activated* cell, the intracellular

concentration of Ca^{2+} increases to 10^{-5}–10^{-6} M in response to stimuli such as membrane depolarization or extracellular/intracellular messengers. This, in combination with the special intrinsic properties of the EF-hand binding site (see above), favors Ca^{2+} over Mg^{2+} binding to the protein. The Ca^{2+}-bound protein undergoes large conformational transformations, triggering a cascade of events along the signal

transduction pathway. Thus, Ca^{2+} plays a regulatory role in the signal-transducing process: the metal-binding site does not bind Ca^{2+} until the respective signal occurs ("on reaction"), but it can debind the metal cation when the latter is no longer needed ("off reaction").

Proteins Containing C2 Domains

► C2 domains are found in membrane trafficking proteins (e.g., synaptotagmin, rabphilin-3A) and signal-transducing proteins (e.g., cytosolic phospholipase A_2, protein kinase C), which perform critical cellular functions such as lipid second messenger generation, protein phosphorylation, vesicular transport, GTPase regulation, and ubiquitin-mediated protein degradation (Nalefski and Falke 1996). Upon Ca^{2+} binding, C2 domains dock to cell membrane targets (e.g., phospholipids, inositol polyphosphates). At one rim of the C2 domain β-sandwich structure, two or three Ca^{2+} bind in a cleft lined by carboxylate and carbonyl groups from loops. In response to intracellular Ca^{2+} signaling, the C2 domains of cytosolic phospholipase A_2 and rabphilin-3A and the C2B domain of synaptotagmin I bind two Ca^{2+} ions with positive cooperativity, and the activated C2 domains subsequently dock to the respective target membrane. In contrast, the activation of the C2 domain of protein kinase C-β and the C2A domain of synaptotagmin I requires binding of three Ca^{2+} ions.

Although designed to specifically bind Ca^{2+}, the C2 domains, when free in solution, exhibit lower affinity for Ca^{2+} ($K_a \sim 10^2$–10^6 M^{-1}) than the EF-hand motifs ($K_a \sim 10^5$–10^7 M^{-1}). Generally, the Ca^{2+} affinity of the C2 modules increases in the presence of the target membrane. Yet, like the EF-hand proteins, the C2 domains are very efficient in discriminating between the native *micromolar* Ca^{2+} and rival *millimolar* Na^+, K^+, and Mg^{2+} cations in the cytoplasm. As in the EF-hand motif, monocations are excluded from the C2 metal-binding site since they are unable to overcome the electrostatic repulsion between the many carboxylate/carbonyl oxygens in the site and, thus, cannot immobilize the Ca-binding loops. On the other hand, Mg^{2+} dications are excluded because compression of the site to accommodate the shorter Mg^{2+}–O distances is countered by repulsion between the ligating oxygens. Thus, at *millimolar* physiological concentrations, Na^+, K^+, and Mg^{2+} fail to bind to the C2 domains and initiate membrane docking. However, at elevated supraphysiological concentrations, Mg^{2+} does bind to the C2 domains (Nalefski and Falke 2002). The Mg^{2+}-bound synaptotagmin III C2A domain is able to induce membrane docking, though less efficiently than the Ca^{2+}-loaded module, whereas the Mg^{2+}-bound C2 domain in cytosolic phospholipase A_2 fails to do so (Nalefski and Falke 2002).

Proteins Containing GLA Domains

GLA domains are essential structural motifs of several proteins involved in the ► blood coagulation process such as factor II (prothrombin), VII, IX, and X, as well as protein C and protein S. These domains contain a network of 10–13 γ-carboxyglutamic acid residues (Gla) coordinated to 7–8 Ca^{2+} and Mg^{2+} ions, which stabilize the structure and maintain the proper conformation for subsequent membrane docking. The rare Gla residue is produced by posttranslational carboxylation of specific Glu residues by a vitamin K–stimulated reaction. Gla has two carboxylate groups attached to the C^{γ} atom, resulting in a net charge of −2. It binds the metal ion predominantly in a chelation bidentate mode where both carboxylates are monodentately bound. Consistent with the presence of a second carboxylate group in Gla, Gla is involved mostly in binding divalent (rather than monovalent) cations during the blood coagulation process. Notably, mutating Gla back to its precursor, Glu, abolishes Ca^{2+} binding (Stenflo and Suttie 1977). Ca^{2+} ions are absolutely required for blood to coagulate: They are needed to stabilize an essential membrane-binding loop. This loop becomes disordered when only Mg^{2+} ions are present in the GLA domain, which fails to dock properly to the target membrane, thus disrupting the coagulation process. On the other hand, Mg^{2+} binding to a few of the metal-binding sites in the GLA domains, with Ca^{2+} occupying the other sites, accelerates the activation of the respective coagulation factors and enhances membrane binding (Shikamoto et al. 2003).

Since binding of both Ca^{2+} and Mg^{2+} (in a proper ratio) to the GLA domain promotes optimal binding to the target molecule, it is not surprising that GLA domains possess two types of metal-binding sites exhibiting different metal selectivity. Interior binding sites are selective for Ca^{2+} and are usually occupied by 4–5 Ca^{2+} ions. Peripheral binding sites, comprising usually three metal cations, exhibit poorer metal selectivity and can be occupied by Ca^{2+} or Mg^{2+} depending on their relative concentration. At physiological conditions where the blood plasma concentration of

free Ca^{2+} is ~1.1–1.3 mM while that of Mg^{2+} is ~0.4–0.6 mM, Ca^{2+} occupies the interior binding sites, whereas three Mg^{2+} ions bind to the other nonselective binding sites (Shikamoto et al. 2003).

Notably, the affinity of Ca^{2+} for the GLA domain ($K_a \sim 10^2$–10^3 M^{-1}) is weaker than that for the EF-hand ($K_a \sim 10^5$–10^7 M^{-1}) and C2 ($K_a \sim 10^2$–10^6 M^{-1}) binding sites (see above). This difference can be attributed to the difference in the concentration ratio between Ca^{2+} and Mg^{2+} in the intracellular and extracellular compartments. Since the EF-hand and C2 domains have to sequester *micro*molar Ca^{2+} against much higher *milli*molar Mg^{2+}, Na^+, and K^+ in the cytosol, their affinity toward the "native" Ca^{2+} has to be precisely tuned. On the other hand, no such stringent requirements are needed for the GLA domains, as the concentration of Ca^{2+} in the blood plasma is quite high (millimolar range) and even surpasses that of its rival, Mg^{2+}.

Calcium Ion Channels

Calcium ion channels transport Ca^{2+} across the cell membrane. They play an essential role in a plethora of biological processes such as the skeletal, smooth, and cardiac muscle contraction; signal transduction; hormone and neurotransmitter secretion; and gene expression. The voltage-gated L-type Ca channel or homologs such as T-, N-, R-, and P-/Q-type Ca channels control selective passage of Ca^{2+} from the *extra*cellular to *intra*cellular compartments, while ryanodine receptor (RyR) or inositol trisphosphate receptor Ca^{2+} channel controls the release of Ca^{2+} from intracellular stores (sarcoplasmic or endoplasmic reticulum). Voltage-gated calcium channels possess remarkable ability to discriminate between the "native" Ca^{2+} and other competing cations, which are usually present in much higher concentrations in the respective biological compartments. Typically, they select Ca^{2+} over Na^+ and K^+ at a ratio of over 1,000:1 and do not conduct Mg^{2+} (Hille 1992). However, the RyR channel exhibits only moderate divalent/monovalent cation selectivity, not exceeding a factor of 7 and poorly discriminates between Ca^{2+} and Mg^{2+} (permeability ratio $P_{Ca2+}/P_{Mg2+} = 1.1$; Tinker et al. 1992).

The ion selectivity of the channel is controlled by its selectivity filter – the narrowest part of the pore comprising several protein residues that specifically interact with the passing metal ion. Although X-ray structures of Ca^{2+}-bound Ca^{2+} channels and their selectivity filters are still lacking, a series of site-directed mutagenesis and channel-blocker binding experiments have determined the composition of the selectivity filters of several Ca^{2+} ion channels. These filters are lined with negatively charged Asp/Glu residues whose side chains face the pore lumen. The selectivity filter of the high voltage-activated voltage-gated Ca^{2+} channels is comprised of four Glu residues (EEEE locus) donated by the pore-forming loops of the channel's four domains, while that of the low voltage-activated counterpart has a ring of two Glu and two Asp residues (EEDD locus), whereas that of the RyR channel consists of four aspartates (DDDD locus). Other loci of Asp/Glu residues at the pore entrance are implicated in fine-tuning the selectivity for Ca^{2+}.

The voltage-gated L-type and RyR channels have different permeation properties: The former exhibits high Ca^{2+} selectivity (see above) and affinity ($K_a \sim 10^6$ M^{-1}) and low conductance, while the latter exhibits lower Ca^{2+} selectivity (see above) and affinity ($K_a \sim 10^3$ M^{-1}) but higher conductance. These differences in the channels' selectivity/conductance are thought to stem from the difference in their physiological function(s) (see above). When the L-type channel allows Ca^{2+} in the cell, the RyR channel releases Ca^{2+} over several (>5) milliseconds, thus elevating the cytoplasmic Ca^{2+} concentration and triggering muscle contraction. Such long-lasting Ca^{2+} efflux is possible because the RyR channel can conduct Ca^{2+} out of the intracellular stores, while allowing passage of K^+/Mg^{2+} in the opposite direction, resulting in a constant driving force for Ca^{2+} release. Thus, the RyR channel's low selectivity and high conductance for both monovalent and divalent cations make it ideal for its physiological role of releasing Ca^{2+} over a long period (Gillespie and Fill 2008).

Competition Between Ca^{2+} and Alien Ln^{3+} for Ca-Binding Sites

Trivalent lanthanide cations, Ln^{3+}, have higher affinity toward oxygen-containing biological ligands (Asp/Glu, Asn/Gln/backbone peptide groups) than divalent Ca^{2+} and, therefore, can successfully compete and substitute for Ca^{2+} in protein-binding sites (Table 1). Although the competition between the "native" Ca^{2+} and nonbiogenic Ln^{3+} does not have immediate

implications for biological processes in vivo, the ▶ unique physicochemical properties of lanthanide cations make them very useful in probing Ca^{2+} and other dication-binding sites in vitro. Lanthanides are extensively being used in both crystallographic and spectroscopic studies of metalloproteins. They are employed in determining the phases of the diffracted X-rays by multiple isomorphous replacement or multiwavelength anomalous dispersion. Furthermore, ▶ luminescent properties of lanthanide ions are utilized in bioanalytical assays to determine the interdomain distance in proteins. The large anisotropic magnetic susceptibility of paramagnetic lanthanides, which gives rise to large pseudocontact shifts that can be observed for residues as far as 40 Å from the metal center, is used to obtain long-distance restraints for protein NMR structure determination.

Determinants of Ca^{2+} Selectivity in Biological Systems

Both experimental and theoretical studies have revealed some key factors governing the metal selectivity process in Ca-binding sites:

1. *Binding Site Dielectric Constant*. Interactions of Na^+, K^+, Ca^{2+}, Mg^{2+}, and Ln^{3+} with oxygen-containing biological ligands are predominantly electrostatic (charge−charge/dipole) and are enhanced in a low dielectric environment. Therefore, the dielectric properties of the metal-binding site play an important role in the metal selectivity process. A buried/partially buried binding pocket with a low dielectric constant enhances the affinity (and competitiveness) of the more positively charged cation of the competing pair of metal ions for the ligating oxygens. Thus, decreasing the solvent exposure of the binding site/channel pore disfavors the substitution of Ca^{2+} by Na^+/K^+ but facilitates the displacement of Ca^{2+} by trivalent lanthanides.
2. *Binding Site Size/Flexibility*. Calcium proteins discriminate between the two divalent contenders, Ca^{2+} and Mg^{2+}, mainly by maintaining a proper size/shape/flexibility of the binding cavity, which is optimized to better suit the coordination requirements of Ca^{2+} than those of Mg^{2+}. Interactions among the many metal ligands and the protein matrix constrain the host metal cavity to an optimal size for Ca^{2+} and endow it with enough stiffness so as not to let a rival cation readjust its size/geometry upon binding. Such a relatively rigid and large binding cavity fits Ca^{2+}, which prefers sevenfold (pentagonal bipyramidal) coordination geometry and binds carboxylate and carbonyl oxygens with Ca−O distances ranging from 2.1 to 2.8 Å, but not the smaller rival Mg^{2+}, which strongly favors sixfold (octahedral) coordination geometry and shorter Mg–O bond distances (2.0–2.2 Å).
3. *Binding Site Overall Charge*. Ca-binding sites and ion channel selectivity filters, which contain constellations of negatively charged Asp, Glu, and Gla residues, effectively discriminate between the "native" Ca^{2+} and monovalent competitors such as Na^+ and K^+ (see above). The elevated negative charge density in a relatively rigid, low dielectric binding site/selectivity filter favors binding of Ca^{2+} over Na^+/K^+, as the monocations lack sufficient positive charge to alleviate the repulsion among the multiple ligating oxygens. On the other hand, trivalent "alien" Ln^{3+}, due mainly to strong charge–charge interactions with the carboxylates, have affinities higher than that of Ca^{2+} and can successfully displace Ca^{2+} from Ca-binding sites. In general, increasing the net negative charge of a relatively rigid and buried Ca-binding site increases its protection against monocation attack but, at the same time, increases its vulnerability to trivalent metal substitution.
4. *Competing Metal Concentrations*. Under physiological conditions, the competition between Ca^{2+} and a rival cation for the ▶ Ca^{2+}-binding site depends not only on the protein properties but also on the cation concentrations in the respective compartments, as exemplified by the EF-hand proteins and Gla domains.

Definitions

1. Ca^{2+} sparklets are local Ca^{2+} signals produced by the opening of dihydropyridine-sensitive,

voltage-gated L-type Ca^{2+} channels in the plasma membrane of neurons and muscle.
2. Ca^{2+} waves are propagating cell-wide increases in cytosolic [Ca^{2+}].
3. Ca^{2+} sparks are local Ca^{2+} release events from the sarcoplasmic reticulum via ryanodine receptors.
4. Ca^{2+} puffs are IP_3-activated, Ca^{2+} release events produced by the opening of clusters of IP_3Rs from the sarcoplasmic reticulum.
5. Optical clamping is the recording of local Ca^{2+} signals using fluorescence microscopy.

Introduction

In eukaryotic cells, Ca^{2+} flux into their cytoplasm via Ca^{2+} permeable channels in the plasma membrane and intracellular organelles triggers a plethora of signaling events that regulate numerous physiological processes, including excitability, secretion, contraction, and gene expression (Hille 2001). The development of bright fluorescent Ca^{2+} indicators and highly sensitive cameras and photomultipliers has allowed the recording of multiple Ca^{2+} signal modalities with high temporal and spatial resolution. In this chapter, we will discuss two of these signals: Ca^{2+} sparklets and Ca^{2+} waves.

Ca^{2+} sparklets are local Ca^{2+} signals produced by the opening of dihydropyridine-sensitive, voltage-gated L-type Ca^{2+} channels in the plasma membrane of neurons and muscle. Ca^{2+} release via small clusters of ryanodine (RYRs) and inositol triphosphate (IP_3Rs) receptors in the endoplasmic or sarcoplasmic reticulum (SR) produces Ca^{2+} sparks and Ca^{2+} puffs, respectively. Ca^{2+} waves that travel within and between cells are initiated and propagated by the sequential activation of Ca^{2+} sparks and Ca^{2+} puffs. The goal of this chapter is to describe the biophysical mechanisms underlying a Ca^{2+} signaling hierarchy ranging from sparklets to waves and to discuss their functional role in health and disease.

Ca^{2+} Sparklets

Using patch-clamp electrophysiological approaches, a detailed biophysical model of L-type Ca^{2+} channels has emerged. These channels have a threshold for activation of about −50 mV. Under physiological conditions, the conductance of single L-type Ca^{2+} channels is about 5 pS, producing currents of about 0.5 pA at −40 mV. L-type Ca^{2+} channels are inactivated by Ca^{2+} and voltage. Furthermore, they can operate in two functional modes. In mode 1, L-type Ca^{2+} channels open briefly (<1 ms) allowing a small amount of Ca^{2+} to enter the cell. The mean open time of L-type Ca^{2+} channels in mode 2 is about 10 ms (Hille 2001). Accordingly, the magnitude and time course of whole-cell L-type Ca^{2+} current depends on voltage, the number of channels activated, their elementary current, as well as gating mode.

Imaging Ca^{2+} Sparklets. Although powerful, patch-clamp electrophysiology could not easily answer two important questions about L-type Ca^{2+} channels. First, what is the spatial organization of functional L-type Ca^{2+} channels? Second, does L-type Ca^{2+} channel activity vary throughout the cell? One reason why patch-clamp electrophysiology cannot adequately address these questions is that in the whole-cell configuration, currents represent an ensemble of the activity of all channels throughout the surface membrane. In the single-channel mode, recordings are limited to a small patch of membrane per cell. Accordingly, these approaches offer limited information on the spatial organization of functional L-type Ca^{2+} channels. Recent advances in fluorescent probe development and imaging technology have helped circumvent these limitations and made it possible to optically record (called "optical clamping") Ca^{2+} sparklets resulting from Ca^{2+} influx via single L-type Ca^{2+} channels (Santana and Navedo 2009).

Ca^{2+} sparklets have been imaged using line-scan confocal microscopy and total internal reflection fluorescence (TIRF). Although line-scan imaging has the potential of recording sparklets with high temporal resolution (1 kHz), it comes at the expense of providing spatial information as one can only image a small volume at a time. TIRF microscopy offers a way around these issues for the following reasons. In TIRF, fluorescence is limited to a thin evanescent field of about 100 nm. Thus, the resolution in the Z-axis of a TIRF system is nearly 10 times higher than that of the typical confocal microscope (about 1 μm) (Santana and Navedo 2009)). This has the potential of dramatically reducing noise. Furthermore, if an electron multiplying CCD cameras capable of detecting photons from a single fluorescent molecule is used, one could image relatively large areas of the cell at relatively fast rates (e.g., 100–500 Hz) and with exquisite sensitivity. In combination, these factors give TIRF microscopy the potential of imaging, with a high signal to noise ratio, small fluorescence signals

Calcium Sparklets and Waves, Table 1 Biophysical properties of L-type Ca^{2+} channels

	Calcium sparklets		Unitary calcium currents (I_{Ca})		
Sparklets' parameters	Arterial myocytes	Cav1.2 (tsA-201)	Arterial myocytes	Cardiac myocytes	Unitary I_{Ca} parameters

produced by Ca^{2+} influx via single Ca^{2+} channels within relatively large portion of the surface membrane. This makes this technique the most favorable approach for the study of the spatial organization of functional L-type Ca^{2+} channels in cardiac and smooth muscle (Santana and Navedo 2010).

Biophysical properties of Ca^{2+} sparklets. An important feature of Ca^{2+} sparklets is that their amplitude is variable, ranging from about 20 nM to several hundred nM Ca^{2+} depending on membrane voltage. Ca^{2+} entry through Ca^{2+} sparklet sites is quantal in nature. Accordingly, the amplitude of Ca^{2+} sparklets depends on the number of quanta activated. Large amplitude, multi-quantal Ca^{2+} sparklets are likely produced by random overlapping openings of adjacent L-type Ca^{2+} channels in the surface membrane of cells (Santana and Navedo 2009) (see Table 1 for description of the biophysical properties of Ca^{2+} sparklets).

L-type Ca^{2+} channels can readily be distinguished from other Ca^{2+}-permeable channels by their unique pharmacological, biophysical, and molecular biological properties. Consistent with this, Ca^{2+} sparklets are activated by the dihydropyridine agonist Bay-K 8644 and are eliminated by dihydropyridine antagonists nifedipine and nisoldipine. Simultaneous recordings of Ca^{2+} signals and L-type Ca^{2+} currents indicate that Ca^{2+} sparklets are associated with an inward Ca^{2+} current. Importantly, Ca^{2+} sparklets have similar voltage dependencies of activity and amplitude as L-type Ca^{2+} channels. Furthermore, Ca^{2+} sparklets in tsA-201 cells expressing L-type Ca^{2+} channels reproduce all the basic features of native Ca^{2+} sparklets including block by nifedipine, activation by Bay-K 8644, bimodal gating modalities, amplitude of quantal event, and voltage dependencies. Finally, arterial myocytes expressing a mutant L-type Ca^{2+} channel that is insensitive to inhibition by dihydropyridines produced dihydropyridine-insensitive low activity and persistent Ca^{2+} sparklets. This finding is important because it eliminates the possibility that Ca^{2+} sparklets are produced by a transient receptor potential or store-operated channel in cardiac or arterial myocytes (Santana and Navedo 2009). Thus, Ca^{2+} sparklets meet all the generally accepted pharmacological, biophysical, and molecular biological criteria used to identify L-type Ca^{2+} channels.

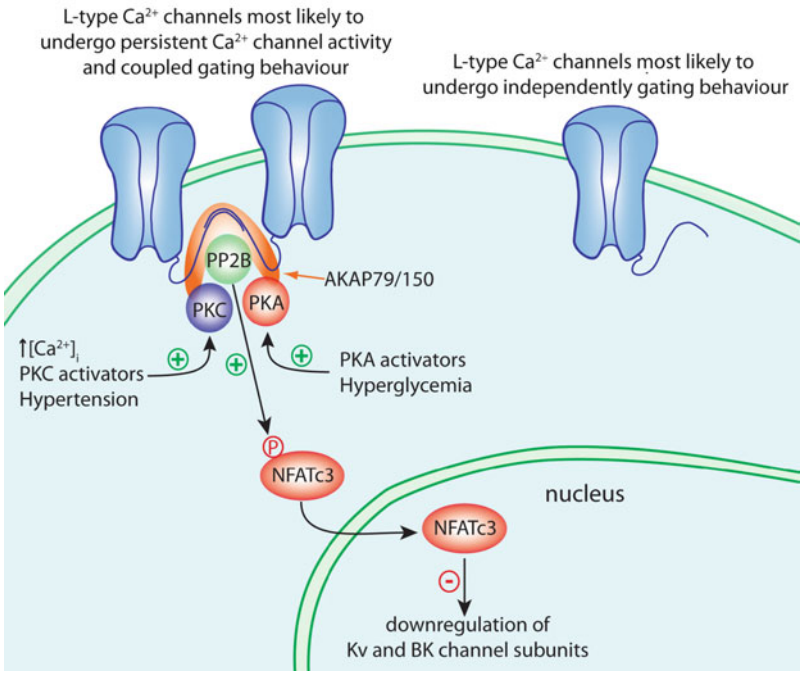
An intriguing feature of Ca^{2+} sparklets sites is that their activity (i.e., nP_s, where n is the number of sparklets and P_s is the probability that a sparklet is activated) and spatial distribution vary within the surface membrane of cardiac and arterial myocytes and tsA-201 cells expressing L-type Ca^{2+} channels. Using an analytical scheme similar to the one used for analysis of single-channel currents, it was found that Ca^{2+} sparklet activity was bimodal, with sites of low activity and sites with high, "persistent" activity. Based on this analysis, Ca^{2+} sparklets were grouped into three categories: silent (i.e., $nP_s = 0$), low (i.e., $0 > nP_s < 0.2$), and high activity (i.e., $nP_s > 0.2$), persistent Ca^{2+} sparklets (Santana and Navedo 2009). The fact that Ca^{2+} sparklets' spatial distribution is variable is interesting because L-type Ca^{2+} channels are broadly distributed throughout the surface membrane of neurons, and cardiac and smooth muscle.

Examination of the physiological role of Ca^{2+} sparklet in arterial myocytes demonstrated that Ca^{2+} sparklet activity regulates local and global $[Ca^{2+}]$ in a voltage-dependent manner. In arterial smooth muscle, persistent Ca^{2+} sparklet activity contributes to $\approx 50\%$ of the dihydropyridine-sensitive Ca^{2+} influx required for maintenance of steady-state cytosolic $[Ca^{2+}]$ under physiological conditions (i.e., 2 mM Ca^{2+} and -40 mV) (Santana and Navedo 2009). On the basis of these data, a new model for steady-state Ca^{2+} influx in arterial myocytes was proposed. In this model, membrane depolarization increases Ca^{2+} influx, at least in part, by promoting L-type Ca^{2+} channels to operate in a persistent gating mode and by increasing the duration of low and high activity, persistent Ca^{2+} sparklets.

Mechanisms for subcellular variations in Ca^{2+} sparklet activity. As mentioned above, Ca^{2+} sparklets activity varies along the surface membrane of cells. This behavior of Ca^{2+} sparklets is not likely due to subcellular variations in the molecular composition or clustering of L-type Ca^{2+} channels, as electrophysiological, immunofluorescence, and imaging data suggest that channels of similar subunit composition are broadly distributed throughout the surface membrane of cells. Rather, recent work indicates that membrane targeting of protein kinase Cα (PKCα), protein kinase A (PKA), and the phosphatase calcineurin by the scaffolding protein **A-k**inase **a**nchoring **p**rotein (AKAP) 150 (the rodent ortholog of human AKAP79) to specific regions of the surface membrane where they can differentially regulate L-type Ca^{2+} channel's function underlies heterogeneous Ca^{2+} sparklet activity in cells (Fig. 1) (Santana and Navedo 2010).

Data supporting this model are compelling. First, AKAP150 is specially suited to perform these tasks as it binds to PKCα, PKA, calcineurin, and L-type Ca^{2+} channels in neurons and muscle. Second, AKAP150 and PKCα colocalize to specific foci at or near the surface membrane of arterial myocytes. Third, loss of AKAP150 prevents PKCα targeting to the surface membrane of arterial myocytes. Importantly and consistent with the model, the loss of AKAP150 also abolishes persistent Ca^{2+} sparklet activity in these cells. Fourth, AKAP is required for PKA-dependent modulation of L-type Ca^{2+} channels in arterial myocytes. Fifth, the actions of PKCα and presumably PKA on the induction of persistent Ca^{2+} sparklet activity are opposed by calcineurin. Accordingly, the level of Ca^{2+} sparklet activity will vary regionally depending on the relative activities of PKCα, PKA, and calcineurin. Sixth, only a subpopulation of L-type Ca^{2+} channels interacts with AKAP150 and associated effector proteins in arterial myocytes (Santana and Navedo 2010). Collectively, these observations suggest that heterogeneous Ca^{2+} sparklet activity results from the concerted regulation of a specific set of signaling proteins on L-type Ca^{2+} channels broadly distributed throughout the surface membrane of cells.

As mentioned above, persistent Ca^{2+} sparklets result from frequent openings of L-type Ca^{2+} channels following PKCα and PKA activation. Therefore, what are the mechanisms underlying regional variations in Ca^{2+} sparklet activity and spatial distribution? Recent studies from several labs provide potential answers to this question. For instance, an increase in cAMP production could activate AKAP150-targeted PKA near a subset of L-type Ca^{2+} channels in the surface membrane, thus promoting persistent Ca^{2+} sparklet activity in those areas. Similarly, an increase in diacylglycerol or cytosolic $[Ca^{2+}]$ could activate PKCα near a subpopulation of L-type Ca^{2+} channel's recruit to the AKAP150-associated protein complex. In this scenario, Ca^{2+} entering the cell binds to calmodulin and promotes the release of PKCα from the AKAP150 complex. Once liberated from the AKAP150 complex, PKCα is free to phosphorylate nearby L-type Ca^{2+} channels, thus inducing persistent Ca^{2+} sparklet activity and contributing to heterogeneous spatial activation of these Ca^{2+} influx events (Fig. 1).



Calcium Sparklets and Waves, Fig. 1 *Proposed mechanisms for heterogeneous Ca^{2+} sparklet activity, coupled gating of L-type Ca^{2+} channels, and the activation of NFATc3 in cardiac and arterial myocytes.* In this model, L-type Ca^{2+} channels are broadly distributed throughout the sarcolemma of cardiac and arterial myocytes. Activation of these channels results in a subcellular increase in $[Ca^{2+}]_i$ called a "Ca^{2+} sparklet". A subpopulation of L-type Ca^{2+} channels is associated with a signaling tetrad composed of AKAP150, PKA, PKC, and PP2B. These L-type Ca^{2+} channels are rapidly modulated by AKAP150-associated PKC, PKA, and PP2B during physiological and pathological conditions such as hypertension and hyperglycemia. The association of AKAP150 with L-type Ca^{2+} channels also promotes coordinated openings and closings of these channels via transient interactions between variable numbers of L-type Ca^{2+} channels' C-termini. This signaling unit is thus able to modulate Ca^{2+} influx and by regulating the activity of the Ca^{2+}-activated phosphatase PP2B control NFATc3-dependent gene expression of Kv and BK channels in cardiac and arterial myocytes. Plus symbols indicate activation; negative symbols indicate inhibition/downregulation

Large amplitude Ca^{2+} sparklets could arise from the random overlapping opening of neighboring L-type Ca^{2+} channels with high open probability. However, not all L-type Ca^{2+} channels gate independently (Santana and Navedo 2010). It was found that small clusters of L-type Ca^{2+} channels could open and closed in a coordinated fashion (called "coupled gating"). Although the mechanisms inducing coupled gating of L-type Ca^{2+} channels are not entirely clear, data suggest this gating modality involves transient interactions between variable numbers of L-type Ca^{2+} channels' C-termini in an AKAP150-associated protein complex (Fig. 1). Multiple lines of evidence support this model. First, PKCα increases the probability of coupled gating between L-type Ca^{2+} channels. Second, displacement of calmodulin (CaM) away from its putative binding site (e.g., IQ domain) in the C-termini of L-type Ca^{2+} channels increases coupled gating activity. Third, AKAP150 is required for coupled gating between L-type Ca^{2+} channels. Accordingly, in the absence of AKAP150, L-type Ca^{2+} channel's gating is mostly stochastic even after the activation of PKCα. Fourth, an L-type Ca^{2+} channel construct lacking amino acids 1670–2171, which eliminates a large section of the C-termini of these channels that includes the AKAP150 binding region, showed no coupled gating activity. Consistent with this conclusion, Förster resonance energy transfer (FRET) analysis suggested that the C-termini of nearby L-type Ca^{2+} channels come into close proximity under conditions that favor coupled gating (Santana and Navedo 2010). Collectively, these data suggest that L-type Ca^{2+} channels are

more likely to undergo coupled gating in regions of the cell where these channels interact with an AKAP150-associated protein complex. The mechanisms for coupled gating between L-type Ca^{2+} channels may involve a rearrangement of CaM within the IQ domain that induces transient interactions between a variable numbers of adjacent L-type Ca^{2+} channels via their C-termini. Future studies are required to address these issues.

Functional significance of Ca^{2+} sparklets during health and disease. In principle, functional coupling of L-type Ca^{2+} channels could have profound functional implications on excitation-contraction (EC) coupling and excitation-transcription (ET) coupling in cardiac and arterial myocytes. In cardiac myocytes, Ca^{2+} sparklets activate Ca^{2+} release via small clusters of RyRs located in nearby junctional SR via the mechanisms of Ca^{2+}-induced Ca^{2+} release (CICR). Tight, local control of Ca^{2+} spark activation by sparklets forms the basis for the generation of cell-wide increases in cytosolic [Ca^{2+}] that triggers contraction in cardiac muscle (Wang et al. 2004). In these cells, the coupling strength between sparklets and sparks is proportional to the amount of Ca^{2+} flux through L-type Ca^{2+} channels. Accordingly, at least in principle, the probability of Ca^{2+} spark activation could be higher in areas within the surface membrane in which L-type Ca^{2+} channels open coordinately.

Unlike cardiac myocytes, in arterial smooth muscle, RyRs and L-type Ca^{2+} channels do not form tight SR Ca^{2+} release units. In arterial myocytes, activation of L-type Ca^{2+} channels results in an increase in cytosolic [Ca^{2+}] that directly activates the contractile machinery. Thus, an increase in the probability of coupled L-type Ca^{2+} channels results in an increase in Ca^{2+} influx and global [Ca^{2+}] that activates contraction.

Arterial tone is elevated during pathological conditions such as diabetes and hypertension, which increases the probability of stroke, coronary artery disease, and cardiac hypertrophy. Multiple studies suggest that increased L-type Ca^{2+} channel activity is a major contributor to these pathological changes. Interestingly, increased L-type Ca^{2+} channel activity also underlies lethal cardiac arrhythmias in human with Timothy Syndrome (TS) caused by a single point mutation (G436R) in these channels. Consistent with this, Ca^{2+} sparklet activity is increased in arterial myocytes during hypertension and in type II diabetes, and in tsA-201 cells expressing TS-L-type Ca^{2+} channels (Santana and Navedo 2009, 2010). Accordingly, an increase in the number of low activity and persistent Ca^{2+} sparklet sites activated, and the frequency of coupled gating events underlie enhanced Ca^{2+} influx during these pathological conditions.

The mechanisms underlying increased Ca^{2+} sparklet activity during hypertension, type II diabetes, and TS vary depending on the pathological condition. Although AKAP is critical for local activation of persistent Ca^{2+} sparklets in all cases, enhanced Ca^{2+} sparklets' activity during hypertension results primarily from an increase in L-type Ca^{2+} channels' expression and PKCα activity, while activation of PKA contributes to higher persistent Ca^{2+} sparklets' activity during hyperglycemia and type II diabetes (Fig. 1). In the case of TS, an arginine for glycine substitution at position 436 in L-type Ca^{2+} channels increases the open time and P_o of these channels, thus enhancing Ca^{2+} sparklet activity (Santana and Navedo 2009, 2010). Regardless of the mechanism, an increase in Ca^{2+} sparklet activity and coupled gating could translate into enhanced Ca^{2+} influx that contributes to the development of type II diabetes, hypertension, and Ca^{2+}-dependent cardiac arrhythmias associated with TS.

The increase in persistent Ca^{2+} sparklet activity and coupled gating has important functional consequences in arterial myocytes during hypertension and possibly type II diabetes, as this Ca^{2+} signal activates the transcription factor NFATc3 via calcineurin (Fig. 1) (Santana and Navedo 2010). Activation of AKAP-targeted PKCα or AKAP-targeted PKA during hypertension or type II diabetes, respectively, induces persistent Ca^{2+} sparklet activity and enhances coupled gating behavior. This produces an increase in local intracellular Ca^{2+} influx that activates nearby calcineurin. Once activated, calcineurin is able to dephosphorylate the transcription factor NFATc3. Upon dephosphorylation, NFATc3 translocates to the nucleus of arterial myocytes where it can modify the expression of Kv and BK channel subunits. Downregulation of Kv and BK channel subunits, thus, decreases channel function, depolarizes arterial myocytes, and enhances Ca^{2+} sparklets activity, hence increasing Ca^{2+} influx, global $[Ca^{2+}]_i$, and myogenic tone. Importantly, and consistent with the model proposed above, loss of AKAP150 or PKCα protects

against the development of experimental hypertension. Collectively, data support a model in which a signaling pentad composed by AKAP, PKCα, PKA, calcineurin, and L-type Ca^{2+} channels contributes to the regulation of gene expression, Ca^{2+} influx, and excitability during physiological and pathological conditions.

Ca^{2+} Waves

Though Ca^{2+} sparklets are highly localized Ca^{2+} signals produced by the opening of L-type Ca^{2+} channels in the surface membrane, Ca^{2+} waves are spontaneous transient increases in global cytosolic [Ca^{2+}] produced by Ca^{2+} release via RyRs or IP_3Rs in the SR. This Ca^{2+} signaling modality could propagate from one end of a cell to the other. Ca^{2+} waves were first observed in the 1970s as elevations in cytosolic [Ca^{2+}] in medaka fish eggs during the fertilizing process with the use of the chemiluminescent indicators (Jaffe 1991). Subsequently, the development of novel fluorescent indicators and optical imaging techniques helped expand our understanding of the mechanisms underlying the generation, propagation, and functional consequences of Ca^{2+} waves. To date, Ca^{2+} waves have been recorded from many different cell types including oocytes and eggs, as well as excitable (e.g., neuron, cardiac, and arterial myocytes) and non-excitable cells (e.g., hepatocytes, astrocytes, and endothelial cells) (Jaffe 1991). Ca^{2+} waves are initiated by different molecular entities and displayed different forms, velocities, and patterns, depending on the cell type and stimulus (Table 2). For the purpose of this entry, the discussion of Ca^{2+} waves will be centered on their generation, propagation, and functional role in cardiac and arterial myocytes.

Molecular mechanisms underlying the generation and propagation of Ca^{2+} waves in cardiac and smooth muscle. The SR in cardiac and arterial myocytes serves as an intracellular Ca^{2+} store that releases its content when RyRs and/or IP_3Rs is activated. The sequential activation of these channels generates Ca^{2+} waves that could propagate throughout the cytoplasm of these cells (Fig. 2) (Wier and Blatter 1991). In cardiac myocytes, Ca^{2+} waves are associated with a pathological state in which the SR is "overloaded" with Ca^{2+}. This increases the probability of spontaneous Ca^{2+} release via RyRs and the subsequent activation of nearby clusters of these channels by the mechanism of CICR (Fig. 2). Whether a Ca^{2+} wave develops would depend on the amplitude and duration of the triggering Ca^{2+} release event and the sensitivity of adjacent RyRs to this Ca^{2+} signal. Multiple studies indicate that increases in SR Ca^{2+} content enhance the sensitivity of RyRs to cytosolic Ca^{2+}. Thus, during SR Ca^{2+} overload, RyRs exist in a hypersensitive state that makes them susceptible to activation by the opening of nearby RyRs in the leading edge of the traveling wave (Keller et al. 2007). IP_3Rs are not involved in Ca^{2+} waves' generation and propagation in cardiac myocytes, but have been implicated in the regulation of cardiac hypertrophy via a calcineurin-dependent mechanism.

The mechanisms underlying the generation and propagation of Ca^{2+} waves in arterial myocytes are not clearly understood. In these cells, Ca^{2+} waves result from intracellular Ca^{2+} release via RyRs and/or IP_3Rs due to electrical, mechanical, or α-adrenergic stimulation (Fig. 2) (Wray and Burdyga 2010). Notably, several studies suggest that Ca^{2+} influx via L-type Ca^{2+} channels (i.e., Ca^{2+} sparklets) is important for the sustained generation of Ca^{2+} waves in arterial myocytes. However, it seems that the molecular entity or entities underlying the generation of Ca^{2+} waves will depend on the stimulus provided. For example, Ca^{2+} sparks at frequent discharge sites have been implicated in the generation of Ca^{2+} waves (Wray and Burdyga 2010). Consistent with this, caffeine, which increases the sensitivity of RyRs to cytosolic Ca^{2+}, has been shown to increase the frequency of Ca^{2+} waves in vascular myocytes. Meanwhile, ryanodine, an alkaloid that binds to RyRs and locks the receptor in a sub-conductance state that depletes SR Ca^{2+}, was shown to eliminate Ca^{2+} sparks and Ca^{2+} waves in pressurized cerebral arteries. These observations support the view that Ca^{2+} waves are produced and propagated by the gating of clusters of RyRs, at least in pressurized cerebral arteries that have not been exposed to agonists that elevate IP_3.

On the other hand, multiple studies have suggested that IP_3Rs are involved in agonist-induced Ca^{2+} waves, with possible involvement of RyRs via a CICR mechanism in arterial myocytes (Fig. 2). Indeed, vasoconstrictors, such as UTP, have been shown to promote Ca^{2+} waves through a mechanism that involved the activation of IP_3Rs. Whether Ca^{2+} release through IP_3Rs facilitates the recruitment of adjacent RyRs in order to amplify and propagate agonist-induced Ca^{2+} waves in arterial myocytes is not clear. A model in which stimulus-induced propagating Ca^{2+} waves will

Calcium Sparklets and Waves, Fig. 2 *Proposed model for the generation of Ca^{2+} waves in cardiac and arterial myocytes.* Ca^{2+} waves are produced by the sequential activation of RyRs and/or IP_3Rs in the SR of cardiac and arterial myocytes. In cardiac myocytes, Ca^{2+} waves are a pathological phenomenon associated with SR Ca^{2+} overload. In these cells, Ca^{2+} waves are produced and propagated exclusively by spontaneous or triggered release of Ca^{2+} via RyRs by the mechanism of CICR. In arterial myocytes, Ca^{2+} waves result from SR Ca^{2+} release via RyRs and/or IP3Rs due to electrical, mechanical, or α-adrenergic stimulation. Whether CICR between RyRs and IP_3Rs occurs in these cells is not clear yet. In this model, independently gating or coupled L-type Ca^{2+} channels contribute to Ca^{2+} influx into a common global cytosolic Ca^{2+} pool from which SERCA pumps Ca^{2+} into the SR network of cardiac and arterial myocytes

depend on the level of expression, subcellular distribution, and activation of both RyRs and IP_3Rs in the SR of arterial myocytes could help reconcile these findings (Wray and Burdyga 2010). Alternatively, a mechanism similar to the one described in cardiac myocytes in which RyRs are sensitized to cytosolic Ca^{2+} during high SR Ca^{2+} load may play a pivotal role in the propagation of agonist-induced Ca^{2+} waves. Future studies should examine these issues.

Functional consequences of Ca^{2+} waves. In cardiac myocytes, Ca^{2+} waves do not seem to be physiologically relevant for either Ca^{2+}-dependent signal transduction or normal EC coupling. Rather, Ca^{2+} waves are believed to be a pathological manifestation of SR

Ca^{2+} overload that activates a depolarizing inward membrane current in cardiac myocytes responsible for delayed afterdepolarizations that could trigger ventricular arrhythmias (Cheng and Lederer 2008; Keller et al. 2007).

In smooth muscle, Ca^{2+} waves play a key physiological role. Ca^{2+} waves have been suggested to contribute to the development of myogenic tone during changes in response to activation of α-adrenergic receptor signaling (Wray and Burdyga 2010). Accordingly, activation of IP_3 signaling can evoke Ca^{2+} waves that elevate cytosolic [Ca^{2+}], thus inducing the phosphorylation of the myosin light chain (MLC) by the myosin light chain kinase. Phosphorylation of MLC will induce cross-bridge cycling and cell shortening (Wray and Burdyga 2010).

The functional role of Ca^{2+} waves during the development of myogenic tone by arterial smooth muscle in response to increases in intravascular pressure is controversial. Two studies using cerebral arteries have reached opposite conclusions with regard to the role of Ca^{2+} waves on EC coupling. The Nelson and Jaggar groups (Jaggar et al. 1998) have published compelling data suggesting that the net effect of pressure-induced Ca^{2+} waves is to oppose contraction, and that, consistent with the current dogma, intravascular pressure elevates global cytosolic [Ca^{2+}] primarily by promoting Ca^{2+} influx via L-type Ca^{2+} channels. Meanwhile, Donald Welsh's group recognizes the importance of Ca^{2+} influx via L-type Ca^{2+} channels on EC coupling, but argues that pressure increases the frequency of Ca^{2+} waves in a voltage-insensitive manner, which instead facilitates tone development by providing part of the Ca^{2+} necessary to the global Ca^{2+} pool that activates the contractile machinery in arterial myocytes. Although interesting, this model is at odds with work from many laboratories, indicating that global cytosolic [Ca^{2+}] in arterial myocytes is most regulated by Ca^{2+} sparklets in a voltage-dependent manner (Santana and Navedo 2009; Wier and Blatter 1991; Wray and Burdyga 2010). Thus, while the reasons for these seemingly contradictory findings are unclear, it is possible that variations in experimental conditions (e.g., effectiveness of the inhibitors in a given experimental setting) may contribute to these differences. Future studies should further examine this issue and provide unambiguous answers about the functional role of Ca^{2+} waves on EC coupling in arterial myocytes.

Concluding Remarks

Advances in imaging technology have provided a unique opportunity to gain insight into the regulatory mechanisms and dynamics of Ca^{2+} signaling events and their functional role in cells. Such is the case with the optical recording of Ca^{2+} sparklets and Ca^{2+} waves in cardiac and arterial myocytes. Indeed, one of the most paradigm shifting observations made using optical approaches is that the open probability of L-type Ca^{2+} channels varies regionally within the surface membrane of cells. The recording of Ca^{2+} sparklets revealed the regulatory mechanisms underlying heterogeneous sparklet activity, uncovered a gating modality not described before for L-type Ca^{2+} channels (e.g., coupled gating), and provided insight into the functional role of this Ca^{2+} signal during physiological and pathological conditions. Similarly, the recording of Ca^{2+} waves and the groundbreaking discovery of Ca^{2+} sparks as the building block for the generation and propagation of Ca^{2+} waves provided an opportunity to determine how transient, local, and global increases in cytosolic [Ca^{2+}] regulate cell excitability.

Calcium as an intracellular messenger; Calcium diffusion; Calmodulin; EF-hand proteins; Local signaling

Definition

All eukaryotic cells use ionized calcium (Ca^{2+}) as a messenger. An increase or decrease of Ca^{2+} concentration in the cytosol, or in organellar compartments, can lead to changes in cell function, structure, or viability. To encode information and control specific cellular processes, Ca^{2+} signals need to be temporally and spatially regulated. The diffusive movement of Ca^{2+} within cells is critical in turning local signals into whole-cell (global) events. Cells possess mechanisms to both aid and hinder the spread of Ca^{2+}, depending on their physiological context. Furthermore, Ca^{2+} channels themselves are regulated by Ca^{2+} to provide either positive or negative feedback control of Ca^{2+} fluxes.

Overview

Ca^{2+} is a versatile intracellular messenger. Cellular Ca^{2+} signals can span from brief, nanoscopic flickers, close to the mouth of channels, up to global events that spread regeneratively through cells and last for many tens of seconds (Berridge 2006). Furthermore, Ca^{2+} signals can spread between cells to coordinate the activities of tissues (Leybaert and Sanderson 2012). The spatial and temporal properties of Ca^{2+} signals are determined by the Ca^{2+} transport systems expressed within a particular cell type. There is a wide range of Ca^{2+} channels, pumps, buffers, and effector molecules encoded within the eukaryotic genome. Cells select from this "Ca^{2+} signaling toolkit" those components that generate Ca^{2+} signals to suit their physiology (Berridge et al. 2000). Specificity in Ca^{2+} signaling is encoded in the location, amplitude, and frequency of Ca^{2+} signals and, in some cases, by cross talk with other signal transduction cascades. In particular, specificity is achieved by expressing Ca^{2+} channels and effector molecules within privileged compartments where Ca^{2+} changes can arise with complete isolation from the rest of the cell. By compartmentalizing Ca^{2+} signals within specific domains, cells can use this simple divalent cation to control multiple, simultaneous processes. Aberrant changes in the distribution, amplitude, or kinetics of Ca^{2+} signals cause explicit pathological outcomes (Sammels et al. 2010).

In resting cells, the average cytosolic Ca^{2+} concentration is ~100 nM. Stimulation of cells via a variety of means (e.g., hormonal, electrical, mechanical) can elicit an increase of the cytosolic Ca^{2+} concentration. The amplitude of the Ca^{2+} rise depends on the cell type, the nature of the stimulus, and where it is measured. For example, hormonal stimulation of non-excitable cells typically evokes repetitive whole-cell Ca^{2+} oscillations. The frequency of such Ca^{2+} oscillations, or their cumulative Ca^{2+} signal, determines the extent of cellular response. Typically, Ca^{2+} oscillations in non-excitable cells arise via the repetitive release of Ca^{2+} from intracellular stores, principally the endoplasmic reticulum (ER). In contrast, electrical stimulation of excitable cells (e.g., myocytes, neurons) activates voltage-operated Ca^{2+} channels (VOCs) that allow the influx of Ca^{2+} from the extracellular space. This Ca^{2+} influx signal can remain localized around the mouth of the channel or trigger the release of Ca^{2+} from intracellular stores – a process known as Ca^{2+}-induced Ca^{2+} release (CICR). The self-amplification of Ca^{2+} signals by CICR is critical in turning local signals into whole-cell responses.

Ca^{2+} Channels

Ca^{2+} channels that mediate the influx of Ca^{2+} from the extracellular space are generally characterized by their activation mechanism. For example, receptor-operated Ca^{2+} channels (e.g., glutamate- and glycine-binding NMDA receptors) and second messenger-operated Ca^{2+} channels (e.g., cyclic nucleotide-gated ion

channels and arachidonate-regulated Orai channels) are opened by the binding of an external or internal ligand, respectively. VOCs are widely expressed in excitable tissues and can be divided into three families – the Ca_V1 family of L-type channels; the Ca_V2 family of N-, P-/Q-, and R-type channels; and the Ca_V3 family of T-type channels – which have specific gating characteristics, pharmacologies, and functions (Catterall et al. 2005). The transient receptor potential (TRP) family includes a number of Ca^{2+}-permeable channels with distinct activation mechanisms (Gees et al. 2010). The release of Ca^{2+} from internal stores occurs through several different types of channel (Bootman et al. 2002), including inositol 1,4,5-trisphosphate receptors ($InsP_3Rs$), ryanodine receptors (RyRs), polycystin-2 (a member of the TRP family), and putative the NAADP-sensitive two-pore channels (TPCs).

Ca^{2+} Buffers

Cells express a number of Ca^{2+}-binding proteins that reversibly buffer Ca^{2+} changes within various cellular compartments. The involvement of Ca^{2+} buffers can be critical in shaping both the spatial and temporal properties of Ca^{2+} signals (Schwaller 2010). Two prominent cytosolic Ca^{2+} buffers are parvalbumin and calbindin D-28 k, which possess high-affinity (micromolar) Ca^{2+}-binding motifs known as EF-hands (see below) that allow them to adsorb Ca^{2+} ions as they diffuse away from channels. Within the ER, Ca^{2+}-binding proteins, such as calsequestrin and calreticulin, facilitate the accumulation of large amounts of Ca^{2+}, which is necessary for rapid cell signaling. Mitochondria also play a key role in buffering Ca^{2+} due to their ability to sequester substantial amounts of Ca^{2+} whenever the cytosolic Ca^{2+} concentration rises. The uptake of Ca^{2+} into the mitochondrial matrix stimulates the citric acid cycle to produce more ATP. When mitochondrial Ca^{2+} uptake is exaggerated, or occurs simultaneously with specific messengers (e.g., arachidonate, ceramide, reactive oxygen species), a substantial "permeability transition pore" (mPT) can be activated. mPT underlies the release of intramitochondrial proteins such as cytochrome C that trigger apoptosis (Duchen and Szabadkai 2010).

Proteins Mediating the Action of Ca^{2+}

The cellular actions of Ca^{2+} are almost entirely mediated by binding to specific proteins that then change their activity, or the activity of further binding partners. Some moieties, such as the Ca^{2+}-dependent transcriptional repressor DREAM, are active when the cytosolic/nuclear Ca^{2+} concentration is low and inhibited when the Ca^{2+} level rises. In the majority of cases, an elevation of Ca^{2+} concentration is an activation signal. Ca^{2+} binds to proteins via specific motifs. Two common motifs are EF-hands and C2 domains (Clapham 2007). The universal Ca^{2+} sensor, calmodulin (CaM), is plausibly the best-known example of an EF-hand-containing protein. CaM is ubiquitously expressed and mediates many effects of Ca^{2+} on cell metabolism and growth. In particular, CaM mediates the activation of Ca^{2+}-sensitive enzymes including Ca^{2+}/calmodulin-dependent protein kinases (CaMKs), the phosphatase calcineurin, myosin light-chain kinase (MLCK), and phosphorylase kinase. CaM has four EF-hands, which bind Ca^{2+} in a cooperative manner, thus allowing the Ca^{2+}/CaM interaction to provide a rapid switch in activity. Subtle changes in the amino acid sequences defining EF-hand motifs can alter the affinity of a protein for Ca^{2+}. A well-known C2 domain-containing protein is synaptotagmin, which facilitates neurotransmitter vesicle exocytosis in response to opening of nearby VOCs. The use of different Ca^{2+}-binding motifs with varying affinities allows Ca^{2+} to regulate cellular processes over a >100-fold range of concentrations. A pertinent example of this can be seen in neurons, which possess Ca^{2+}-binding proteins sensitive to submicromolar Ca^{2+} levels (e.g., neuronal Ca^{2+}-sensor proteins) up to synaptotagmin that is activated by Ca^{2+} in the ~100 micromolar range (Burgoyne and Weiss 2001).

Reversing Ca^{2+} Signals

Ca^{2+} signals are reversed by a range of pumps and exchanger molecules that are designed to reduce the resting cytosolic Ca^{2+} concentration to ~100 nM. Tissue-specific expression of different pump/exchanger combinations alters the kinetics of Ca^{2+} signal recovery. In tissues requiring rapid Ca^{2+}

transients, such as cardiac muscle cells, Na^+/Ca^{2+} exchangers provide a fast rate of Ca^{2+} transport critical for cells to reset between contractions. The plasma membrane Ca^{2+}-ATPase (PMCA) and sarco-/endoplasmic reticulum (SERCA) pumps have lower transport rates but higher affinities, which means that they operate at relatively low cytosolic Ca^{2+} concentrations.

Local Ca^{2+} Signaling

While whole-cell Ca^{2+} signals can regulate events such as contraction and gene transcription, it is becoming increasingly apparent that local Ca^{2+} signals are critically important in the regulation of cell function. Since cells have so many Ca^{2+}-sensitive processes, their simultaneous regulation can only be achieved by constraining Ca^{2+} within privileged compartments where Ca^{2+} source and effector proteins are in close proximity. A classic example of such a compartment is neuronal dendritic spines, where the folding of the plasma membrane delineates a microscopic signaling space. In other situations, Ca^{2+} signal compartmentalization relies on the close proximity of membranes from different structures or organelles. For example, privileged Ca^{2+} signaling compartments are formed by the close association of the ER to either the mitochondria to promote the flux of Ca^{2+} between these organelles or to the plasma membrane to regulate K^+ channels to control membrane excitability in neurons. Ca^{2+} can have sequential local and global signaling functions. For example, Orai1 channels on the plasma membrane are activated when ER stores are depleted of Ca^{2+} (Luik et al. 2006). The Ca^{2+} ions that enter cells through Orai1 channels can act locally to switch on mitogen-activated protein kinases and cAMP production before diffusing into cells to stimulate other events.

A particular local Ca^{2+} signaling compartment is found in cardiac myocytes of the heart. The plasma membrane of cardiac cells (sarcolemma) has deep invaginations known as "transverse tubules" (T-tubules). These thin (~100–200 nm in diameter) inward projections of the sarcolemma are like a system of tire spokes occurring at each of the Z-lines (longitudinal spacing ~1.8 μm). It is principally along the T-tubule membranes that VOCs are triggered to initiate cardiac contraction. Closely opposed to the T-tubules are elements of the sarcoplasmic reticulum (SR), bearing the Ca^{2+}-conducting RyRs. The VOCs on the T-tubules and the RyRs on the SR sit opposite each other across a small span (~15 nm) of cytoplasm. Together, the membrane with the VOCs and the membrane with the RyRs form a "dyadic junction." During electrical excitation of a cardiac myocyte, the action potential sweeps down the T-tubule and activates the VOCs to produce a small, local Ca^{2+} signal known as a "Ca^{2+} sparklet." The consequent Ca^{2+} influx signal is amplified by the RyRs via the CICR process described earlier. Ca^{2+} ions diffuse out of the dyadic junction, bind to the EF-hand-containing protein troponin C, and thereby trigger contraction. The simultaneous electrical activation of Ca^{2+} signals at many thousands of dyadic junctions leads to the global signal required for cardiac contraction. However, this whole-cell Ca^{2+} signal relies on the initial local communication between VOCs and RyRs.

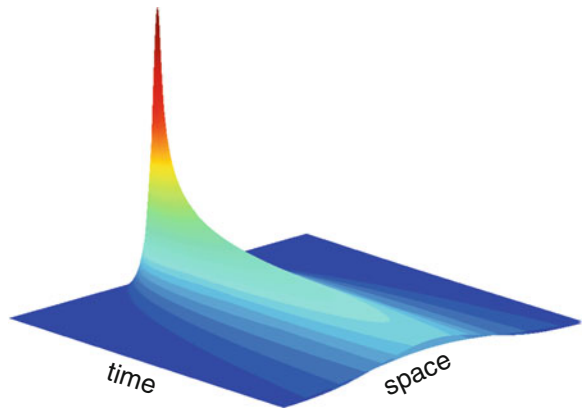
The example of dyadic junctions is particularly interesting because it is one of the few Ca^{2+} signaling compartments where the locations and numbers of Ca^{2+} channels are reasonably well known. It has been estimated that ~10 L-type VOCs in the T-tubule membrane face ~100 RYR in the closely apposed SR junctional membrane. The Ca^{2+} sparklets produced by opening L-type VOCs represent the movement of ~300 Ca^{2+} ions from the extracellular space into the dyadic junction. Approximately 15 RyRs sense this Ca^{2+} influx and respond via CICR to produce a larger and long-lasting "Ca^{2+} spark." The transition from Ca^{2+} sparklet to Ca^{2+} spark and then to whole-cell response demonstrates how local events can feed global responses.

Another way of controlling the response of specific effector proteins is to alter their proximity to a particular Ca^{2+} source. For example, the protein synaptotagmin, mentioned above, has a relatively low affinity for Ca^{2+}, but it can be physically associated with a VOC so that it can rapidly respond to an elevation of Ca^{2+} concentration and trigger synaptic vesicle release. Other proteins may sense an elevated Ca^{2+} concentration and migrate toward it. An example of such a protein is the Ras GTPase-activating protein RASAL, which binds Ca^{2+} via a C2 domain and cycles on and off the plasma membrane in synchrony with Ca^{2+} oscillations. A further example is regulation of

mitochondrial movement by Rho GTPases proteins called Miro. These proteins possess EF-hands to sense Ca^{2+} and also interact with other proteins involved in mitochondrial movement along microtubules. At resting cytosolic Ca^{2+} levels, Miro proteins facilitate mitochondrial movement by increasing the proportion of mitochondria associated with kinesin motor proteins, but elevation of Ca^{2+} concentration rapidly halts mitochondrial translocation. In this way, mitochondria can become trapped near the compartments with elevated Ca^{2+}concentration.

Ca^{2+} Diffusion

Diffusion is the main mechanism by which Ca^{2+} moves through the cell. Ca^{2+} moves from regions of relatively high concentration to areas of low concentration using two mechanisms: diffusion of free Ca^{2+} ions and diffusion of buffer-bound Ca^{2+}. Typically, less than 5% of the total Ca^{2+} concentration is free ions, so the majority of Ca^{2+} diffuses bound to mobile buffers. In addition to endogenous mobile buffers, exogenously introduced Ca^{2+} chelators such as EGTA, BAPTA, and fluorescent Ca^{2+} reporters (commonly used to measure cellular Ca^{2+}) affect the speed of intracellular Ca^{2+} transport. To characterize the combined effect of buffered and free diffusion on the spatiotemporal spread of Ca^{2+}, an effective Ca^{2+} diffusion D_{eff} coefficient is often considered. In a wider sense, D_{eff} corresponds to a coarse-grained description of the more detailed buffer kinetics, collapsing all binding and unbinding events to one number. A common approach to compute D_{eff} is the fast buffer approximation (Wagner and Keizer 1994; Smith et al. 2001). It is based on the assumption that buffer kinetics are fast, resulting in an instant equilibrium of bound and unbound buffer. As with all approximations, the fast buffer approximation is only valid under certain conditions. Importantly, D_{eff} is computed from the diffusion coefficients of the mobile buffers, the total buffer concentrations and the buffer dissociation constants. Therefore, D_{eff} varies between different cellular compartments such as the cytosol or the ER due to the expression of different buffers. Moreover, the local cellular geometry influences the speed of Ca^{2+} diffusion. In compartments like the ER, D_{eff} is further reduced since ER tortuosity acts as an obstacle for diffusion (Ölveczky and Verkman 1998).



Calcium, Local and Global Cell Messenger, Fig. 1 Ca^{2+} diffusion profile from a point source located in the center of the spatial domain

As buffers generally diffuse more slowly than free Ca^{2+} ions, D_{eff} is smaller than the value of free Ca^{2+} diffusion. For example, cytosolic D_{eff} is in the range of 20–40 $\mu m^2/s$, while the diffusion coefficient for free cytosolic Ca^{2+} is 223 $\mu m^2/s$. Cells can hinder the diffusion of Ca^{2+} in order to keep Ca^{2+} signals localized to their site of origin. In particular, cells can express Ca^{2+} pumps or mitochondria to act as a firewall, preventing the diffusive spread of Ca^{2+} ions. Notable examples have been seen with apical-only Ca^{2+} signals in pancreatic acinar cells (Walsh et al. 2009), subsarcolemmal Ca^{2+} signals in atrial myocytes (Mackenzie et al. 2004), and the discontinuity between the cytosolic and subplasma membrane Ca^{2+} in smooth muscle (caused by the SR forming a "superficial buffer barrier").

A potential consequence of Ca^{2+} being transported by mobile buffers is facilitated diffusion. When Ca^{2+} diffusion is described by a single effective diffusion coefficient, D_{eff}, the spatial Ca^{2+} concentration profile around a point source evolves in time as shown in Fig. 1. The Ca^{2+} concentration decreases smoothly on either side of the point source, and the peak Ca^{2+} concentration decays steadily over time. The exact spatiotemporal profile of such a response depends on the conductance of the Ca^{2+} channel and the local buffering conditions. When buffers are considered explicitly, this monotonic evolution of the concentration profile may be disrupted. A localized peak in the Ca^{2+} concentration emerges at some distance from the Ca^{2+} source. This is the fingerprint of facilitated diffusion. The mechanism for this process resembles that of a "piggyback ride." Ca^{2+} binds to buffers at the source,

and then Ca^{2+}-bound buffers diffuse away from it. After some time, which is determined by buffer off rates, Ca^{2+} dissociates from the buffers. In turn, this leads to a local increase in the Ca^{2+} concentration.

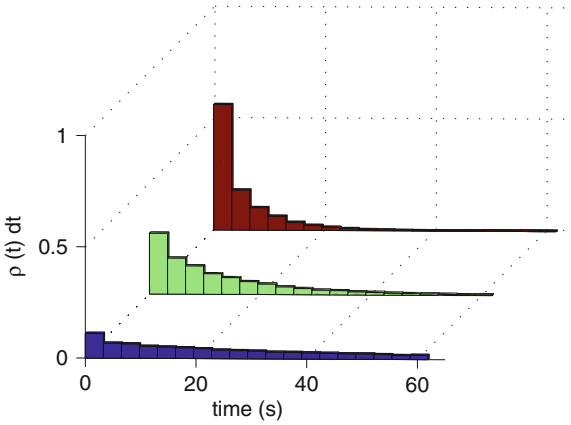
In addition to controlling cellular activities, local Ca^{2+} signals can regulate channel opening too. Many Ca^{2+} channels possess sites at which Ca^{2+} can bind and are positively or negatively regulated by the ions they liberate. Deciphering the profile of a Ca^{2+} signal around the mouth of an ion channel is key to understanding the Ca^{2+}-dependent gating of ion channels. As with all binding processes, the rate with which Ca^{2+} binds to a designated binding site depends on the number of Ca^{2+} ions in the vicinity of the binding site. The more Ca^{2+} ions around a particular binding site, the higher the probability that a Ca^{2+} ion binds in a given period of time. Therefore, averaged Ca^{2+} concentrations such as the cytosolic bulk Ca^{2+} concentration do not determine how Ca^{2+} signaling events proceed. All the information for channel gating is encoded in the local Ca^{2+} dynamics.

A prominent example of localized Ca^{2+} signaling is the "Ca^{2+} puff" that arises from activation of $InsP_3Rs$ on the ER (Bootman et al. 1997; Smith et al. 2009). Stimulation of cells with hormonal agonists evokes the production of $InsP_3$ from a membrane lipid precursor. $InsP_3$ is highly diffusible inside cells and thus rapidly makes its way from the plasma membrane to the ER, where it binds to, and activates, $InsP_3Rs$ to produce the Ca^{2+} oscillations mentioned above. Ca^{2+} puffs can be considered as an elementary event of Ca^{2+} signaling, rather like the Ca^{2+} sparks described earlier. An intriguing feature of Ca^{2+} signaling is that regular, periodic Ca^{2+} signals can rely on underlying stochastic activation of Ca^{2+} release channels. In the following section, how this random activation manifests itself for $InsP_3R$ to trigger a Ca^{2+} puff is illustrated.

Although $InsP_3Rs$ require the binding of $InsP_3$ to open, they are actually activated by Ca^{2+} itself. The activation of $InsP_3Rs$ by Ca^{2+} means that they have the ability to augment Ca^{2+} responses via CICR. $InsP_3Rs$ usually form clusters, which are expressed at spatially discrete locations on the membrane of the ER or SR. Although the number of $InsP_3Rs$ per cluster varies between cells and among cell types, it is generally accepted that a cluster comprises only tens of $InsP_3Rs$. This small number of ion channels per cluster has significant consequences for the cluster behavior: it is driven by randomness. Early experiments examining Ca^{2+} puff generation pointed toward the stochastic initiation of these events (Marchant et al. 1999; Bootman et al. 1997). After flash photolysis of $InsP_3$, it took a varying amount of time for the first Ca^{2+} puff to emerge. These experimental findings were corroborated by modeling studies, clearly demonstrating that stochastic effects dominate Ca^{2+} puff dynamics (Swillens et al. 1998; Falcke 2003) and see Thurley et al. (2012) for a recent review.

The randomness of Ca^{2+} puff generation originates from the small number of $InsP_3$- and Ca^{2+}-binding sites per cluster. Although the molecular details of Ca^{2+} and $InsP_3$ binding to the $InsP_3R$ are still being investigated, a large class of models agrees on $InsP_3$- and Ca^{2+}-dependent activation, as well as Ca^{2+}-dependent inactivation. One model that has received broad attention and ongoing modifications to accommodate new experimental results was originally proposed by De Young and Keizer (Shuai et al. 2007; De Young and Keizer 1992; Swaminathan et al. 2009). The De Young and Keizer model assumes three binding sites per $InsP_3R$ subunit (one for $InsP_3$, one for activating Ca^{2+}, and one for inhibitory Ca^{2+}), resulting in eight possible subunit states. One of these states corresponds to an activated subunit. Due to early measurements (Bezprozvanny et al. 1991), the tetrameric $InsP_3R$ is deemed open when at least three of the four subunits are in the activated state. Hence, there are four possible open states of an $InsP_3R$. Denoting the probability of an activated subunit as p_{ac}, the probability of an open $InsP_3R$ is given by $P_{op} = 4p_{ac}^3 - 3p_{ac}^4$.

The channel open probability, P_{op}, would be an adequate description at the cluster level if a cluster contained a large number of $InsP_3Rs$. However, the small $InsP_3R$ numbers per cluster necessitate a different approach. At the level of a single subunit, the continuous binding and unbinding of Ca^{2+} and $InsP_3$ translates into random transitions among the eight subunit states. Under the often-used assumption that the four subunits are independent, these transitions occur simultaneously at all four subunits. Therefore, a single binding event suffices to switch an $InsP_3R$ from inactivation to activation. It is this abrupt and stochastic state change that forms the basis for the fluctuating behavior of $InsP_3Rs$ and the randomness of Ca^{2+} puff initiation. Moving one level up in the kinetic hierarchy, the dynamics of an $InsP_3R$ as continuous jumps between different channel states may be conceptualized. While there is usually only



Calcium, Local and Global Cell Messenger, Fig. 2 Ca^{2+} puff initiation in a cluster of 8 DeYK channels for a Ca^{2+} concentration of 0.03 μM (*blue*), 0.05 μM (*green*), and 0.07 μM (*red*). The IP_3 concentration is 0.4 μM

one activated subunit state, the finding that at least three subunits have to be activated for channel opening leads to multiple activated channel states (see above). Hence, an $InsP_3R$ opens when the channel arrives in one of these activated states for the first time. This idea led to the identification of Ca^{2+} puffs as a first passage time process, which in turn allowed for a thorough mathematical treatment of puff initiation times (Thul and Falcke 2006, 2007). On a conceptual level, this observation renders the initiation of a Ca^{2+} puff similar to the generation of a neuronal action potential. A neuron only fires an action potential once the membrane voltage is sufficiently depolarized for the first time, and reaching this threshold is completely random. It is important to note that the requirement of multiple subunits to simultaneously be in the activated state for the first time allows individual subunits to visit their respective activated state multiple times before channel opening. Therefore, if p_f denotes the probability of a single subunit to arrive at the activated subunit state for the first time, the probability P_f for an $InsP_3R$ to open for the first time is *not* given by $4p_f^3 - 3p_f^4$. The computation of P_f requires more sophisticated mathematical tools (solution of a renewal equation, extensive combinatorics) as described in Thul and Falcke (2007).

In Fig. 2, the results from stochastic simulations of a cluster of eight tetrameric $InsP_3Rs$ are plotted where each channel subunit is described by the De Young–Keizer (DK) model. The three histograms depict the probability to initiate a puff in a small time interval $[t, t + dt]$ for different values of the basal Ca^{2+} concentration. The parameter values of the original DK model are used, but adjust the binding constant for the activating Ca^{2+} binding site to reflect the large Ca^{2+} concentrations that occur at an open $InsP_3R$ cluster. Upon increasing the basal Ca^{2+} concentration, Ca^{2+} puff generation is more likely to occur for shorter times. Moreover, the tail of the distribution shortens. This is consistent with the activating role of Ca^{2+} at low Ca^{2+} concentrations. A small increase in the basal Ca^{2+} concentration significantly raises the transition probability to the open channel state. The large peak at small times reflects the priming of $InsP_3Rs$ by $InsP_3$. At a concentration of 0.4 μM, most subunits have activating $InsP_3$ bound. Hence, only activating Ca^{2+} has to bind to trigger a puff. This example shows how Ca^{2+} can control its own release within cells.

Calcium, Neuronal Sensor Proteins

James B. Ames
Department of Chemistry, University of California, Davis, CA, USA

Synonyms

CaM; DREAM; Frq1; GCAP; KChIP; NCS-1

Definitions

Calmodulin, Downstream response element antagonist modulator, Yeast frequenin, Guanylate cyclase activator protein, Potassium channel–interacting protein, Neuronal calcium sensor protein-1.

Background

Intracellular calcium (Ca^{2+}) regulates a variety of neuronal signal transduction processes in the brain and retina. The effects of changes in neuronal Ca^{2+} are mediated primarily by an emerging class of neuronal calcium sensor (NCS) proteins (Weiss et al. 2010) that belong to the EF-hand superfamily. The human genome encodes 14 members of the NCS family. The amino acid sequences of NCS proteins are highly conserved from yeast to humans (Fig. 1). Recoverin, the first NCS protein to be discovered (Dizhoor et al. 1991), and guanylate cyclase–activating proteins (GCAPs) (Dizhoor et al. 1994; Palczewski et al. 1994) are expressed exclusively in the retina where they serve as Ca^{2+} sensors in vision. Other NCS proteins are expressed in the brain and spinal cord such as neurocalcin (Hidaka and Okazaki 1993), frequenin (NCS1) (Pongs et al. 1993), visinin-like proteins (Braunewell and Klein-Szanto 2009), K^+ channel–interacting proteins (KChIPs) (An et al. 2000), DREAM/calsenilin (Carrion et al. 1999), and hippocalcin (Kobayashi et al. 1992). Frequenin is also expressed outside of the central nervous system as well as in invertebrates including flies, worms, and yeast (Frq1) (Hendricks et al. 1999). The common features of these proteins are an approximately 200-residue chain containing four EF-hand motifs, the sequence CPXG in the first EF-hand that markedly impairs its capacity to bind Ca^{2+}, and an amino-terminal myristoylation consensus sequence.

The structurally similar NCS proteins have remarkably different physiologic functions (Table 1). Perhaps the best characterized NCS protein is recoverin that serves as a calcium sensor in retinal rod cells. Recoverin prolongs the lifetime of light-excited rhodopsin by inhibiting rhodopsin kinase (RK) only at high Ca^{2+} levels. Hence, recoverin makes receptor desensitization Ca^{2+} dependent, and the resulting shortened lifetime of rhodopsin at low Ca^{2+} levels

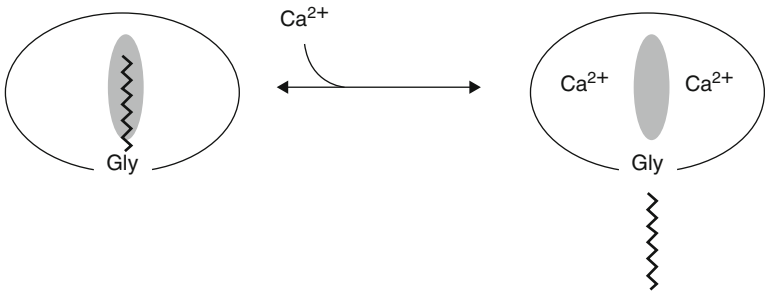
Calcium, Neuronal Sensor Proteins, Table 1 Function of NCS proteins

NCS protein	Function
Recoverin	Inhibit rhodopsin kinase in retinal rods
GCAP1	Activate guanylate cyclase in retinal cones
GCAP2	Activate guanylate cyclase in retinal rods
GCIP	Inhibit guanylate cyclase in frog photoreceptors
KChIP1	Regulate K^+ channel gating kinetics in brain
KChIP2	Regulate K^+ channel gating kinetics in cardiac cells
Calsenilin/ DREAM	Repress transcription of prodynorphin and c-fos genes
Frequenin (NCS1)	Activate PI(4) kinase and regulate Ca^{2+} and K^+ channels
Neurocalcin δ	Unknown
Hippocalcin	Activate phospholipase D and MAP kinase signaling
VILIP-1	Activate guanylate cyclase and traffic nicotinic receptors

may promote visual recovery and contribute to the adaptation to background light. Recoverin may also function in the rod inner segment and was identified as the antigen in cancer-associated retinopathy, an autoimmune disease of the retina caused by a primary tumor in another tissue. Other NCS proteins in retinal rods include the guanylate cyclase–activating proteins (GCAP1 and GCAP2) that activate retinal guanylate cyclase only at low Ca^{2+} levels and inhibit the cyclase at high Ca^{2+} (Dizhoor et al. 1994; Palczewski et al. 1994). GCAPs are important for regulating the recovery phase of visual excitation, and particular mutants are linked to various forms of retinal degeneration. Yeast and mammalian frequenins bind and activate a particular PtdIns 4-OH kinase isoform (Pik1 gene in yeast) (Hendricks et al. 1999; Strahl et al. 2007) required for vesicular trafficking in the late secretory pathway. Mammalian frequenin (NCS1) also regulates voltage-gated Ca^{2+} and K^+ channels. The KChIPs regulate the gating kinetics of voltage-gated, A-type K^+ channels (An et al. 2000). The DREAM/calsenilin/KChIP3 protein binds to specific DNA sequences in the prodynorphin and c-fos genes (Carrion et al. 1999) and serves as a calcium sensor and transcriptional repressor for pain modulation (Cheng et al. 2002). Hence, the functions of the NCS proteins appear to be quite diverse and nonoverlapping.



Calcium, Neuronal Sensor Proteins, Fig. 2 Schematic diagram of calcium-myristoyl switch in recoverin. The binding of two Ca^{2+} ions promotes the extrusion of the myristoyl group and exposure of other hydrophobic residues (marked by the *shaded oval*)

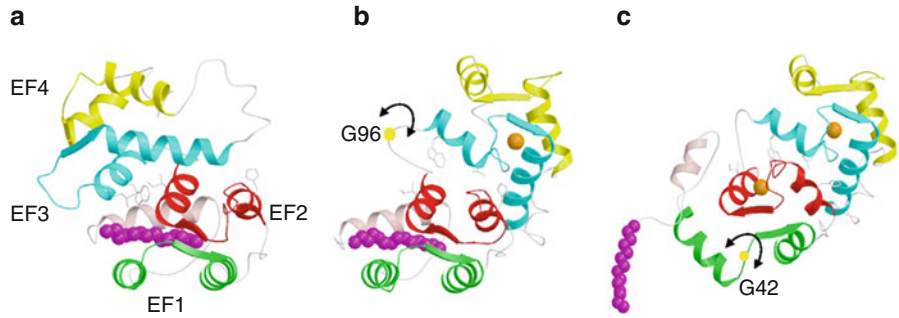
Mass spectrometric analysis of retinal recoverin and some of the other NCS proteins revealed that they are myristoylated at the amino terminus. Recoverin contains an N-terminal myristoyl (14:0) or related fatty acyl group (12:0, 14:1, 14:2). Retinal recoverin and myristoylated recombinant recoverin, but not unmyristoylated recoverin, bind to membranes in a Ca^{2+}-dependent manner. Likewise, bovine neurocalcin and hippocalcin contain an N-terminal myristoyl group, and both exhibit Ca^{2+}-induced membrane binding. These findings led to the proposal that NCS proteins possess a Ca^{2+}-myristoyl switch (Fig. 2). The covalently attached fatty acid is highly sequestered in recoverin in the calcium-free state. The binding of calcium to recoverin leads to the extrusion of the fatty acid, making it available to interact with lipid bilayer membranes or other hydrophobic sites. The Ca^{2+}-myristoyl switch function by recoverin also enables its light-dependent protein translocation in retinal rods.

In this entry, the atomic-level structures of various NCS proteins and their target complexes will be discussed and compared with that of calmodulin. The large effect of N-terminal myristoylation is examined on the structures of recoverin, GCAP1, and NCS1. Ca^{2+}-induced extrusion of the myristoyl group exposes unique hydrophobic binding sites in each protein that in turn interact with various target proteins. An emerging theme is that N-terminal myristoylation is critical for shaping each NCS family member into a unique structure, which upon Ca^{2+}-induced extrusion of the myristoyl group exposes a unique set of previously masked residues, thereby exposing a distinctive ensemble of hydrophobic residues to associate specifically with a particular physiological target.

Structure of Recoverin's CA^{2+}-Myristoyl Switch

The X-ray crystal structure of recombinant unmyristoylated recoverin (Flaherty et al. 1993) showed it to contain a compact array of EF-hand motifs, in contrast to the dumbbell shape of calmodulin and troponin C. The four EF-hands are organized into two domains: The first EF-hand, EF-1 (residues 27–56, colored green in Figs. 1 and 3), interacts with EF-2 (residues 63–92, red) to form the N-terminal domain, and EF-3 (residues 101–130, cyan) and EF-4 (residues 148–177, yellow) form the C-terminal domain. The linker between the two domains is U shaped rather than α-helical. Ca^{2+} is bound to EF-3, and Sm^{3+} (used to derive phases) is bound to EF-2. The other two EF-hands possess novel features that prevented ion binding. EF-1 is disabled by a Cys-Pro sequence in the binding loop. EF-4 contains an internal salt bridge in the binding loop that competes with Ca^{2+} binding. Myristoylated recoverin, the physiologically active form, has thus far eluded crystallization.

The structures of myristoylated recoverin in solution with 0, 1, and 2 Ca^{2+} bound have been determined by nuclear magnetic resonance (NMR) spectroscopy (Ames et al. 1997) (Fig. 3). In the Ca^{2+}-free state, the myristoyl group is sequestered in a deep hydrophobic cavity in the N-terminal domain. The cavity is formed by five α-helices. The two helices of EF-1 (residues 26–36 and 46–56), the exiting helix of EF-2 (residues 83–93), and entering helix of EF-3 (residues 100–109) lie perpendicular to the fatty acyl chain and form a boxlike arrangement that surrounds the myristoyl group laterally. A long, amphipathic α-helix near the N-terminus (residues 4–16) packs closely against and

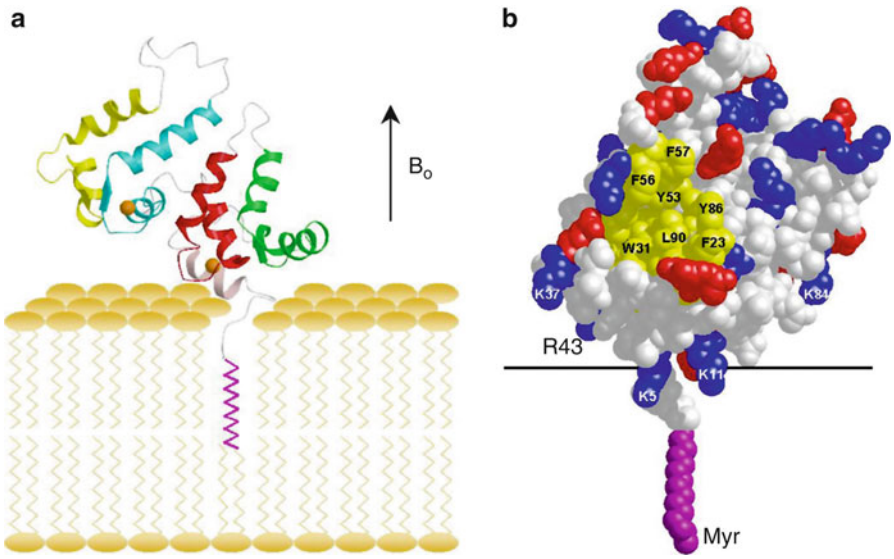


Calcium, Neuronal Sensor Proteins, Fig. 3 Three-dimensional structures of myristoylated recoverin with 0 Ca^{2+} bound (**a**), 1 Ca^{2+} bound (**b**), and 2 Ca^{2+} bound (**c**). The first step of the mechanism involves the binding of Ca^{2+} to EF3 that causes minor structural changes within the EF-hand that sterically promote a 45° swiveling of the two domains, resulting in a partial unclamping of the myristoyl group and a dramatic rearrangement at the domain interface. The resulting altered interaction between EF2 and EF3 facilitates the binding of a second Ca^{2+} to the protein at EF2 in the second step, which causes structural changes within the N-terminal domain that directly lead to the ejection of the fatty acyl group

runs antiparallel to the fatty acyl group and serves as a lid on top of the four-helix box. The N-terminal residues Gly 2 and Asn 3 form a tight hairpin turn that connects the myristoyl group to the N-terminal helix. This turn positions the myristoyl group inside the hydrophobic cavity and gives the impression of a cocked trigger. The bond angle strain stored in the tight hairpin turn may help eject the myristoyl group from the pocket once Ca^{2+} binds to the protein.

The structure of myristoylated recoverin with one Ca^{2+} bound at EF-3 (half-saturated recoverin, Fig. 3b) (Ames et al. 2002) represents a hybrid structure of the Ca^{2+}-free and Ca^{2+}-saturated states. The structure of the N-terminal domain (residues 2–92, green and red in Fig. 3) of half-saturated recoverin (Fig. 3b) resembles that of Ca^{2+}-free state (Fig. 3a) and is very different from that of the Ca^{2+}-saturated form (Fig. 3c). Conversely, the structure of the C-terminal domain (residues 102–202, cyan and yellow in Fig. 3) of half-saturated recoverin more closely resembles that of the Ca^{2+}-saturated state. Most striking in the structure of half-saturated recoverin is that the myristoyl group is flanked by a long N-terminal helix (residues 5–17) and is sequestered in a hydrophobic cavity containing many aromatic residues from EF-1 and EF-2 (F23, W31, Y53, F56, F83, and Y86). An important structural change induced by Ca^{2+} binding at EF-3 is that the carbonyl end of the fatty acyl group in the half-saturated species is displaced far away from hydrophobic residues of EF-3 (W104 and L108, Fig. 3a, b) and becomes somewhat solvent exposed. By contrast, the myristoyl group of Ca^{2+}-free recoverin is highly sequestered by residues of EF-3.

The structure of myristoylated recoverin with two Ca^{2+} bound shows the amino-terminal myristoyl group to be extruded (Ames et al. 1997) (Fig. 3c). The N-terminal eight residues are solvent exposed and highly flexible and thus serve as a mobile arm to position the myristoyl group outside the protein when Ca^{2+} is bound. The flexible arm is followed by a short α-helix (residues 9–17) that precedes the four EF-hand motifs, arranged in a tandem array as was seen in the X-ray structure. Calcium ions are bound to EF-2 and EF-3. EF-3 has the classic "open conformation" similar to the Ca^{2+}-occupied EF-hands in calmodulin and troponin C. EF-2 is somewhat unusual and the helix-packing angle of Ca^{2+}-bound EF-2 (120°) in recoverin more closely resembles that of the Ca^{2+}-free EF-hands (in the "closed conformation") found in calmodulin and troponin C. The overall topology of Ca^{2+}-bound myristoylated recoverin is similar to the X-ray structure of unmyristoylated recoverin described above. The RMS deviation of the main chain atoms in the EF-hand motifs is 1.5 Å in comparing Ca^{2+}-bound myristoylated recoverin to unmyristoylated recoverin. Hence, in Ca^{2+}-saturated recoverin, the N-terminal myristoyl group is solvent exposed and does not influence the interior protein structure.



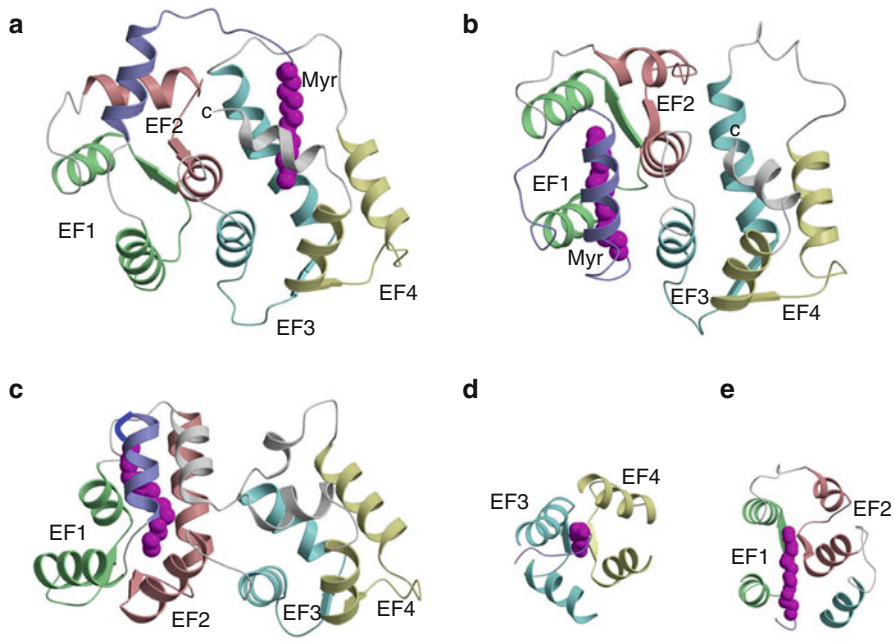
Calcium, Neuronal Sensor Proteins, Fig. 4 Main chain structure (**a**) and space-filling representation (**b**) of myristoylated recoverin bound to oriented lipid bilayers determined by solid-state NMR (Valentine et al. 2003). Hydrophobic residues are *yellow*, bound Ca^{2+} ions are *orange*, and charged residues are *red* and *blue*

The Ca^{2+}-induced exposure of the myristoyl group (Figs. 2 and 3) enables recoverin to bind to membranes only at high Ca^{2+} (Zozulya and Stryer 1992). Recent solid-state NMR studies have determined the structure of Ca^{2+}-bound myristoylated recoverin bound to oriented lipid bilayer membranes (Fig. 4) (Valentine et al. 2003). The protein is positioned on the membrane surface such that its long molecular axis is oriented 45° with respect to the membrane normal. The N-terminal region of recoverin points toward the membrane surface, with close contacts formed by basic residues K5, K11, K22, K37, R43, and K84. This orientation of membrane-bound recoverin allows an exposed hydrophobic crevice (lined primarily by residues F23, W31, F35, I52, Y53, F56, Y86, and L90) near the membrane surface that may serve as a potential binding site for the target protein, rhodopsin kinase (Fig. 4b).

Structural Diversity of NCS Proteins

Myristoylation Reshapes Structure of NCS Proteins. Three-dimensional structures have been determined recently for GCAP1 (Stephen et al. 2007) and NCS1 (Lim et al. 2011) that contain a sequestered myristoyl group (Fig. 5). Surprisingly, the myristoylated forms of GCAP1, NCS1, and recoverin all have very distinct three-dimensional folds (Fig. 5). The overall root-mean-squared deviations are 2.8 and 3.4 Å when comparing the main chain structures of Ca^{2+}-free NCS1 with recoverin and GCAP1, respectively. These very different structures reveal that the N-terminal myristoyl group is sequestered inside different protein cavities at different locations in each case. In NCS1, the N-terminal myristoyl group is sequestered inside a cavity near the C-terminus formed between the helices of EF3 and EF4 (Fig. 5a). The fatty acyl chain in NCS1 is nearly parallel to the helices of EF3 and EF4 that form walls that surround the myristoyl moiety (Fig. 5d). This arrangement in NCS1 is in stark contrast to recoverin where the myristoyl group is sequestered inside a protein cavity near the N-terminus (Fig. 5b). The myristate in recoverin is wedged perpendicularly between the helices of EF1 and EF2 (Fig. 5e) that contrasts with the parallel arrangement in NCS1 (Fig. 5d). For GCAP1 (Fig. 5c), the myristoyl group is located in between the N-terminal and C-terminal domains. In essence, the myristate bridges both domains of GCAP1 by interacting with helices at each end of the protein. The structural location and environment around the myristoyl group is very different in the various NCS proteins (Fig. 5). It is suggested that each NCS protein may adopt a distinct structure because its N-terminal myristoyl group associates with patches of hydrophobic residues that are unique to that protein.

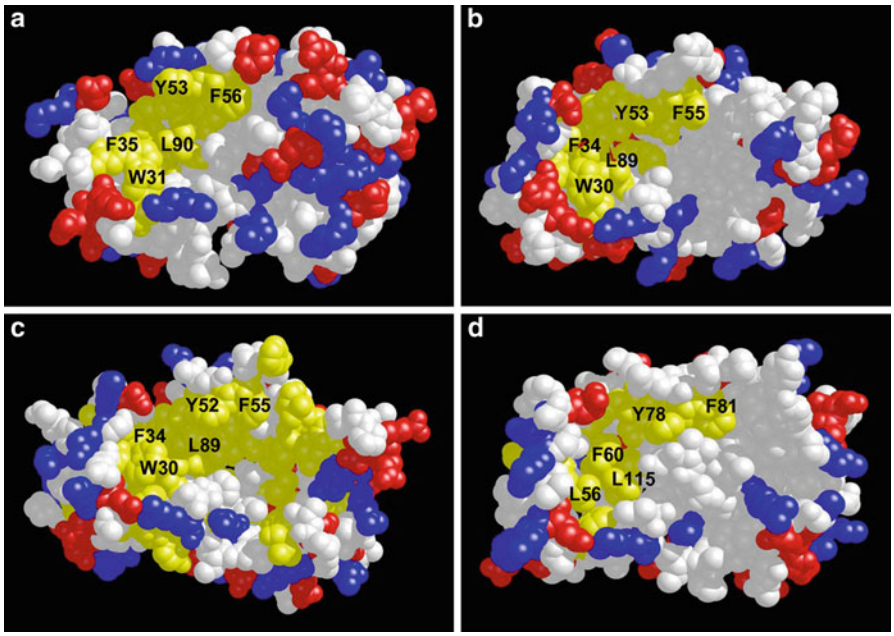
Nonconserved residues of NCS proteins interact closely with the N-terminal myristoyl group and help stabilize the novel protein structure in each case. NCS1, recoverin, and GCAP1 all have nonconserved residues near the N-terminus (called an N-terminal arm



Calcium, Neuronal Sensor Proteins, Fig. 5 Main chain structures of Ca^{2+}-free myrisoylated NCS1 (212e) (**a**), recoverin (1iku) (**b**), and GCAP1 (2r2i) (**c**). Close-up views of the myristate-binding pocket in NCS1 (**d**) and recoverin (**e**). EF-hands and myristoyl group (*magenta*) are colored as defined in Fig. 1

highlighted purple in Fig. 5) that make specific contacts with the myristoyl moiety. GCAP1 also contains an extra helix at the C-terminus that contacts the N-terminal arm and myristoyl group (Fig. 5c). Thus, nonconserved residues at the N-terminus, C-terminus, and loop between EF3 and EF4 all play a role in creating a unique environment around the myristoyl group. In Ncs1, the long N-terminal arm and particular hydrophobic residues in the C-terminal helix are crucial for placing the C14 fatty acyl chain in a cavity between EF3 and EF4 (Fig. 5d). By contrast, the much shorter N-terminal arm in both recoverin and GCAP1 prevents the myristoyl group from reaching the C-terminal cavity and, instead, places the fatty acyl chain between EF1 and EF2 (Fig. 5e). It is proposed that nonconserved residues at the N-terminus, C-terminus, and/or loop between EF3 and EF4 may play a role in forming unique myristoyl-binding environments in other NCS proteins, such as VILIPs, neurocalcins, and hippocalcins that may help explain their capacity to associate with functionally diverse target proteins.

Structures of Ca^{2+}-bound NCS Proteins. Three-dimensional structures have been determined for unmyristoylated forms of Ca^{2+}-bound neurocalcin (Vijay-Kumar and Kumar 1999), frequenin (Bourne et al. 2001), KChIP1 (Zhou et al. 2004), and Frq1 (Strahl et al. 2007). The first eight residues from the N-terminus are unstructured and solvent exposed in each case, consistent with an extruded myristoyl group that causes Ca^{2+}-induced membrane localization of NCS proteins (Zozulya and Stryer 1992). The overall main chain structures of the Ca^{2+}-bound NCS proteins are very similar in each case, which is not too surprising given their sequence relatedness. However, if the main chain structures are so similar, then how can one explain their ability to bind unique target proteins? One distinguishing structural property is the number and location of bound Ca^{2+}. Recoverin has Ca^{2+} bound at EF-2 and EF-3; KChIP1 has Ca^{2+} bound at EF-3 and EF-4; and frequenin, neurocalcin, and GCAP2 have Ca^{2+} bound at EF2, EF3, and EF4. Another important structural property is the distribution of charged and hydrophobic residues on the protein surface. Surface representations of hydrophobicity and charge density of the various NCS structures are shown in Fig. 6. All NCS structures exhibit a similar exposed hydrophobic surface located on the N-terminal half of the protein, formed primarily by residues in EF-1 and EF-2 (F35, W31, F56, F57, Y86, and L90 for recoverin in Fig. 6a). The exposed hydrophobic residues in this region are highly conserved (labeled and colored yellow in Fig. 6) and correspond to residues of recoverin that interact with the myristoyl group in the Ca^{2+}-free state (Fig. 3a).

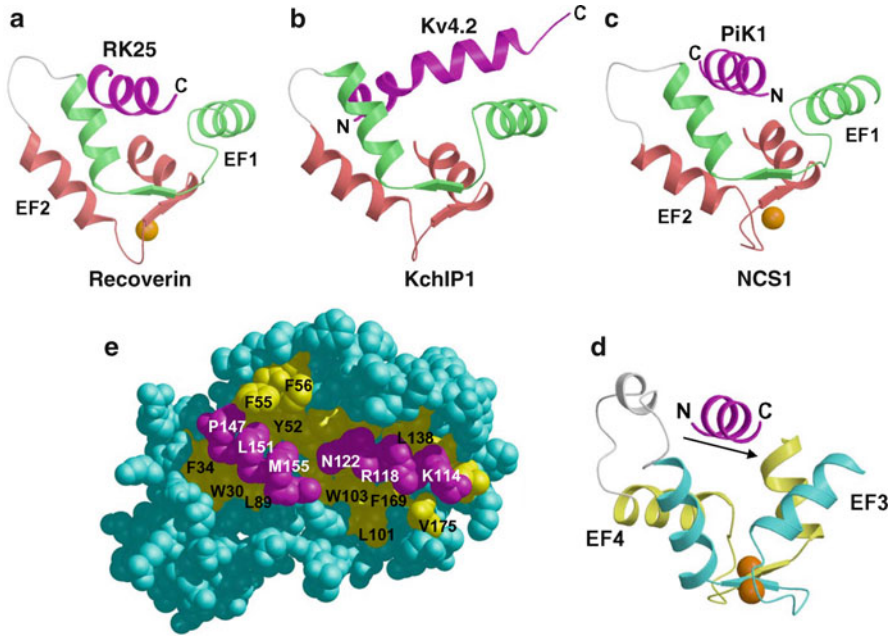


Calcium, Neuronal Sensor Proteins, Fig. 6 Space-filling representations of the Ca^{2+}-bound structures of recoverin (**a**), NCS1 (**b**), neurocalcin (**c**), and KChIP1 (**d**). Exposed hydrophobic residues are *yellow*, neutral residues are *white*, and charge residues are *red* and *blue*

A similar hydrophobic patch is also seen in membrane-bound recoverin (Fig. 4b). These exposed residues in the hydrophobic patch have been implicated in target recognition from mutagenesis studies, and these residues very likely form intermolecular contacts with target proteins as has been demonstrated in the recent crystal structure of KChIP1 (see below).

The distribution of charged (red and blue) and hydrophobic (yellow) residues on the surface of the C-terminal half of the NCS proteins is highly variable (Fig. 6). Frequenin exhibits exposed hydrophobic residues in the C-terminal domain that fuse together with the exposed hydrophobic crevice in the N-terminal domain, forming one continuous and elongated patch (Fig. 6b). By contrast, recoverin (Fig. 6a) has mostly charged residues on the surface of the C-terminal half, whereas neurocalcin (Fig. 6c) and KChIP1 (Fig. 6d) have mostly neutral residues shown in white. The different patterns of charge distribution on the C-terminal surface of NCS proteins might be important for conferring target specificity.

Ca^{2+}-sensitive dimerization of NCS proteins is another structural characteristic that could influence target recognition. Neurocalcin, recoverin, VILIP-1, and KChIP1 exist as dimers in their X-ray crystal structures. Hydrodynamic studies have confirmed that neurocalcin and DREAM form dimers in solution at high Ca^{2+} and are monomeric in the Ca^{2+}-free state. Indeed, the recent NMR structure of Ca^{2+}-bound DREAM forms a dimer in solution with intermolecular contacts involving Leu residues near the C-terminus. By contrast, GCAP2 forms a dimer only in the Ca^{2+}-free state and is monomeric at high Ca^{2+}. Ca^{2+}-sensitive dimerization of GCAP-2 has been demonstrated to control its ability to activate retinal guanylate cyclase. Ca^{2+}-sensitive protein oligomerization is also important physiologically for DREAM: The Ca^{2+}-free DREAM protein serves as a transcriptional repressor by binding to DNA response elements as a protein tetramer (Carrion et al. 1999). Ca^{2+}-induced dimerization of DREAM appears to disrupt DNA binding and may activate transcription of prodynorphin and c-fos genes (Carrion et al. 1999). In a related fashion, Ca^{2+}-bound KChIP1 forms a dimer in solution and in complex with an N-terminal fragment of the Kv4.2 K^+ channel (Zhou et al. 2004). By contrast, the full-length Kv4.2 channel tetramer binds to KChIP1 with a 4:4 stoichiometry, suggesting that KChIP1 dimers may assemble as a protein tetramer to recognize the channel. Such a protein tetramerization of KChIP1 may be Ca^{2+} sensitive like it is for DREAM. In short, the oligomerization properties of some NCS proteins appear to be Ca^{2+} sensitive, which may play a role in target recognition.



Calcium, Neuronal Sensor Proteins, Fig. 7 Ribbon diagrams illustrating intermolecular interactions for recoverin bound to RK25 (**a**), KChIP1 bound to Kv4.2 (**b**), NCS1 (N-domain) bound to Pik1(111–151) (**c**), NCS1 (C-domain) bound to Pik1(111–151) (**d**), and space-filling view of NCS1 bound to Pik1(111–151) (**e**). In each case, a target helix (*magenta*) is inserted in groove formed by the helices of the EF-hands. The intermolecular interactions are mostly hydrophobic as described in the text

Target Recognition by NCS Proteins

Recoverin Bound to Rhodopsin Kinase Fragment (RK25). The structure of Ca^{2+}-bound recoverin bound to a functional fragment of rhodopsin kinase (residues 1–25, hereafter referred to as RK25) was the first atomic-resolution structure of a Ca^{2+}-myristoyl switch protein bound to a functional target protein (Ames et al. 2006) (Fig. 7a). The structure of this complex revealed that RK25 forms a long amphipathic α-helix, whose hydrophobic surface interacts with the N-terminal hydrophobic groove of recoverin described above (Fig. 6). The structure of recoverin in the complex is quite similar to that of Ca^{2+}-bound recoverin alone in solution (root-mean-squared deviation = 1.8 Å). The structure of RK25 in the complex consists of an amphipathic α-helix (residues 4–16). The hydrophobic surface of the RK25 helix (L6, V9, V10, A11, F15) interacts with the exposed hydrophobic groove on recoverin (W31, F35, F49, I52, Y53, F56, F57, Y86, and L90). Mutagenesis studies on recoverin and RK have shown that many of the hydrophobic residues at the binding interface are essential for the high affinity interaction. These hydrophobic contacts are supplemented by a π-cation interaction involving F3 (RK25) and K192 from recoverin. Dipolar residues on the opposite face of the RK25 helix (S5, T8, N12, I16) are solvent exposed. The helical structure of RK25 in the complex is stabilized mostly by hydrophobic intermolecular interactions with recoverin, as free RK25 in solution is completely unstructured.

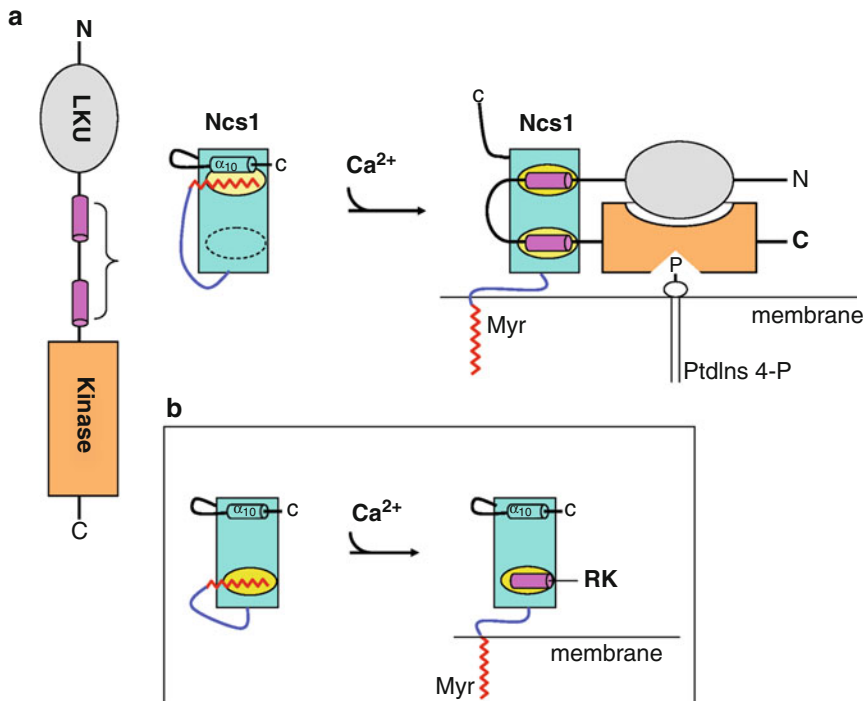
The Ca^{2+}-myristoyl switch mechanism of recoverin (i.e., Ca^{2+}-induced extrusion of the N-terminal myristoyl group, Fig. 2) is structurally coupled to Ca^{2+}-induced inhibition of RK. The exposed hydrophobic residues of recoverin that interact with rhodopsin kinase correspond to the same residues that contact the N-terminal myristoyl group in the structure of Ca^{2+}-free recoverin (Ames et al. 1997). The size of the myristoyl group is similar to the length and width of the RK25 helix in the complex, which explains why both effectively compete for binding to the exposed hydrophobic groove (Fig. 4b). The Ca^{2+}-induced exposure of the N-terminal hydrophobic groove therefore explains why recoverin binds to rhodopsin kinase only at high Ca^{2+} levels. In the Ca^{2+}-free state, the covalently attached myristoyl group sequesters the N-terminal hydrophobic groove and cover up the target-binding site. Ca^{2+}-induced extrusion of the myristoyl group of recoverin causes exposure of residues that bind and inhibit RK (Fig. 8b). This mechanism elegantly explains how recoverin controls both the localization and activity of RK in response to light. In the dark (high Ca^{2+}), Ca^{2+}-bound recoverin binds to RK

(thereby inhibiting it) and delivers RK to the membrane via a Ca^{2+}-myristoyl switch that pre-positions RK near rhodopsin. Upon light activation (low Ca^{2+}), recoverin rapidly dissociates from both RK and the membrane, allowing RK to bind efficiently to its nearby substrate, rhodopsin, and cause rapid desensitization.

NCS1 Bound to Phosphatidylinositol 4-Kinase Fragment (Pik1). The structure of Ca^{2+}-bound NCS1 (or yeast Frq1 (Strahl et al. 2007)) bound to a functional fragment of Pik1 (residues 111–159, hereafter referred to as Pik1(111–159)) was determined by NMR (Lim et al. 2011) (Fig. 7c, d). The structure of NCS1 in the complex is very similar to the crystal structure in the absence of target (Bourne et al. 2001) with a concave solvent-exposed groove lined by two separate hydrophobic patches (highlighted yellow in Fig. 6). These two hydrophobic surfaces represent bipartite binding sites on NCS1 that interact with two helical segments in Pik1(111–159) (Fig. 7e). The structure of Pik1(111–159) in the complex adopts a conformation that contains two α-helices (residues 114–127 and 143–156) connected by a disordered loop. The N-terminal helix contains hydrophobic residues (I115, C116, L119, and I123) that contact C-terminal residues of NCS1 (L101, W103, V125, V128, L138, I152, L155, and F169). Interestingly, these same hydrophobic residues in Ca^{2+}-free NCS1 make close contacts with the myristoyl group. Therefore, Ca^{2+}-induced extrusion of the myristoyl group causes exposure of hydrophobic residues in Ncs1 that forms part of the Pik1-binding site (Figs. 7e and 8). The C-terminal helix of Pik1(111–159) contains many hydrophobic residues (V145, A148, I150, and I154) that contact the exposed N-terminal hydrophobic groove of NCS1 (W30, F34, F48, I51, Y52, F55, F85, and L89), very similar to the exposed hydrophobic groove seen in all NCS proteins (Fig. 6). The two helices of Pik1(111–159) do not interact with one another or with the unstructured connecting loop and are highly stabilized by interactions with NCS1.

Nonconserved residues in NCS1 at the C-terminus and immediately following EF3 may be structurally important for explaining target specificity. The nonconserved C-terminal region of NCS1 (residues, 180–190) is structurally disordered in the target complex, in contrast to a well-defined C-terminal helix seen in Ca^{2+}-free NCS1 in the absence of target (Lim et al. 2011). The C-terminal helix in Ca^{2+}-free NCS1 (target-free state) makes contact with the myristoyl group and residues in EF3 and EF4 (L101, A104, M121, I152, F169, and S173). These same residues in Ca^{2+}-bound NCS1 make contact with Pik1 in the complex (Fig. 7e). Therefore, the N-terminal Pik1 helix appears to substitute for and perhaps displace the C-terminal helix of Frq1, likely leading to the observed C-terminal destabilization in the complex (Fig. 8a). The corresponding C-terminal helix of KChIP1 is similarly displaced upon its binding to the Kv4.3 channel but not upon its binding to Kv4.2. The C-terminal helix in recoverin forms a stable interaction with EF3 and EF4, enabling the C-terminal helix to perhaps serve as a built-in competitive inhibitor that would presumably block its ability to bind to targets like Pik1 and Kv4.3. This role for the C-terminus may explain why the C-terminal sequences of NCS proteins are not well conserved (Fig. 1). Another nonconserved region of NCS1 implicated in target specificity is the stretch between EF3 and EF4 (residues 134–146). This region of NCS1 adopts a short α-helix in the complex that contacts the N-terminal helix of Pik1. By contrast, the region between EF3 and EF4 is unstructured in DREAM, Frq1, GCAP2, and KChIP1.

The structure of the Ncs1-Pik1 complex (Figs. 5a and 7c, d) suggest how a Ca^{2+}-myristoyl switch might promote activation of PtdIns 4-kinase (Fig. 8a). Under resting basal conditions, NCS1 exists in its Ca^{2+}-free state with a sequestered myristoyl group buried in the C-domain that covers part of its binding site for PtdIns 4-kinase (highlighted yellow in Figs. 7e and 8) and prevents binding of Ncs1 to Pik1. The fatty acyl chain has the same molecular dimensions (length and width) as the N-terminal helix of Pik1(111–159), which explains why the myristoyl group and Pik1 helix can effectively compete for the same binding site in Ncs1. A rise in cytosolic Ca^{2+} will cause Ca^{2+}-induced conformational changes in Ncs1, resulting in extrusion of the N-terminal myristoyl group. Ca^{2+}-induced extrusion of the myristoyl group exposes a hydrophobic crevice in the C-terminal domain of Ncs1, and concomitantly, Ca^{2+}-induced structural changes in its N-domain result in formation of a second exposed hydrophobic crevice, also seen in all known Ca^{2+}-bound NCS proteins. These two separate hydrophobic sites on the surface of Ca^{2+}-bound NCS1 are different from Ca^{2+}-bound recoverin that contains only one exposed hydrophobic patch (Fig. 8b) that interacts



Calcium, Neuronal Sensor Proteins, Fig. 8 Schematic diagram of calcium-myristoyl switch coupled to target regulation illustrated for NCS1 (**a**) and recoverin (**b**)

with a single target helix in rhodopsin kinase (Ames et al. 2006). The two exposed hydrophobic sites on Ncs1 bind to the hydrophobic faces of the two antiparallel amphipathic α-helices in Pik1(111–159) (colored magenta in Fig. 8a). The Ca^{2+}-induced binding of NCS1 to PtdIns 4-kinase may promote structural changes that cause increased lipid kinase activity. Simultaneously, Ncs1 binding to PtdIns 4-kinase will also promote membrane localization of the lipid kinase because Ca^{2+}-bound NCS1 contains an extruded myristoyl group that serves as a membrane anchor. Thus, Ncs1 controls both delivery of PtdIns 4-kinase to the membrane where its substrates are located and formation of the optimally active state of the enzyme.

Mechanisms of Target Recognition. NCS proteins bind to helical target proteins analogous to the target binding seen for CaM (Fig. 7). Helical segments of target proteins bind to an exposed hydrophobic crevice formed by the two EF-hands in either the N-terminal or C-terminal domain in NCS proteins. In recoverin, the two N-terminal EF-hands form an exposed hydrophobic groove that interacts with a hydrophobic target helix from rhodopsin kinase (RK25) (Ames et al. 2006) (Fig. 7a). The N-terminal EF-hands of KChIP1 interact with a target helix derived from the T1 domain of Kv4.2 channels (Fig. 7b) (Zhou et al. 2004). The orientation of the target helices bound to recoverin and KChIP1 is somewhat similar: The C-terminal end of the target helix is spatially close to the N-terminal helix of EF-1. By contrast, the Pik1 target helix binds to NCS1 in almost the exact opposite orientation (Fig. 7c). The N-terminal end of the Pik1 helix is closest to EF1 (green) in NCS1, whereas the C-terminal end of the RK25 target helix is closest to the corresponding region of recoverin. Nonconserved residues in NCS1 (G33 and D37) make important contacts with the Pik1 target helix and presumably assist in imposing the observed orientation of the helix. Thus, the requirement that the helix (in this case, from Pik1) must bind to NCS1 with a polarity opposite to that observed for the helices in other target-NCS family member complexes could clearly contribute to dictating the substrate specificity of frequenins, as compared to other NCS subtypes. Another important structural feature seen in the NCS1-Pik1 interaction is that two helical segments of the target are captured in the complex, whereas in the target complexes characterized for recoverin and KChIP1, only one helix is bound. Therefore, selective substrate recognition by NCS proteins may be explained by both by the orientation of the bound target helix and the number of target helices bound.

Summary

The molecular structures of NCS proteins were reviewed, and structural determinants important for target recognition were examined. N-terminal myristoylation has a profound effect on the structures of Ca^{2+}-free recoverin, GCAP1, and NCS1 (Fig. 5). Surprisingly, the sequestered myristoyl group interacts with quite different protein residues in each case and, therefore, is able to reshape these homologous NCS proteins into very different structures. The structures of the Ca^{2+}-bound NCS proteins all contain an extruded N-terminus with an exposed hydrophobic crevice implicated in target binding. It is proposed that N-terminal myristoylation is critical for shaping each NCS family member into a unique structure, which upon Ca^{2+}-induced extrusion of the myristoyl group exposes a unique set of previously masked residues, thereby exposing a distinctive ensemble of hydrophobic residues to associate specifically with a particular physiological target. Differences in their surface charge density and protein dimerization properties may also help to explain NCS target specificity and functional diversity. In the future, atomic-resolution structures of additional NCS proteins both with a sequestered myristoyl group and in their extruded forms bound to their respective target proteins are needed to improve our understanding of how this structurally conserved family of proteins can uniquely recognize their diverse biological targets.

Calcium, Physical and Chemical Properties

Fathi Habashi
Department of Mining, Metallurgical, and Materials Engineering, Laval University, Quebec City, Canada

Calcium is the fifth most abundant element in the earth's crust. Some important, naturally occurring compounds are the carbonate (limestone), the sulfate, and complex silicates. It is a typical metal: it has the tendency to lose its outermost electrons and in doing so it achieves the inert gas electronic structure. Also its two outermost electrons are lost in one step. It is a ductile metal and can be formed by casting, extrusion, rolling, etc. The metal is used as a reducing agent, while CaO produced from limestone by calcination is used as a flux in iron and steel production, in gas desulfurization processes, and other metallurgical operations. Calcium hydroxide, obtained by dissolving CaO in water, is used as a pH control reagent in hydrometallurgy.

Both, gypsum, $CaSO_4{\cdot}2H_2O$, and anhydrite, $CaSO_4$, are widely distributed in the earth's crust and are used as materials of construction.

Physical Properties

Atomic number	20
Atomic weight	40.08
Relative abundance, %	3.63
Density at 20°C	1.55
Melting point, °C	838
Boiling point, °C	1,440
Specific heat (0–100°C), J g^{-1} K^{-1}	0.624
Heat of fusion, J/g	217.7
Heat of vaporization, J/g	4,187
Thermal expansion (0–400°C), K^{-1}	22.3×10^{-6}
Electrical resistivity at 0°C, Ω cm	3.91×10^{-6}
Thermal conductivity at 20°C, W cm^{-1} K^{-1}	1.26
Crystal structure at room temperature	Face-centered cubic
Lattice constant, nm	0.5582
Crystal structure above 448°C	Body-centered cubic

(*continued*)

Chemical Properties

Calcium is produced by the thermal reduction of lime with aluminum in a retort under vacuum at 1,200°C; the vapors of calcium are then collected in a condenser. The metal is unstable in moist air, rapidly forming a hydration coating. It can be stored in dry air at room temperature. It reacts spontaneously with water to form $Ca(OH)_2$ and hydrogen gas; when finely divided, it will ignite in air. Being a typical metal, all its compounds are colorless and exhibit only one valence state, +2, in all of its reactions.

Naturally occurring calcium phosphate is treated for the production of fertilizers. Calcium carbide is produced by reacting quicklime with coke in furnaces which are heated electrically to 2,000°C. It is used to produce acetylene by reaction with water. Calcium cyanamide is synthesized from calcium carbide and nitrogen at 900–1,000°C:

$$CaC_2 + N_2 \rightarrow CaCN_2 + C$$

It is used as a fertilizer since ammonia is generated when it comes in contact with water:

$$CaCN_2 + 3H_2O \rightarrow 2NH_3 + CaCO_3$$

Definitions

Calcium: A soft gray alkaline earth metal. Ionic calcium (Ca^{2+}) is essential for numerous cellular functions, as well as biomineralization.

Calcium-binding protein: Any protein or enzyme that requires the binding of a calcium ion to fulfill either a functional or structural role.

Binding site: Region in the protein where metal ions will bind as a result of electrostatic interactions with ligands of opposite charge.

Ligand: Ion, atom, or molecule that binds to a metal ion to form a coordination complex.

Tertiary structure: Three-dimensional shape of a protein, enzyme, or molecule.

Diverse Roles of Calcium-Binding Proteins

In the intracellular environment, calcium functions as a second messenger to facilitate a wide variety of functions related to muscle contraction, neurotransmitter release, and enzyme activation. Additionally, calcium and calcium-binding proteins (CaBPs) are involved in almost every aspect of the eukaryotic cell life cycle including cell differentiation and proliferation, membrane stability, apoptosis, and intracellular signaling. Control of these diverse functions is regulated by changes in cytosolic calcium levels, which increase from $\sim 10^{-7}$ M at rest to $\sim 10^{-5}$ M when activated. In response to increased cytosolic calcium, intracellular proteins such as calmodulin (CaM) and protein kinase C (PKC) bind calcium.

The cellular activities regulated by calcium, while numerous, are all dependent upon the abilities of different proteins to bind calcium selectively over other metals and to do so with affinities consistent with the concentration of free calcium available in any given environment. Therefore, the interface between calcium and biological activity can be localized to the protein calcium-binding sites; regions of the protein that have evolved to chelate calcium and translate the binding event into a conformational change capable of inducing activity not observed in the calcium-free state. Recent research efforts detailed in this entry demonstrate an increasingly diverse list of calcium-binding sites correlating with an equally diverse set of biological functions regulated by calcium-binding proteins. This entry will therefore focus on the description of common features and differences of different types of calcium-binding sites in proteins based in part on recent statistical analyses of structural data and identification of newly identified calcium-binding sites.

Sequential Classifications of Calcium-Binding Sites

Since the initial identification of EF-hand calcium-binding sites with a helix-loop-helix motif (Kretsinger and Nockolds 1973), calcium-binding sites have been divided into EF-hand and non-EF-hand types. Binding sites were also previously described as being either continuous or noncontinuous, based on the relative sequence positions of the binding residues.

Calcium-binding sites are further separated into three distinct classes. Class I sites are comprised of consecutive amino acids in the primary sequence which would include canonical EF-hand (e.g., calmodulin), pseudo EF-hand (e.g., S100 proteins), and other noncanonical EF-hand (e.g., calpain) motifs. Class II sites include a similar stretch of consecutive amino acids, but also include a coordinating ligand that is close to the other binding ligands in the three-dimensional structure, but distant in the sequence (e.g., HCV helicase, PDB ID 1hei). Class III sites, the least commonly observed, include multiple coordination ligands in close spatial proximity but still distant in the sequence (e.g., the C2 domain of the enzyme protein kinase C (PKC)).

Coordination Chemistry of a Calcium-Binding Site

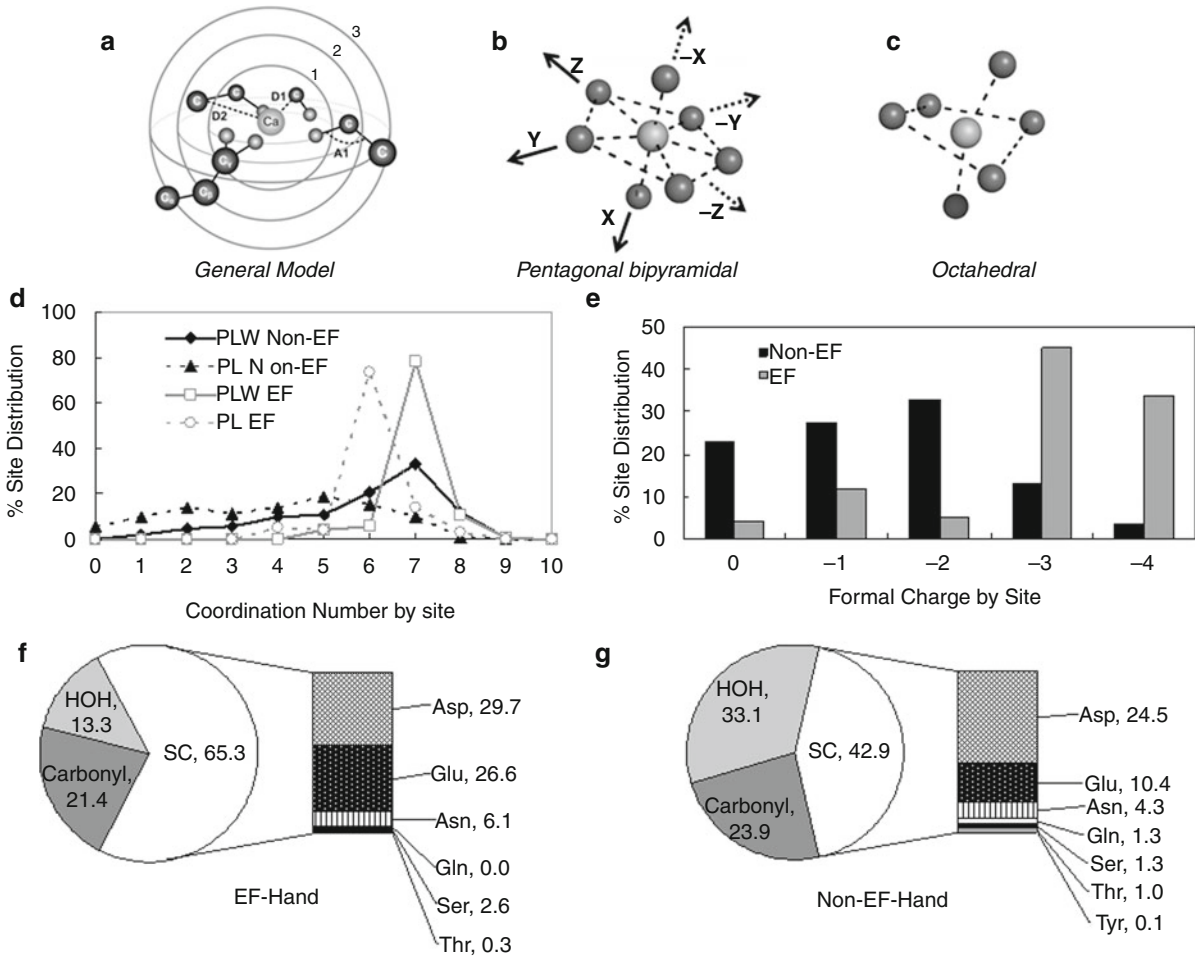
Metal-binding sites can be described by a central shell of hydrophilic ligands that chelate the metal ion, with surrounding concentric shells of hydrophobic atoms, usually carbon, covalently bound to the ligand atoms and other carbon atoms (Fig. 1a). Binding of calcium is almost exclusively coordinated in proteins by oxygen ligands which originate in side-chain carboxyl (Asp, Glu), carboxamide (Asn, Gln), and hydroxyl (Ser, Thr) groups. Carbonyl oxygen from the main chain may also contribute to coordination, as well as oxygen from water molecules which are observed to form hydrogen bonds with Asp, Ser, and Asn residues. Nitrogen, which binds Zn^{2+} and may associate with calcium in small molecules, is rarely observed in the structures of calcium-binding sites.

The Protein Data Bank (PDB) currently includes structures for ~1,500 CaBPs not classified as EF-hand or EF-like motifs. These latter calcium-binding sites, some of which lack well-structured and recognizable geometric configurations and include binding ligands sequentially distant from each other in the structure, present interesting challenges for determining functional implications. A recent statistical evaluation of different calcium-binding sites from the PDB has demonstrated that EF-hand and non-EF-hand proteins are differentiable based on structural parameters, including distance between the ligand and the ion; distance between ligands; angles between the carbon covalently bound to the oxygen ligand, the oxygen ligand itself and the calcium ion; coordination number; ligand preference; and ligand charge (Fig. 1d–g) (Kirberger et al. 2008). Results of this analysis indicate that EF-hand sites typically utilize more formal charge (3 ± 1 vs. 1 ± 1), higher coordination numbers (7 ± 1 vs. 6 ± 2), and more protein ligands (6 ± 1 vs. 4 ± 2) than non-EF-hand sites. EF-hand sites also use fewer water ligands (1 ± 0 vs. 2 ± 2). Additionally, the order of ligand preference for EF-hand sites was found to be *sidechain Asp (29.7%) > sidechain Glu (26.6%) > mainchain carbonyl (21.4%) > H_2O (13.3%), while for non-EF-hand sites, the order was H_2O (33.1%) > sidechain Asp (24.5%) > mainchain carbonyl (23.9%) > sidechain Glu (10.4%)*. The combination of ligand preference, decrease in charge utilization and increase in water coordination, account for fact that 20% of non-EF-hand sites exhibit a net change of zero.

Diversified Geometric Properties

Early work with calcium-binding proteins observed examples of highly organized coordination geometries, including either pentagonal-bipyramidal (Fig. 1b), where the ion is surrounded by a planar grouping of five oxygen atoms with additional oxygen atoms superior and inferior to the plane, or octahedral (Fig. 1c), with similar ligand coordination above and below a planar ring of only four oxygen atoms. Analyses of many of these binding sites indicate that the pentagonal-bipyramidal geometry may be constructed by ligands either continuous (e.g., CaM) or discontinuous (e.g., PKC) in the sequence, and this geometry is often observed with intracellular proteins that exhibit high affinity for calcium.

More recent analyses of calcium-binding sites in proteins exhibiting diversified functions in different cellular environment, however, reveal much greater variability in binding coordination geometries than was previously assumed. A simplified and more generalized set of coordination geometries may be applied based on a Hull property describing the spatial relationship of the calcium ion to the interior volume of the surrounding binding ligands. First, a holospheric binding geometry where oxygen ligands surround calcium on all sides is observed in both the pentagonal-bipyramidal and octahedral geometries (Fig. 2a).

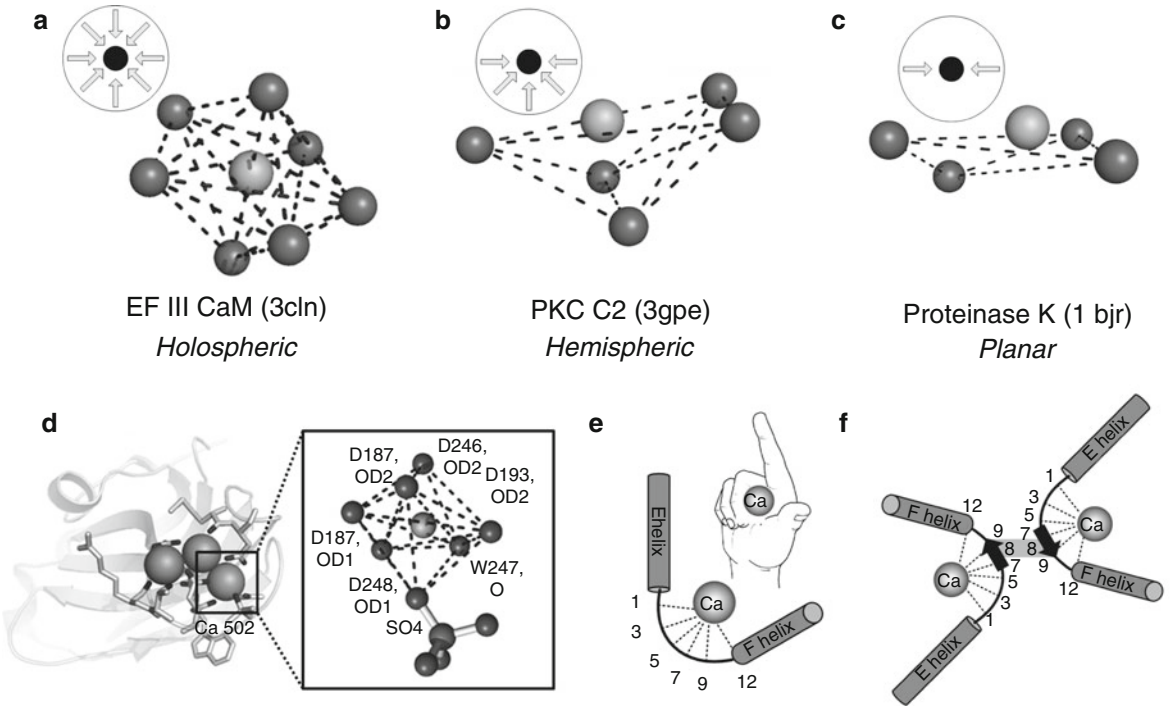


Calcium-Binding Protein Site Types, Fig. 1 (**a**) General binding model. Calcium is surrounded by a first shell of hydrophilic ligands (oxygen), which is in turn surrounded by concentric second and third shells of hydrophobic atoms; in this example, covalently bound carbon from side chains. (**b**) Pentagonal-bipyramidal geometry associated with EF-Hand binding motif. (**c**) Octahedral binding geometry for calcium. Also observed with binding of Mg^{2+}. Calcium-binding statistics for EF-hand and non-EF-hand motifs showing differences between (**d**) coordination number and (**e**) formal charge. The ligand distribution between (**f**) EF-hand and (**g**) non-EF-hand shows that non-EF-hand binding sites include fewer side-chain ligands, with increased substitution of water molecules. Also, side-chain Glu is reduced compared to EF-hand

This model is shared by the majority of calcium-binding sites with high coordination number for calcium (i.e., greater than four). When possible, proteins fold in such a way as to provide a pentagonal-bipyramidal geometry for binding.

Second, a hemispheric coordination scheme is observed with an open concavity (i.e., bowl structure) coordinating the ion such as calcium-binding sites in helicase and PKC C2 domain (Fig. 2b). A more irregular, planar binding site is described in Fig. 2c, which may be coordinated by as few as three binding ligands such as a calcium binding site in proteinase K. Completion of this geometry may involve increased utilization of water or other small molecules (e.g., sulfate ions) or cofactors in addition to ligand atoms contributed by the protein itself.

Third, a specific geometry is observed even in the C2 domain-binding site clusters, where binding ligand atoms are shared by more than one calcium ion (Fig. 2d). This type of calcium-binding site was first observed in thermolysin and later in the cadherin family. Additionally, when variations of this model



Calcium-Binding Protein Site Types, Fig. 2 (**a**) Holospheric binding where calcium is surrounded on all sides by oxygen ligands. This would include both pentagonal-bipyramidal and octahedral geometries. (**b**) Hemispheric binding where the calcium ion is exposed on one hemispheric surface. (**c**) Planar binding where the calcium ion is bound in a ring structure with exposure above and below the plane. (**d**) C2 domain from PKC. The coordination for the pentagonal-bipyramidal geometry for Ca-502 is completed with a sulfate ion. (**e**) EF-hand motif. (**f**) Paired EF-hand motifs with conserved hydrophobic residues in position 8 (Val, Leu, or Ile). Cooperative binding between the two EF-hand motifs is related to formation of hydrogen bonds between residues in loop position 8 which create two short antiparallel β-strands

are observed (e.g., octahedral, bowl, or planar geometry), these binding sites appear to be structurally incomplete pentagonal-bipyramidal geometries, rather than unique structures, or occur within monomeric units that form dimers which may then form a holospheric geometry. These observations suggest that the properties of calcium drive the evolution of CaBPs to provide binding sites unique to the chemistry of calcium.

Calcium-Binding Affinity and Selectivity

Corresponding to the cellular locations and concentration of calcium ions, calcium-binding proteins have affinity with K_d values ranging from nM to mM. Factors contributing to calcium-binding affinities of proteins are largely electrostatic interactions based on the number of charged ligand residues, residue types, and the binding site microenvironment. Since calcium-binding sites are often energetically coupled, the resulting cooperativity and calcium-induced conformational changes can also contribute to the measured affinity, and these factors make it difficult to experimentally determine affinity values for each of the sites as isolated binding events. Affinity values for paired binding sites have been reported, but are typically calculated based on upper and lower limits derived from the relationship between macroscopic and microscopic binding constants as described by Linse et al. (1991), or as relative affinities based on order of occupancy (i.e., higher affinity sites are populated first). Second, for higher affinity binding sites, analytical instruments lack sensitivity to analyze samples at concentrations comparable with their binding affinities, so experimental methods (e.g., high-resolution NMR) typically involve protein concentrations much higher than their metal binding affinity, which precludes accurate determination of binding affinity constants (Permyakov and Kretsinger 2010).

In addition, in many of the non-EF-hand binding sites, the lack of well-structured and recognizable geometric configurations, the fact that many sites include binding ligands sequentially distant from each other in the structure, and the lack of structures detailing proteins in both the *apo*- and *holo*-forms, present interesting challenges for determining functional implications and estimating contributions to affinity from calcium-induced conformational changes. This is why the literature remains relatively sparse with affinity data, or presents inconsistent data with respect to affinity.

Different approaches have been made to circumvent the issue of cooperativity. Early efforts involved analyses of individual EF-hand motifs isolated as peptides. Another approach involved spectrofluorometric analysis, where the macroscopic calcium affinities (expressed in dissociation constants K_d) for the N- and C-terminal domains of CaM each comprising a pair of cooperative binding sites (EF I and EF II in the N-terminal and EF III and EF IV in the C-terminal), was determined by monitoring Phe and Tyr residues which exhibit fluorescence changes upon binding of metal ions. Ye et al. determined site-specific K_d for CaM EF-loops I–IV (34, 245, 185, and 814 uM, respectively) by grafting the loops into a scaffold protein (Ye et al. 2005). This approach provides a new strategy to estimate cooperativity of coupled EF-hand proteins. The contribution of the cooperativity to the calcium binding affinity for the C-terminal domain is 40% greater than that of the N-terminal domain. Related studies have suggested optimal calcium binding requires four charged ligands, and affinity decreases with the addition or subtraction of charged residues from this number.

Proteins exhibit selectivity for different physiologically relevant metals depending on their environment and the nature of their functions, which is how calcium sensor proteins selectively bind intracellular calcium in an environment with fourfold higher levels of free magnesium. Binding of calcium is almost exclusively coordinated in proteins by oxygen ligands. Nitrogen, which binds Zn^{2+} and may associate with calcium in small molecules, is only infrequently observed in the structures of calcium-binding sites and, then, observed mostly in cases where the site has no net negative charge. Proteins that require metal cofactors, in general, are optimally activated only upon binding of their preferred target metal ions. However, CaBPs may bind magnesium ions at low affinity in a resting state, and the magnesium is then replaced by calcium resulting in a fully potentiated conformer. Similarly, the introduction of toxic metal ions can effectively occupy the native site, but can alter the overall conformation sufficiently enough to inhibit protein function. Typically, selectivity can be evaluated qualitatively, but not quantitatively, due to the previously noted issues with cooperativity and problems establishing accurate K_d values.

Characteristics of Different Types of Calcium-Binding Proteins

The increasingly populous superfamily of EF-hand proteins, comprising approximately 70 different genomic subfamilies, can be divided into two major groups based on calcium-binding sites: The canonical EF-hand motif which is the most common protein calcium binding structural domain and the more recently characterized noncanonical EF-loops which include the pseudo EF-hands observed in the N-termini of S100 and S100-like proteins.

Canonical EF-Hand Binding Motif

The canonical EF-hand motif (Fig. 2e) is highly conserved in both eukaryotes and prokaryotes. This sequential motif, described extensively in the literature, is 29 amino acids in length comprising a 12-residue loop surrounded by two flanking α-helices positioned in a relatively perpendicular orientation. Analyses of metadata from online databases (e.g., PFAM, ProSite) indicate that the length of the entering (E) and exiting (F) helices are typically nine and eight residues in length, respectively. Loop residues are assigned relative position numbers 1–12. Binding of calcium is coordinated by residues in loop positions 1(x-axis), 3(y), 5(z), 7($-y$), 9($-x$), and 12($-z$), forming a pentagonal-bipyramidal geometry (see section "Coordination Chemistry of a Calcium-Binding Site" and Fig. 1b).

Ligands observed within the EF-Loop are typically Asp at position 1; Asp or Asn at position 3; Asp, Ser, or Asn at position 5; a water molecule at position 9; and a bidentate Glu at position 12 which may initially anchor calcium and thus initiate rotation of loop residues to form the binding site. The coordinating ligand from position 7 is usually a carbonyl oxygen, while the noncoordinating residue in position 6 is frequently a flexible Gly.

Prior to 1997, structural analyses revealed that almost all EF-hand proteins included 2–6 paired motifs (e.g., calmodulin, parvalbumin, calcineurin, and troponin C). Interaction between the paired EF-loops may be related to the conserved hydrophobic residues in loop position 8 (Val, Leu, or Ile). Binding of Ca^{2+} in paired EF-hands is cooperative, and typically binding in one of the sites enhances the binding affinity of the second site (i.e., positive cooperativity). The hydrophobic residues in the canonical EF-loop position 8 between paired EF-hand sites form two short antiparallel β-strands (Fig. 2f), and it has been suggested that this EFβ-scaffold governs Ca^{2+} binding and the associated structural changes and represents the structural basis for positive cooperativity between the sites (Forsen et al. 1991).

Noncanonical EF-Hand Binding Motifs

Noncanonical EF-loops, including the pseudo EF-hand motif found in the S100 protein family, are characterized by binding geometries structurally similar to canonical sites, but exhibiting more variation in either the length of the binding loop and/or flanking helices, the absence of helices, or compositional changes within the binding loop.

The pseudo EF-hand motif is found in the S100 and S100-like proteins, including calbindin D_{9k} and calcyclin (S100A6). The S100 proteins generally are of lower molecular weight (∼9–14 kDa). The full range of functions associated with S100 proteins remains unknown, but different S100 proteins have been identified with a substantial number of extracellular and intracellular activities, including regulatory activities related to phosphorylation, enzymes, and intracellular calcium release associated with ryanodine receptor function, as well as increased expression in inflammatory responses and cancer metastasis. In cells, these proteins may organize as covalently bound homodimers or heterodimers, with some exceptions including calbindin D_{9k} which is a monomer. Dimerization of S100 proteins appears to directly relate to their biological activities, and the structural basis for this self-assembly is driven by binding with calcium.

The pseudo EF-hand binding geometry is similar to the pentagonal-bipyramidal conformation observed with the canonical EF-hand, but significant differences are observed in the binding loop. Rather than a 12-residue loop, pseudo EF-hand extends to 14 residues where the calcium ion is coordinated predominantly with main-chain carbonyl oxygen atoms from residues occupying positions 1, 4, 6, and 9, with a water molecule coordinated by residue 11 and a bidentate (Asp or Glu) ligand in loop position 14. Because the majority of binding ligands originate from the backbone itself, the nature of the associated residue is less restricted than what is observed with canonical EF-hand binding sites. Additionally, where the canonical EF-loops typically have a formal charge between −2 and −4, less formal charge is observed in the pseudo EF-loops due to dominance of carbonyl oxygen binding ligands. An example of this can be seen with calprotectin (PDB ID 1×k4) which binds calcium with zero formal charge

This motif is usually observed to be paired with, and to sequentially precede, a canonical EF-hand which exhibits higher binding affinity for calcium. From the N-terminal, helices are labeled consecutively H1–H4. The pseudo EF-hand loop (L1) is flanked by H1 and H2, while the canonical EF-hand loop (L2) is surrounded by helices H3 and H4. The two motifs are separated by a flexible hinge region, while a short peptide extension appears at the C-terminal. Comparison of sequences indicates that the greatest homology is observed in the canonical EF-site, with the most variance observed in the hinge region and a C-terminal extension following the canonical EF-site.

The functional role of the pseudo EF-hand appears to be a more recent evolutionary feature producing lower affinity in the N-terminal domain and allowing significant calcium-induced changes in the canonical EF-hand, which in turn expresses a hydrophobic cleft necessary for target recognition and peptide binding.

Calpain, grancalcin, and ALG-2 are classified in the penta-EF-hand protein family. Penta-EF-hands have five binding sites. Not all sites are necessarily active and may be characterized as either EF-hand sites or incomplete EF-hands. The incomplete EF-hands typically exhibit the helix-loop-helix structure of canonical EF-hand, but a reduction in the number of residues in the loop sequence results in incomplete pentagonal-bipyramidal geometry. ALG-2 (apoptosis-linked gene 2, PDB ID 1hqv) includes four calcium-binding sites. The sites surrounding Ca-997 and Ca-998 are canonical EF-hand motifs, while the binding site chelating Ca-999 represents an incomplete pentagonal-bipyramidal geometry, comprising a short stretch of seven residues and water (Table 1). The final binding

Calcium-Binding Protein Site Types, Table 1 Examples of diverse calcium-binding sites

PDBID	Protein/enzyme/ assembly	Binding site ligands	Seq. class	Struct class	Geometry
3gpe	PKC (Ca 501)	M186-O, D187-OD1, D246-OD2, D248-OD1, D248-OD2, D254-OD2, 1 H2O	III	Holospheric	Pentagonal-bipyramidal
3gpe	PKC (Ca 502)	D187-OD1, D187-OD2, D193-OD2, D246-OD1, W247-O, D248-OD1, PO_4	III	Holospheric	Pentagonal-bipyramidal

3mi4	Trypsin	E70-OE1, N72-O, V75-O, EB0-OE2, 2H2O	II	Holospheric	Octahedral
2prk	Proteinase K (Ca 280A)	P175-O, V177-O, D200-OD1, D200-OD2, 4 H2O	II	Holospheric	Pentagonal-bipyramidal
2prk	Proteinase K (Ca 281A)	T16-O, D260-OD1, D260-OD2, 3 H2O	–	Hemispheric	–
1bci	Phospholipase A2 (cytosolic, C2 Domain, Ca 1950A)	T1041-O, N1065-OD1, D1043-Od1, D1043-OD2, D1040-OD1, MES4000-O3S, 1 H2O	III	Holospheric	Pentagonal-bipyramidal
1bci	Phospholipase A2 (cytosolic, C2 Domain, Ca 1951A)	D1093-OD1, D1093-OD2, D1040-OD1, D1040-OD2, D1043-OD2, A1094-O, N1095-OD1, 1 H2O	III	Holospheric	Pentagonal-bipyramidal
3qfy	Phospholipase A2 (extracellular)	Y28-O, G32-O, G30-O, D49-OD1, D49-OD2	II	Hemispheric	Bipyramidal (incomplete)
3l4m	MauG (Ca 400 Chain A)	N66-OD1, T275-O, P277-O, 4 H2O	–	Holospheric	Pentagonal-bipyramidal
1qmd	alpha-toxin (phospholipase C, Ca 403)	A337-O, D269-O, D336-OD1, G271-O	–	Hemispheric	Bowl
3mt5	Human BKK+ channel Ca2+ gated K+ channel in	D892-O, Q889-O, D897-OD2, D895-OD1	I	Hemispheric	Bowl
2aef	Methanobacterium autotrophicum (Ca602)	D184-OD1, D184-OD2, E210-OE2, E212-OE2, 3 H2O	II	Holospheric	Pentagonal-bipyramidal

PDB ID, File identifier in Protein Data bank. Seq Class, Sequential classification. Struct Class = General structural classification. Calcium ions listed in column 2 are identified by their sequence number in the PDB file (e.g., Ca 602). Binding site ligands are defined as [*Residue Type*][*Residue Sequence Number*][−][*Atom type*]. So, D184-OD1 describes the delta oxygen 1 for aspartic acid at sequence position 184

site for Ca-996 includes a single side-chain ligand atom and water molecules, resulting in a planar binding structure.

Interestingly, calcium-binding proteins with an odd number of EF-hand motifs such as calpain often form a dimer to ensure pairing of the odd EF-hand motifs. Additionally, some proteins originally identified with odd numbers of EF-hand motifs may in fact have "hidden" EF-hands in their structures. The N-terminal domain of STIM1, an ER protein that responds to depletion of luminal Ca^{2+} by activating store-operated Ca^{2+} (SOC) channels on the plasma membrane and thereby facilitating extracellular Ca^{2+} influx into the cytoplasm, contains several functionally important regions including an ER signal peptide and a canonical EF-hand domain. Preliminary investigations on STIM1 had indicated that the observed canonical EF-hand domain functioned as a solitary binding site for Ca^{2+}, but a second hidden EF-hand site, albeit lacking conserved calcium-binding ligand residues, was later revealed by X-ray crystallography and was found to stabilize the canonical EF-hand through hydrogen bonding between the paired loops and coupled flanking helices and to exhibit the cooperative binding effects associated with EF-hand pairs (Stathopulos et al. 2008). Single EF-hand motifs have also been identified in both bacteria and virus genomes, but it remains to be seen whether these single EF-hand motifs are stabilized with a hidden EF-hand site located elsewhere in the protein.

Non-EF-Hand Continuous Calcium-Binding Sites

A significant proportion of calcium-binding structures currently in the PDB includes structures not sequentially or structurally identifiable as canonical EF-hand motifs and may represent structural classes yet to be categorized. This group includes an increasing number of calcium-binding sites structurally similar to EF-hands but with increasing variability in the loop or helices. Table 1 summarizes many of the binding site examples discussed in this section.

Human low-density lipoprotein receptor contains two atypical calcium-binding sites found in extended loop regions. The NMR structure of this protein (PDB ID 1hz8) does not include water molecules, so the structures appear incomplete. This is apparent in the binding site surrounding Ca-84 which exhibits a distorted, incomplete pentagonal-bipyramidal geometry comprised of six binding ligand atoms. However, these ligands span an unusually long region of the loop (17 residues), and the loop itself is partially restricted by the formation of a disulfide bond. The second binding site coordinating Ca-83 is comprised of only four ligand atoms which fail to surround the ion, although this may be due to the absence of water molecules in the PDB file.

Another example is α-lactalbumin, an extracellular protein from the C-type lysozyme family that participates in the formation of lactose synthetase, a precursor enzyme involved in lactose synthesis. The calcium-binding site in α-lactalbumin consists of a short four-residue N-terminal side helix, a four-residue loop, and a longer (at least 12-residue) C-terminal side helix (PDB ID 1hml). Despite this significant variance from the canonical EF-hand loop, this site retains a pentagonal-bipyramidal binding geometry comprised of five protein ligand atoms and two water molecules. This site is also interesting because, with the exception of oxygen from the two water molecules and a single side-chain carboxyl oxygen from D82 in the loop region, the remaining binding ligand atoms are contributed by residues in α-helices.

Calcium and Enzymes

The potential for calcium binding to play a catalytic role in enzymes has been a subject of long-term debate. It is clear that calcium plays an important role in structural stability, folding, and regulation of enzymatic activity. The relationship between calcium and the generation of trypsin from trypsinogen was being investigated as early as 1913 (Mellanby and Woolley 1913), and research has shown that calcium can stabilize the structures of different enzymes, including thermolysin, trypsin, and proteinase K, which enables them to perform their catalytic activities. Many of the binding sites associated with these enzymes exhibit pentagonal-bipyramidal geometries, as observed with canonical EF-hand sites.

Trypsin contains a single high-affinity calcium-binding site with an octahedral binding geometry where the superior and inferior apices are both water molecules. Binding of calcium prevents autodegradation and is necessary for the structural integrity of the active enzyme. Proteinase K has two calcium-binding sites: a higher affinity site exhibiting pentagonal-bipyramidal geometry comprised of four ligand atoms from amino acid residues (two in close sequential proximity with a bidentate

ligand more distant in the sequence) and four water molecules and a second calcium-binding site linked between residues in distant parts of the sequence (T16-O and bidentate D260) and bound with three water molecules. As with trypsin, binding of calcium in proteinase K is reported to stabilize the enzyme structure and facilitate structural changes necessary for catalytic activity.

Calpain is a cysteine protease that regulates cellular functions by cleaving a number of different substrate proteins (i.e., kinases, phosphatases, and transcription factors). Calpain binds three calcium ions: two in canonical EF-hand geometries and a third in a modified EF-hand involving two bidentate ligands Asp-225 and Asp-223.

Calcium-dependent phospholipase A2 (PLA2) enzymes include cytosolic and extracellular isoforms. Cytosolic PLA2 (cPLA2), which plays a role in production of lipid mediators of inflammation, contains a C2 domain with two calcium-binding sites. Both sites exhibit pentagonal-bipyramidal geometry despite sequential separation of binding ligand residues. The roles of extracellular phospholipase A2 enzymes differ significantly from PLA2 in the cytosol. Extracellular PLA2 in venom helps to immobilize prey, while pancreatic PLA2 plays an important role in the breakdown of phospholipids in dietary fat. Significant structural differences are also observed with extracellular enzyme PLA2 (PDB ID 3q4y), which incorporates a hemispheric calcium-binding site. Residues comprising the site are summarized in Table 1. This site includes a bidentate ligand D49 originating in an α-helix, similar to the bidentate anchoring ligand in the exiting helix of the canonical EF-loop. However, this ligand is sequentially distant from the other binding ligands. Additionally, binding ligands are not observed in the region in the pentagonal plane corresponding to the −y-axis (EF-loop position 7), which is normally occupied by carbonyl oxygen in the canonical EF-hand, or in the −x-axis space normally occupied by a water molecule. The resulting binding geometry in the crystal structure of phospholipase A2 therefore suggests an incomplete pentagonal-bipyramidal geometry.

Recently, calcium-binding sites were identified in a class of heme-containing peroxidases including canine myeloperoxidase, horseradish peroxidase, cationic peanut peroxidase, manganese peroxidase, lignin peroxidase, bacterial diheme cytochrome c peroxidase (BCCP), and the diheme enzyme MauG from *Paracoccus denitrificans*. The X-ray structure of MauG (PDB ID 3l4m) revealed that the calcium-binding site in MauG includes oxygen from the side-chain ligand atom (N66-OD1), two carbonyl oxygen atoms (T275 and P277), and four water molecules. Calcium "bridges" the two hemes via a hydrogen-bonded network of waters that connect to the propionate moiety of each heme. The presence of calcium was shown to be important in maintaining an appropriate structural environment for the hemes, which allows it to generate the *bis*-Fe(IV) intermediate and catalyze a complex six-electron oxidation of a protein substrate. This calcium-binding site is very unique since calcium is coordinated by oxygen atoms from four water molecules and three noncharged ligand residues. Despite the limited charge in the site, MauG apparently binds calcium with relatively high affinity (K_d 5.3 μM) (Shin et al. 2010). The reason for this unusually high affinity is not clear. It is possible that such strong affinity originates from the enhanced electrostatic force from the charged propionate side chain associated with the hydrophobic heme.

This example suggests that charge is not the sole factor influencing binding affinity. Moreover, the structural similarity of these calcium-binding sites in enzymes indicates calcium can be coordinated with much greater flexibility than what is suggested by the highly conserved and more densely charged canonical EF-hand loops.

C2 Domain with a Cluster of Calcium Ions

The C2 membrane-targeting domain is identified in cellular proteins that fulfill a role in signal transduction, including synaptotagmin I, phospholipase A, and the β-isoform of protein kinase C (PKC) (PDB ID 1a25). C2 domains contain a core calcium-binding region (CBR) where calcium binding, often accompanied by binding of additional cofactors as observed with certain isoforms of PKC, initiates conformational changes that allow the domain to identify membrane-attached targets, such as anionic phospholipids. C2 domain motifs diverge from the canonical EF-hand in several important ways. First, proteins with C2 domains exhibit β-sandwich architecture, compared to the predominantly α-helical nature of proteins with canonical EF-hands. Because of this architecture, a series of interstrand loops cluster at the end of the β-sandwich. In the C2 domain, a cleft is formed by

these loops which are densely packed with aspartic acid residues. This cleft accommodates binding of multiple calcium ions as seen with PKC (Fig. 2d), which is presumed to be cooperative and necessary for stabilizing the structure in order for the domain to recognize its molecular target. Second, the binding ligands can originate from sequentially distant regions of the protein, as seen with Ca-502 in PKCα (PDB ID 3gpe) where the binding site is formed by ligands D187 (bidentate), D193, D246, W247 (carbonyl), D248, and SO_4. The overall geometry is holospheric (Fig. 2a), conforming to a pentagonal-bipyramidal geometry with oxygen from sulfate replacing the water molecule at the (−x) position. The crystal structure of PKCα shows binding of two additional calcium ions. One of these is coordinated in a pentagonal-bipyramidal geometry, while the other occupies a hemispheric bowl geometry (Fig. 2b). Unusually, several ligands appear to be shared between calcium ions in the structure (Table 1). Similar binding models in C2 domains are observed with PKCβ (PDB ID 1a25) and cadherins. Such clustering of calcium ions is not commonly seen for cytosolic calcium-binding proteins with strong calcium-binding affinities. Consistent with this observation, the reported lower calcium-binding affinities for this class of calcium-binding sites (∼mM), correspond to the higher calcium content in the environment.

Calcium in Ion Channels

Ion channels describe transmembrane protein assemblies that allow the regulated movement of ions (Na^+, K^+, Ca^{2+}) across cellular compartments. Calcium channels, which facilitate the transfer of calcium across membranes, may be either ligand-gated or voltage-gated. Examples of ligand-gated calcium channels include IP_3 and ryanodine receptors. Voltage-gated calcium channels (VGCC) regulate the entry of calcium into the cell following changes in the membrane potential. This calcium influx in turn drives diverse cellular functions including cardiac muscle contraction and neurotransmitter release. Voltage-gated calcium channels, through their Ca_v protein subunits, may be regulated through an indirect calcium feedback mechanism mediated by binding of calcium to CaM which can interact with an isoleucine-glutamine (IQ) motif located in the N-terminal region of Ca_v.

Conversely, voltage-activated K^+ channels (e.g., BK or Slo1 channels) can be directly activated by increases in intracellular calcium which provides a feedback mechanism where opening of these channels hyperpolarizes the membrane and initiates closing of calcium channels, thereby reducing calcium influx. A calcium-binding site identified in BK K^+ channel is believed to contribute to this calcium regulatory mechanism. This binding site, identified as a "calcium bowl" (Schreiber and Salkoff 1997), is hemispheric, comprised of four binding residues (D892-O, Q889-O, D897-OD2, D895-OD1) originating in an Asp-rich sequence DQDDDDDPD, as seen in the PDB crystal structure for human BK (PDB ID 3mt5). Mutations or deletions of residues in this sequence have been shown to desensitize channel activity; however, further evidence suggests the existence of a second calcium-binding site that remains to be identified (Schreiber and Salkoff 1997). Similarly, the dimeric crystal structure of MthK calcium-gated K^+ channel in *Methanobacterium autotrophicum* (PDB ID 2aef) reveals two symmetrical calcium-binding sites believed to stabilize the RCK (regulate the conductance of K^+) domains. Unlike human BK, however, these binding sites conform to pentagonal-bipyramidal geometry with the addition of water molecules (Table 1), and the residues comprising the binding sites span a longer region of the sequence than the BK K^+ channel binding site.

Definitions

Metal ions play several major roles in the structures and functions of proteins. The bindings of some metal ions increase the stabilities of proteins or of protein domains. Some transition metal ions take part in catalysis in many enzymes. The oxygen, nitrogen, and sulfur atoms of several amino acid side chains, as well as the carbonyl oxygen of the peptide group and the carboxylate of the C-terminal residue may be involved in coordination of metal ions. Binding of the Ca^{2+} ion is limited to not only oxygen-containing ligands, primarily the carboxylates of Asp (aspartic acid) and of Glu (glutamic acid), but also the oxygens of Asn (asparagine), Gln (glutamine), Ser (serine), Thr (threonine), Tyr (tyrosine), and of the main chain peptides. A water oxygen may be in the primary coordination sphere of the Ca^{2+} ion; in turn, this water may be involved in a hydrogen bond with an oxygen from the protein. Sometimes, for example, in C2 domains or calsequestrin, several Ca^{2+} ions are bound near one another. However, they do not bind one another directly but are instead bridged by an oxygen. Most proteins that bind a metal cation, such as Ca^{2+}, bind it with reasonable specificity. The ligands involved might bind other metals; one infers that the selectivity of the protein reflects an optimization by natural selection.

Calcium-binding proteins can be considered in three categories – those in the cytosol whose activity or biological function is modulated by variation in $[Ca^{2+}]_{cyt}$; those, usually extracytosolic, whose binding of calcium, at constant $[Ca^{2+}]_{out}$, is essential to their functions; and those involved in calcium channels and pumps, where the concept of macroscopic $[Ca^{2+}]$ is problematic.

The variation in $[Ca^{2+}]_{cyt}$ over time and region is a form of information. This information can be transduced into a change in protein conformation and/or enzyme activity by interaction with a calcium-modulated protein(s) in the cytosol or associated with a membrane protein facing the cytosol.

Calcium binding is essential to the functions of many extracytosolic calcium-binding proteins; however, these functions are not (usually) modulated by calcium since $[Ca^{2+}]_{out}$ is (usually) constant.

Calcium pump proteins and calcium channels proteins are intrinsic to the membrane across which the calcium is transported.

All members of a protein domain have a similar tertiary structure, excepting those that are intrinsically disordered, have statistically significant similarity in amino acid sequence, and have evolved from a single precursor domain. A single protein domain belongs to only one domain family.

A chimeric protein is a single polypeptide chain that consists of two or more, nonhomologous domains. It has evolved by gene splicing.

Two proteins (domains) in different species are orthologs if they are related by speciation. If two proteins, in the same or in different species, are related by gene duplication they are paralogs.

Two, or more, subfamilies of proteins, each having two or more homologous domains are congruent if the common precursor to all of these subfamilies had the full complement of domains and all of the subfamilies are related by duplication of the entire, encoding gene. Congruent subfamilies are characterized by having all of their domains 1 more similar to one another than to other domains within the same proteins; correspondingly all domains 2, etc.

Horizontal gene transfer (HGT) is inferred to have occurred if two distantly related species share a protein domain with little evidence that the domain was present in an ancestor common to both species. HGT is well established to have occurred among bacteria and perhaps from eukaryotes to prokaryotes.

Overview

Calcium is unique in biological systems. Ca^{2+} is the only metal cation demonstrated to function as a secondary messenger in the cytosols of eukaryotes. The information in this pulse of Ca^{2+} ions (Berridge 2006) is transduced into a change of conformation of a calcium-modulated protein(s).

However, there are many extracytosolic proteins whose functions are dependent on the binding of calcium. Most intriguing, and least understood, are those intrinsic membrane proteins (complexes) involved in calcium pumps or channels. This article will summarize the characteristics of some representative, major families from each of these three groups – calcium-modulated proteins, extracytosolic calcium-binding proteins, and calcium pump proteins. It is not comprehensive but rather is a broad introduction to the more detailed articles in this volume.

Many of the functional characteristics of calcium-binding proteins (CaBPs) can be rationalized from the characteristics of calcium coordination. In proteins the Ca^{2+} ion (atomic radius 0.99 Å) is usually bound by seven oxygen atoms at the vertices of an approximate pentagonal bipyramid at average Ca-O distance 2.3 Å; the oxygen atoms have some lateral flexibility. In contrast the Mg^{2+} ion (ionic radius 0.65 Å) is usually coordinated by six oxygens with average Mg-O distance 2.0 Å at the vertices of an octahedron. These six oxygens are in close van der Waals contact with one another. Although many small molecules bind magnesium with higher affinity than they bind calcium, most proteins, both in the cytosol and extracellular, bind calcium with higher affinity.

The dissociation constant is the ratio of the off rate to on rate [K_d (M) = k_{off} (s^{-1}) / k_{on} (s^{-1} M^{-1})]. The rate limiting dehydration of calcium is fast, $Ca(H_2O)_7^{2+} \sim 10^{-8}$ s^{-1}; while that of $Mg(H_2O)_6^{2+}$ is slow, $\sim 10^{-4.6}$ s^{-1}. This difference reflects the loose pentagonal verses the tight octahedral packing of the oxygen ligands. The cation must be (partially) dehydrated before it can bind to the protein. These rates are important for modeling the flux of Ca^{2+} ions through the cytosol and their attendant binding by proteins. The increase in affinity of most proteins for calcium relative to magnesium derives primarily from the difference in k_{on}.

Most, CaBPs, in the cytosols of eukaryotic cells are involved in information transduction. These calcium-modulated proteins are in the apo- or magnesi-form in the so-called resting cell with calcium concentration $\sim 10^{-7}$ M, that is, pCa ~7.0. Following a stimulus to the cell, the concentration of cytosolic calcium, $[Ca^{2+}]_{cyt}$, rises to pCa ~4.0 and the calcium-modulated protein is then in the calci-form with a conformation and activity different from that in its apo-form. These calcium-modulated proteins might modify the activity of an enzyme or a structural protein or they themselves might be enzymes.

The second group consists of (usually) extracytosolic proteins. They require calcium for stability and/or activity but are not activated, or inhibited, by calcium since they reside in an environment of (near) constant calcium concentration.

Calcium pumps and channels are intrinsic membrane proteins or components of such complexes.

Calcium Modulated Proteins in the Cytosols of Eukaryotic Cells

Many of these calcium-modulated proteins contain 2–12 tandem EF-hand domains. Others contain one or two C2 domains or four annexin domains (Permyakov and Kretsinger 2010).

EF-Hand Proteins

Parvalbumin was the first EF-hand protein to have its crystal structure and its amino acid sequence determined. It has a canonical pair of EF-hands and it has been studied extensively (reviewed by Permyakov 2006, 2009; Permyakov and Kretsinger 2010). Many of the techniques used to study calcium-binding proteins in general, and EF-hands in particular, have been refined in investigations of parvalbumin. For these reasons, it has become a paradigm; even though, its full range of functions has yet to be determined.

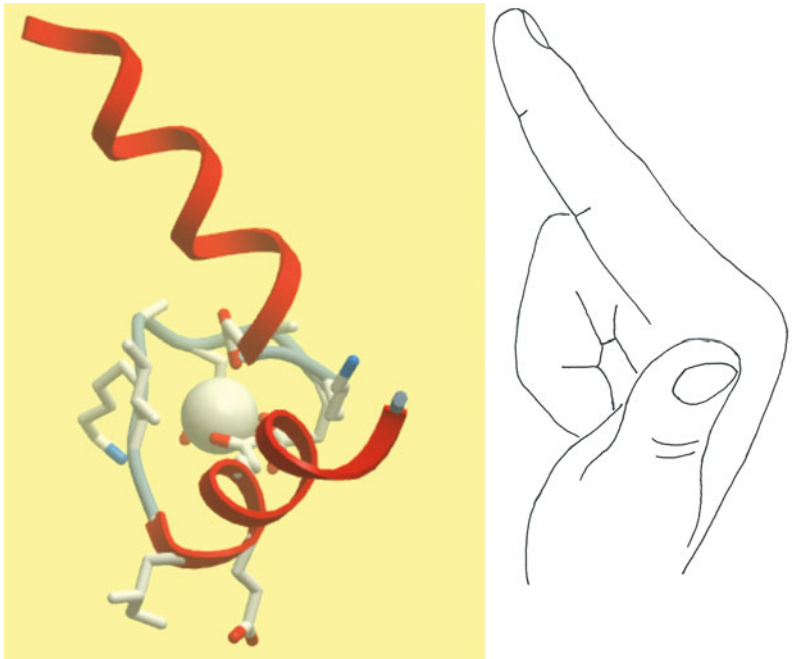
The canonical EF-hand (Fig. 1) consists of α-helix E (forefinger, residues 1–10), a loop around the Ca^{2+} ion (clenched middle finger, 10–21), and α-helix F (thumb, 19–29). Residue 1 is often Glu; the insides of the helices (palmer surfaces) usually have hydrophobic residues that contact the insides of the other EF-hand of the pair. The side chains of the five residues, approximating the vertices of an octahedron (X, residue 10; Y, 12; Z, 14; −X, 18; and −Z, 21), provide oxygen atoms to coordinate the Ca^{2+} ion; residue 16 at -Y bonds to Ca^{2+} with its carbonyl oxygen. The positions of these ligands within the loop are often referred to as 1, 3, 5, 7, 9, and 12. The Ca^{2+} ion is actually seven coordinate in a pentagonal bipyramid with major axis: X, −X. There are five oxygens in the Y,Z plane since the −Z ligand (residue 21, usually Glu) coordinates Ca^{2+} with both oxygens of its carboxylate group. In magnesi-EF-hands the Mg^{2+} ion is six coordinate; this carboxylate coordinates with only one of its oxygens. Gly at 15 permits a tight bend; residue 17 has a hydrophobic side chain that attaches the loop to the hydrophobic core of the pair of EF-hands.

Several variations to this canonical calcium coordination scheme have been inferred from amino acid sequences and confirmed in crystal structures of other EF-hand proteins. Nearly one third of all known EF-hands do not bind calcium; those with no indels (insertions or deletions), have a non-oxygen containing side chain substituted at position 10, 12, 14, 18, or 21. Other EF-hands have indels, most notable is EF-hand 1 of the S-100 subfamily, in which several carbonyl oxygen atoms, instead of oxygens of side chains, coordinate the Ca^{2+} ion.

All members of a homolog family of proteins are inferred to have evolved from a common precursor domain in a single ancestral organism. The most parsimonious interpretation is that all of the EF-hand domains are homologs; however, the significances of sequence alignments are weak since the domains are only 30 residues long. Additional criteria, such as the fact that nearly all EF-hand proteins occur in pairs (Fig. 2) and that in most EF-hand proteins at least one of the two EF-hands binds calcium are included. Many (portions of) domains have been suggested to resemble the EF-hand based on their amino acid sequences. They are not recognized as EF-hands unless they have passed a Hidden Markov Model test based on unambiguous EF-hands of known structure. Most EF-hand containing proteins have been found in eukaryotes; however, there are several examples in eubacteria. EF-hand proteins, for example, calmodulin (Fig. 2), have been found in all eukaryotes subject to thorough investigation. This distribution might reflect an origin in the bacterium that gave rise to eukaryotic cells; other bacteria may have lost their EF-hands. Or, the precursor EF-hand may have arisen in an early eukaryote and its encoding gene have been transferred to a few bacteria by horizontal gene transfer.

Most EF-hand proteins contain 2–12 tandem copies of the EF-hand domain. EF-hands occur in pairs and are related by an approximate twofold axis of rotation, thereby forming an EF-lobe. Although about one third of all EF-hands are known or inferred not to bind calcium, usually at least one EF-hand domain in any protein does bind calcium with $pK_d(Ca^{2+}) \sim 7.0$. The protein, such as the ubiquitous and archetypical calmodulin, is in the apo- and/or magnesium-form prior to stimulation of the cell; following a rise in $[Ca^{2+}]_{cyt}$, the competent EF-hand(s) binds calcium with attendant change in conformation of itself and probably of the paired EF-hand of that EF-lobe. If the protein is heterochimeric with a non-EF-hand catalytic domain(s), the change in conformation of the EF-hand region activates the enzyme. If the EF-hand protein itself is not catalytic, the change in conformation causes the EF-hand protein to activate a target enzyme or structural protein.

Eighty distinct EF-hand proteins have been identified; however, the functions of only 25 are known. Ten of these are enzymes and have been demonstrated



Calcium-Binding Proteins, Overview, Fig. 1 The EF-hand: The canonical EF-hand consists of α-helix E (forefinger, residues 1–10), a loop around the Ca^{2+} ion (clenched middle finger, 10–21), and α-helix F (thumb, 19–29). The side chains of the five residues, approximating the vertices of an octahedron (X, residue 10; Y, 12; Z, 14; −X, 18; and − Z, 21), provide oxygen atoms to coordinate Ca^{2+}; residue 16 at − Y bonds to Ca^{2+} with its carbonyl oxygen. The positions of these ligands within the loop are often referred to as 1, 3, 5, 7, 9, and 12. Nearly one third of all known EF-hands do not bind calcium; those with no indels (insertions or deletions), have a non-oxygen-containing side chain substituted at position 10, 12, 14, 18, or 21. Other EF-hands have indels, most notable is EF-hand 1 of the S-100 subfamily, in which several carbonyl oxygens, instead of oxygens of side chains, coordinate the Ca^{2+} ion

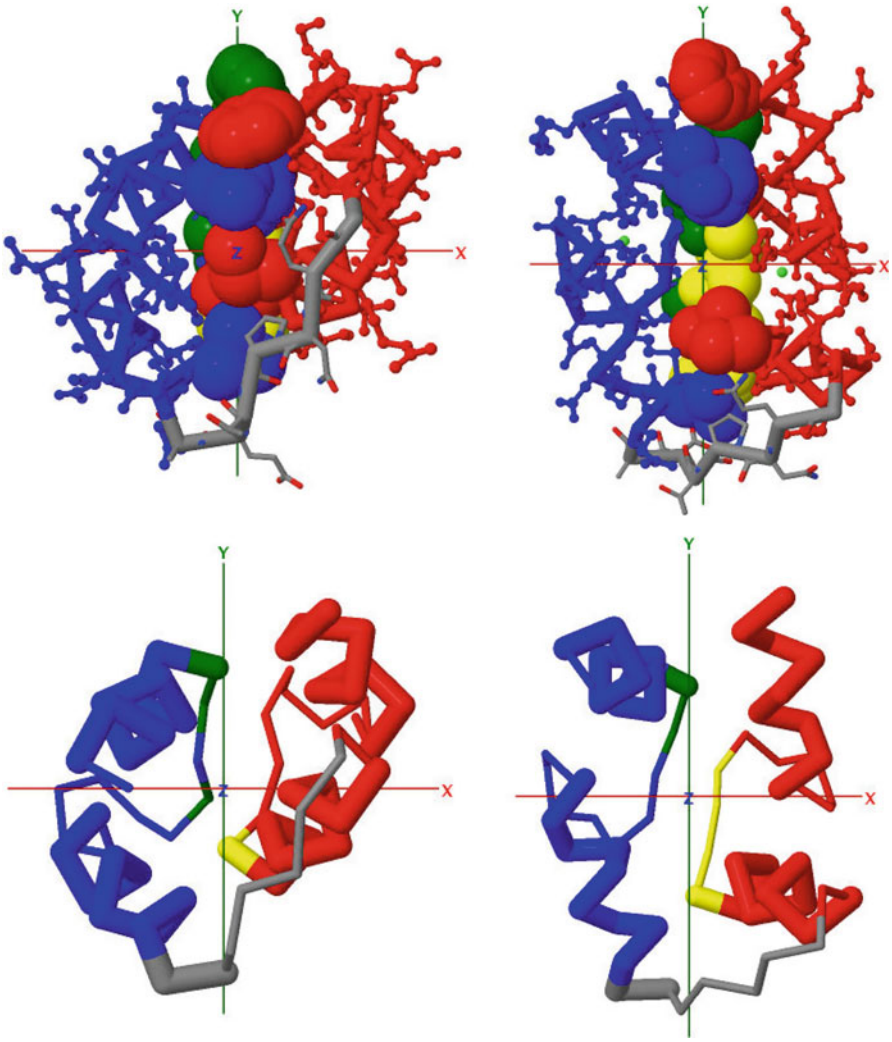
or inferred to be activated by the binding of calcium. Many, but certainly not all, of the remaining 55 function in information transduction pathways as summarized for a few calcium modulated proteins, such as calmodulin. However, others such as intestinal calcium-binding protein, in the S-100 subfamily, probably facilitate the diffusion of calcium through the cytosol; parvalbumin appears to function as a temporal buffer. Thirty, including the ten enzymes are heterochimeric. In addition to their EF-hands, they contain other domains of different evolutionary origin and different conformation. Members of the penta-EF-hand subfamily (calpain, sorcin, ALG-2, and peflin) have two canonical EF-lobes (domains 1 and 2 and 3 and 4). They form homo- or heterodimers by pairing their fifth EF-hands to form a canonical EF-lobe.

It is not unusual for a basic protein domain to find many uses, often spliced together with other domains. The EF-hand is one of the most widely distributed domains in eukaryotes, perhaps reflecting the range and subtlety of calcium signaling. For example, the downstream regulation element antagonist modulator (DREAM) upon binding calcium dissociates from a DNA-binding regulatory element that otherwise functions as a gene silencer. This might provide a precedent for long-term potentiation.

C2 Domain Proteins

The C2 domain was originally identified as the second of four domains (Cl though C4) in the α, β, and γ isoforms of mammalian calcium-dependent protein kinase C. It exists in both calcium-binding and nonbinding forms. Both interact with membranes and with multiple other proteins. The C2 domain is widely distributed in eukaryotes but rare or nonexistent in prokaryotes; it is, after the EF-hand, the most frequently occurring calcium sensor.

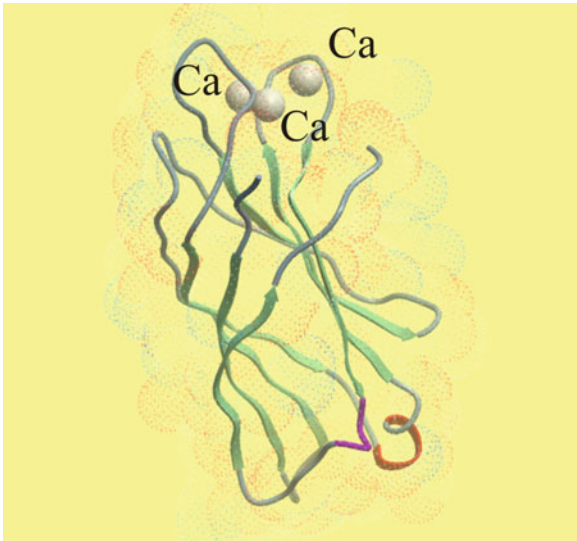
C2 domains are about 130 residues long; they fold autonomously and form a compact β-sandwich composed of two, four stranded β-sheets (Fig. 3).



Calcium-Binding Proteins, Overview, Fig. 2 Calmodulin, N-lobe: EF-hand domains, 1 (Odd) and 2 (Even), are related by an approximate twofold axis, z, perpendicular to the plane of view. The apo-form (Protein Data Bank, 1DMO) is on the *left*; the calci-form (3CLN) is on the *right*. Both EF-lobes are represented as α-carbon traces, *lower pair*. The atoms (both side chain and main chain) within ± 2.0 Å of the yz-plane are shown as van der Waals spheres, *upper pair*. These are mostly side chain atoms at the interface of the two EF-hands in the EF-lobe. Upon binding calcium the E and the F helices tilt apart from one another and apart from the other EF-hand of the lobe. This "opening" relieves close contacts between the side chains of residues Met36, Phe19 (Odd) and Met72, Phe68 (Even) and permits binding of calmodulin to specific targets. *Red*, odd domain; *blue*, even domain; *green*, Ca^{2+} ions (Courtesy of Hiroshi Kawasaki, Department of Supramolecular Biology, Graduate School of Nanobioscience, Yokohama City University, Yokohama 230-0045, Japan)

Three loops at the top of the domain and four at the bottom connect the eight β-strands. Calcium binding occurs at the top three loops. The calcium-binding sites are formed primarily by Asp side chains that serve as bidentate ligands bridging two or three Ca^{2+} ions. Most, but not all, C2 domains are activated by calcium binding and then dock to a specific membrane.

Protein kinase Cα (PKCα) has two C2 domains that dock to different membrane surfaces during an intracellular calcium signal (Corbin et al. 2007). They discriminate two different mechanisms of C2 domain-directed intracellular targeting – messenger-activated target affinity (MATA) and target-activated messenger affinity (TAMA).



Calcium-Binding Proteins, Overview, Fig. 3 Structure of the C2A domain of synaptotagmin I (PDB file 1B7N): Three Ca^{2+} ions are bound at the top edge of the β-sandwich, which consists of two β-sheets, four strands each

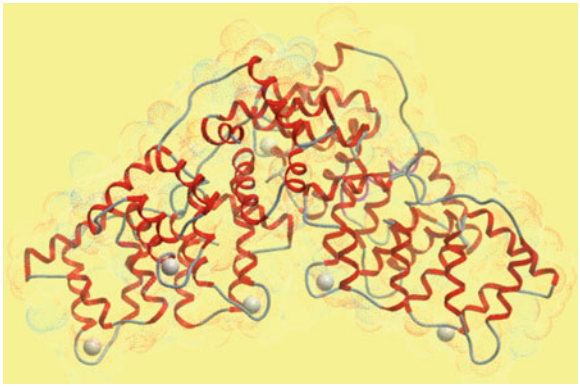
Synaptotagmin has an established docking role in secretion and also appears to be a key component of the endocytosis machinery. It is a major calcium sensor that triggers release of neurotransmitters. The presence of distinct synaptotagmins on the membranes of synaptic vesicles and on active zones of the membranes that fuse during neurotransmitter release suggests an explanation for the existence of multiple synaptotagmins (Südhof 2002). The large cytosolic region of synaptotagmin contains two C2 domains. The first of them, C2A, may function in neurotransmitter release through its calcium-dependent interaction with syntaxin and phospholipids.

Phospholipase C (PLC) mediates the physiological effects of many extracellular stimuli by activation of inositol lipid-signaling pathways. In response to many extracellular stimuli, such as hormones, neurotransmitters, antigens, and growth factors, phospholipases C catalyze the hydrolysis of phosphatidylinositol (4,5)-bisphosphate, thereby generating two second messengers, inositol 1,4,5-trisphosphate and *sn*-1,2-diacylglycerol. Eleven phospholipase C isozymes encoded by different genes have been identified in mammals and, on the basis of their structure and sequence relationships, have been classified into five families designated PLCβ (1–4), PLCγ (1 and 2), PLCδ (1, 3 and 4), PLCε (1), and PLCζ (1).

The phospholipase A2 (PLA2) family consists of several nonhomologous groups of enzymes that catalyze the hydrolysis of the *sn*-2 ester bond in a variety of different phospholipids. The products of this reaction, a free fatty acid, and a lysophospholipid have many different physiological roles. It is assumed that the interaction of the C2 domain with membranes is analogous to the hydrophobic electrostatic switch that modulates reversible membrane binding of several myristoylated proteins. In this case, the electrostatic switch is calcium, which changes the electrostatic properties of the surface of the C2 domain, that is, neutralizes a cluster of negative charges and enables membrane binding. Full activation of phospholipase A2 requires calcium binding to the C2 domain and phosphorylation of several serines (Hirabayashi et al. 2004). The calcium binding induces translocation of phospholipase A2α from the cytosol to the perinuclear membranes.

Annexins

Annexins are ubiquitous calcium- and phospholipid-binding proteins whose many inferred functions have yet to be confirmed. They consist of a core of four homologous annexin domains and of a highly variable N-terminal tail. The core is inferred to have evolved by two cycles of gene duplication and fusion; domains 1 and 3 and domains 2 and 4 resemble one another more closely. No examples of proteins having only a single or only a pair of annexin domains are known. Annexin A6 (VI, old notation), and only A6, has eight domains; it evolved by another cycle of gene duplication and fusion, (Fig. 4). Each annexin domain consists of five α-helices; A, B, D, and E form a right-handed, four helix, bundle. The four domains pack into a flattened trapezoid; the axes of the four, four helix bundles are perpendicular to the surface of the trapezoid. Annexin domains 4 and 1 are related to domains 2 and 3 by a local, twofold axis, also perpendicular to the plane of the trapezoid. It has a slightly convex surface on which the amino and carboxyl termini of each domain come into close apposition and a concave surface on which the ($4 \times 2 =$) eight potential calcium-binding loops – AB and DE – are located. Ca^{2+} ions that bind to this concave surface are inferred to cross-link carbonyl and carboxyl groups of (some of) the eight AB and CD loops with phosphoryl groups of membrane phospholipids. Annexins have lower affinity for calcium than do most EF-hands; therefore, they are inferred to be modulated by changes in calcium concentration within



Calcium-Binding Proteins, Overview, Fig. 4 Structure of annexin A6 (PDB file 1AVC): Annexin A6 has eight domains; all other annexins have four. It evolved by gene duplication and fusion. The two flattened trapezoids (domains 1–4 and domains 5–8) are both seen approximately edge on; they are related by a twofold axis, vertical and in the plane of view. Domains 4 and 1 are related to domains 2 and 3 and domains 8 and 5 are related to domains 6 and 7 by twofold axes perpendicular to the planes of their respective trapezoids. The three Ca^{2+} ions in each trapezoid are indicated by *white spheres*; they are all on the inferred membrane binding, concave surface

limited regions of the cytosol. The convex side of annexin faces the cytoplasm and may interact with other proteins.

The N-terminal tails contain highly variable sequences 35–60 residues long; they are of low complexity and are inherently disordered; only portions of them are seen in crystal structures of annexins. The calcium-dependent membrane aggregation of annexins A1, A2, and A4, is strongly inhibited by phosphorylation of the N-tail; whereas, for annexin A7 aggregation is activated. The N-tail contains several putative Ser and Thr phosphorylation sites as well as consensus sequences for glycosylation and transglutamination. Annexin A1 also has several possible sites in the N-terminal domain for proteolysis; this profoundly modifies its physical and biological properties. The N-tails of the annexins sometimes fold back on this convex surface, reaching to the central pore in the trapezoid formed by packing of the four domains.

Many cytosolic proteins, including members of the EF-hand family, bind selectively to the N-terminal tails of annexins. Several S100 proteins and annexins interact in both calcium-dependent and calcium-independent manners, and form complexes that exhibit specific biological activities (Miwa et al. 2008).

Eukaryotes have ~20 annexin genes; however, annexins are not found in fungi and prokaryotes. Most annexins are encoded by 12–15 exons, the variation depending in large part on the length of the N-terminal tails. For several annexins, particularly those with long N-tails, alternative splicing adds to the diversity of annexin isoforms; this may in turn amplify functional variability within the family as a whole. Any single cell type expresses a range of annexins, but no single annexin is expressed in all cells, implying that regulation of annexin gene expression is tightly controlled (Gerke et al 2005).

Possible Calcium-Modulated Proteins in Prokaryotes

Many prokaryotes have proteins that are inferred to bind calcium based on their amino acid sequences. However, the affinities or selectivities of these proteins for calcium have yet to be determined. There is only inferential evidence of calcium functioning as a second messenger in prokaryotes (Permyakov and Kretsinger 2009).

Extracytosolic Calcium-Binding Proteins

Since $[Ca^{2+}]_{out}$ is usually constant, calcium modulation of extracytosolic proteins is not (usually) possible. However, the functions of most of these proteins appears to be dependent their binding calcium.

Cell Matrix Proteins

Numerous proteins are associated with the very complex and varied extracellular matrices. The extracellular matrix is a network built up from a variety of proteins and proteoglycans. Its interaction with cells is mediated by cell adhesion molecules. Many matrix-matrix, cell-matrix, and cell-cell contacts involve calcium; however, the effective concentration and freedom of diffusion of calcium in these restricted volumes is not well understood. Most extracellular matrix proteins are multidomain, often chimeric proteins. The extracellular calcium-binding modules of known structure can be divided into two groups: the Ca^{2+} ion can either be bound to a single domain or can mediate interactions between independently folded domains in the same or in different proteins.

BM-40 (osteonectin or SPARC, Secreted Protein Acidic and Rich in Cysteine) is a small secreted

glycoprotein, which is involved in the regulation of bone mineralization, tissue remodeling, and cell growth (Permyakov 2009). It is secreted by osteoblasts during bone formation, initiating mineralization and promoting crystal formation of the mineral. BM-40 also shows affinity for collagen in addition to bone mineral calcium. Its short N-terminal sequence, rich in glutamic acid residues, binds several Ca^{2+} ions with low affinity (dissociation constant 5–10 mM). The domain is followed by a domain homologous to follistatin and a C-terminal extracellular (EC) calcium-binding domain. The EC domain of BM-40 has a compact structure with high α-helical content and is stabilized by two disulfide bonds. The domain binds two Ca^{2+} ions through a canonical pair of EF-hands. One EF-hand of BM-40 is unusual: it has a one-residue insertion into the EF-hand consensus sequence; this is accommodated by a *cis*-peptide bond. Another unusual feature of the BM-40 EC domain is the presence of an amphiphilic α-helix that lies across the cleft formed by the helices of the EF-hand pair, as do target peptides in calmodulin.

Calcium-Binding Proteins Involved in Biomineralization

The main mineral components of bone and teeth are calcium and phosphate (of shells, calcium carbonate). Ninety per cent of the organic matrix of bone is collagenous and consists mainly of type I collagen, the remaining 10% consists of over 200 proteins of various sorts. The major bone matrix proteins, other than collagen, are osteocalcin, matrix GLA protein, osteonectin, proteoglycans, acidic glycoprotein 75, osteopontin, bone sialoprotein, fibronectin, vitronectin, and thrombospondin. These proteins bind calcium ions with $K_d(Ca^{2+})$ of about 3 mM and exhibit high affinity to microcrystals of hydroxyapatite, $Ca_5(PO_4)_3OH$, the basic bone mineral (Permyakov 2009).

Osteocalcin is the most abundant noncollagenous protein in bone. Its synthesis in osteoblasts is vitamin K dependent and its concentration in serum is closely linked to bone metabolism. Posttranslational modification by a vitamin K-dependent carboxylase produces three γ-carboxyglutamic acid (Gla) residues at positions 17, 21, and 24. Mature osteocalcin is largely unstructured in the absence of calcium and undergoes a transition to a folded, globular state at physiological concentrations of calcium. Three α-helices comprise a tightly packed core involving conserved hydrophobic residues Leu16, Leu32, Phe38, Ala41, Tyr42, Phe45, and Tyr46. All three Gla's implicated in hydroxyapatite binding are located on the same surface of helix 1 and, together with the conserved residue Asp30 from helix 2, coordinate five Ca^{2+} ions (Permyakov 2009; Permyakov and Kretsinger 2010).

Osteopontin is synthesized at elevated levels by not only osteoblasts, but also by kidney, vascular smooth muscle, and gall bladder cells. It is a potent inhibitor of hydroxyapatite formation. Osteopontin is phosphorylated; however, the role of its phosphate moieties in unclear. It might act as an inhibitor of crystal nucleation in physiological fluids at high super saturation of calcium phosphate. Osteopontin binds to integrins, which are expressed on osteoclasts and initiate bone resorption by mediating adhesion of the osteoclast to osteopontin in bone (Permyakov 2009).

Blood Clotting Proteins

Many enzymes involved in the blood clotting cascade have several Gla residues in an N-terminal Gla domain that specifically binds calcium. As with osteocalcin, their γ-carboxylation is vitamin K dependent. Prothrombin, factor X, factor IX, factor VII, protein C, and protein Z bind phospholipids in a calcium-dependent manner. The accumulation of these proteins on phospholipid surfaces requires a functional, calcium-loaded Gla domain. Factors VII, IX, and X, and protein C share the same domain architecture. The N-terminal Gla domain is followed by two domains homologous to the epidermal growth factor (EGF), and the C-terminal catalytic serine protease domain is homologous to trypsin. Factor X and protein C exist as heterodimers already in their zymogen forms, but factors VII and IX molecules dimerize on activation. The two chains are connected by a single disulfide bond. The Gla and EGF-like domains constitute the light chain; the protease domain is in the heavy chain. All Gla-containing plasma proteins are presumably involved in blood coagulation, some by promoting the process and others by attenuating it.

Thrombin is the central protease of the vertebrate blood coagulation cascade. It is derived from its inactive zymogen form, prothrombin, a 70-kD glycoprotein that is synthesized in the liver and secreted into the blood. Prothrombin, the most studied Gla containing protein, is composed of 579–582 residues, including ten Gla's, and three complex carbohydrate chains. Prothrombin has two Ca^{2+}-binding sites with

a dissociation constant of 0.2 mM and several weaker sites. It has an N-terminal Gla-rich domain, two kringle domains, a short activation peptide, and a thrombin/catalytic/serine proteinase domain. During the activation of prothrombin to thrombin, the N-terminal peptide consisting of 156 residues is cleaved. This peptide, known as fragment-1, contains all ten Gla's and two of the carbohydrate chains of the intact prothrombin. Prothrombin binds to phospholipid dispersions in the presence of calcium and the activation of prothrombin to thrombin is accelerated in the protein-calcium-phospholipid complex. The phospholipid-binding site in prothrombin is located in its fragment-1 region (Permyakov 2009; Permyakov and Kretsinger 2010).

Coagulation factor VIIa consists of N- and C-terminal domains (residues 1–152 and 153–406). The N-terminal region is rich in Gla; it is followed by two EGF-like domains. The Gla and EGF-like domains are required for protein-protein and protein-membrane interactions responsible for complex formation between factor VII and tissue factor on the cell membrane. The C-domain includes the catalytic triad and shares the fold of chymotrypsin-like serine proteases. The function of the serine protease domain is to convert coagulation factors IX and X from zymogens to active enzymes (Permyakov 2009; Permyakov and Kretsinger 2010).

Salivary Protein A and Salivary Protein C

SPA consists of a single, proline-rich peptide chain of 106 residues; SPC contains the entire structure of SPA in its N-terminal part, but continues beyond residue 106 to the C-terminal residue 150. The proteins have a highly negatively charged N-terminus, which contains a total of 11 Gla's and two phosphoserines. Both salivary proteins A and C are found in parotid and submandibular saliva.

Epidermal Growth Factor (EGF)-like Domains

The EGF-like domain is one of the more widely distributed modules in extracellular proteins; it is characterized by six conserved cysteine residues organized in a characteristic pattern of disulfide bonds (1–3, 2–4, and 5–6) and two small β-sheets. EGF-like domains are found in a variety of proteins associated with various biological functions such as blood coagulation and fibrinolysis, activation of complement, cell adhesion and signaling, neurite outgrowth, formation of neuromuscular junctions, and involvement in basement membranes and connective tissue microfibrils. A subset of EGF-like domains contains a bipartite consensus sequence with a D/N-X-D/N-E/Q motif preceding the first cysteine and a X-D/N-X_n-Y/F-X motif between the third and fourth. This consensus contains a calcium-binding site. EGF-like domains play three functional roles: structural stabilization, protein-protein interactions, and spacing unit. High resolution structures of EGF-like domains have revealed a common fold, consisting of a major and a minor double-stranded β-hairpin, stabilized by the three consensus disulphide bonds. Each EGF-like domain contains a calcium-binding site, whose affinity is enhanced by N-terminal linkage to another domain.

Cadherins

Cadherins (calcium-dependent adhesion molecules) are cell adhesion proteins involved in establishing and maintaining intercellular connections and in controlling cell polarity and morphogenesis. They are transmembrane with large extracellular segments consisting of five repeated domains, each about 110 residues long; their adhesive properties reside in the N-terminal domain. Cadherin-mediated cell adhesion depends on the presence of extracellular calcium. Cadherins have conserved, repeat motifs in their extracellular domains, which are responsible for their calcium dependence. Classical cadherins, the first cadherins identified, are essential for cell-cell adhesion, serving to organize the adherens junction. Crystal structures of domains 1 and 2 of cadherin show that both domains are folded as independent modules made up entirely of β-sheets. The structure of the ten residue, interdomain linker is stabilized by three Ca^{2+} ions bound to a cluster of carboxylates contributed by both modules. The extracellular region of cadherins forms a rigid, rod-like structure only in the presence of calcium (Permyakov 2009).

Pentraxins

Pentraxins are a family of highly conserved, multimeric, pattern recognition proteins (Deban et al. 2009). They are divided into short and long classes. C reactive protein, the first pattern recognition receptor identified, and serum amyloid P component (SAP) are short pentraxins produced in the liver. Long pentraxins, including the prototype, PTX3, are expressed in a variety of cells and tissues, most notably dendritic cells and macrophages.

Through interaction with several ligands, including selected pathogens and apoptotic cells, pentraxins play a role in complement activation, pathogen recognition, and apoptotic cell clearance. In addition, PTX3 is involved in the deposition of extracellular matrix and in female fertility. SAP is the major DNA and chromatin-binding glycoprotein of plasma. The interaction is strictly calcium dependent. The physiological role of SAP is not yet defined. It is localized in the glomerular, basement membrane and in the peripheral, microfibrillar mantle of elastic fibers. Its binding to several substrates including oligosaccharides with terminal *N*-acetyl-galactosamine, 6-phosphate-mannose, glucuronic acid, and galactose is calcium dependent. In the crystal structure five identical subunits of SAP are arranged in a flat ring with a substantial hole in the center. The subunits are almost exclusively composed of β-sheets in a lectin-like fold. One face of the disk-shaped molecule contains the sites of interaction with ligands. An acidic functional group of large polyionic ligands bridges two Ca^{2+} ions; this accounts for the strict calcium dependence of its interactions.

Calcium-Binding Lectins

Lectins have no known enzymic activity but exhibit numerous biological activities that are related to their ability to bind carbohydrates in the presence of calcium. Lectins have specific binding sites for carbohydrates and thereby interact with specific cells, cell fractions, or glycoproteins. Proposed functions include promotion of symbiosis, involvement in cell recognition, and organization of supramolecular structures.

Concanavalin A

Con A is a tetramer composed of four identical polypeptide chains of 237 residues each. Each monomer can be schematically visualized as an ellipsoidal dome with a narrow, flat base. It has two calcium-binding sites and a carbohydrate-binding site; all near the apex of the dome. The tetramer structure appears to be required for its agglutination or precipitation activities. In the presence of calcium, Con A preferentially binds to α-D-mannopyranosyl, α-D-glucopyranosyl, and α-D-*N*-acetyl-glucosaminyl residues. The saccharide-binding site is located within 10–14 Å of the two calcium-binding sites. The residues that may participate in saccharide binding are found in close proximity in the three dimensional structure but are not clustered in the amino acid sequence. Most of the residues involved in calcium binding in Con A are clustered near its N-terminus. The two Ca^{2+} ions are bound in two adjoining octahedral sites that are 4.5 Å apart and have a common edge (Permyakov 2009; Permyakov and Kretsinger 2010).

Mannose-Binding Proteins

Mannose-binding proteins are members of the C-type lectin family; they are usually found in the serum and liver of mammals. Carbohydrate recognition domains of all C-type lectins have a similar core structure, which includes a cysteine-rich domain at the N-terminus followed by a collagenous domain, an oligomerization domain, and a C-terminal carbohydrate recognition domain. Monomers assemble into homotrimers, which further associate into larger oligomers. The mannose-binding proteins bind to a number of various monosaccharides containing vicinal, equatorial hydroxyl groups such as those found at the positions 3 and 4 of mannose, including N-acetylglucosamine and fucose. All C-type lectins have a calcium-binding site (site 2 in mannose-binding proteins) at which carbohydrates directly interact with the bound Ca^{2+} ion as well as with amino acids that serve as Ca^{2+} ligands. Mannose-binding proteins have three calcium-binding sites per molecule. The amino acid residues that form the binding site are highly conserved, especially a tripeptide sequence of two calcium ligands flanking a *cis*-proline residue (Permyakov 2009; Permyakov and Kretsinger 2010).

D-Galactose-Binding Protein

Sugar-binding proteins (molecular masses 25–45 kDa) are essential components of high affinity active transport systems for a large variety of carbohydrates, amino acids, and ions. They serve as initial receptors for the simple behavioral response of bacterial chemotaxis. There are remarkable similarities in both the tertiary structure and ligand-binding properties of the L-arabinose-, sulfate-, D-galactose-, Leu/Ile/Val- and leucine-specific binding proteins. All five proteins are ellipsoidal in shape (axial ratios about 2:1) and are composed of two similar yet distinct globular domains. The two domains in all of the structures are connected by three separate peptide segments. Although these interdomain connecting segments are widely separated in the primary structure, they are spatially nearby. The calcium-binding loop in D-galactose-binding protein adopts a conformation very similar to the loop in the

EF-hand, but it is not immediately preceded and followed by helices and is not homologous (Permyakov 2009; Permyakov and Kretsinger 2010).

Calcium-Binding Hydrolytic Enzymes

Many enzymes, which catalyze the hydrolysis of ester, phosphodiester, and peptide bonds, bind calcium. The binding of calcium to the enzymes might serve three functions. Ca^{2+} ions can stabilize an intermediate in the active site as in phospholipase A_2 and staphylococcal nuclease. Calcium stabilizes the enzyme at high temperatures as in thermolysin. It is also essential in the activation of zymogens as in trypsin, phospholipase A_2, and calpain.

Phospholipase A_2 (molecular mass 14 kDa) catalyzes the specific hydrolysis of the fatty acid ester bonds at the C2 position of 1,2-diacyl sn-phosphoglycerides. Both secreted and intracellular forms of phospholipase A_2 have been described. Phospholipases A_2 from mammalian pancreas as well as bee and snake venoms belong to the secreted forms; they are homologous monomers 118–129 residues long with particular conservation of the residues thought to be involved in calcium binding and in forming the active site. Calcium is an obligatory cofactor for interfacial catalysis by secreted phospholipase A_2 from virtually all sources. Calcium is coordinated near the active site by six ligands that form an octahedron. This relatively high affinity calcium-binding site is involved in the catalytic site of the enzyme. The binding of calcium affects His48, which play an essential role at the active site but is not directly involved in calcium binding. The mechanism for hydrolysis of phospholipids by phospholipase A_2 is similar to that for the hydrolysis of peptide bonds by serine proteases in which calcium stabilizes the tetrahedral intermediate. A low affinity calcium-binding site in phospholipase A_2 is located near its N-terminus and is postulated to be involved in micellar binding. The three-dimensional structure of phospholipase is characterized by a ring of amino acids surrounding the entrance to the active site; this ring structure has been proposed to be involved in micellar binding (Permyakov 2009; Permyakov and Kretsinger 2010).

Extracellular *Staphylococcus aureus* nuclease (molecular mass 16.8 kDa) requires millimolar concentrations of calcium for its activity. It is a monomer of 149 residues; it binds one Ca^{2+} ion. The calcium site is octahedral and consists of side chains and peptide carbonyl groups of Asp19, Asp21, Asp40, Glu43, and Thr41. Calcium coordination in Staphylococcal nuclease is similar to that in the high affinity phospholipase A_2 calcium-binding site. In this enzyme, calcium also takes part in stabilization of an intermediate during the reaction of hydrolysis of the phosphodiester bond according to the mechanism, which is similar to that proposed for phospholipase A_2. The active site of both enzymes is proximal to the calcium site (Permyakov 2009; Permyakov and Kretsinger 2010).

Thermolysin is the best characterized neutral protease produced by bacilli. Thermostable thermolysin like proteases are a group of metalloendopeptidases, which contain one catalytic Zn^{2+} ion and two to four Ca^{2+} ions that are important for stability. The N-terminal domain of thermolysin consists mainly of β-strands; the C-terminal domain is mainly α-helical. Ca^{2+} ions 1 and 2 (Ca1,2) are found in the C-terminal domain in the double calcium-binding site close to the active site zinc. Ca3 is located at the surface in the N-terminal domain, and Ca4 is bound by a surface-located ω-type loop in the C-terminal domain. Removal of calcium by chelators results in a partially unfolded, flexible molecule and in its rapid autolytic degradation. Ca3 and Ca4 are more important for thermal stability of thermolysin-like proteases than are C1,2. On the other hand, the double calcium site is so important that thermolysin cannot exist without this calcium site being occupied (Permyakov 2009; Permyakov and Kretsinger 2010).

Lipases

Lipases are water-soluble enzymes that hydrolyze ester bonds of water-insoluble substrates such as triglycerides, phospholipids, and cholesteryl esters. Lipases are versatile enzymes that have been isolated from a variety of eukaryotes and prokaryotes. They hydrolyze the ester bonds in long chain triacylglycerols. Although the overall similarity of lipases is low and molecular masses vary from 20 to 60 kDa, all lipases share a comparable three-dimensional fold. The amino terminal domain of pancreatic lipase consists of a series of nine β-sheets arranged in a fan-like pattern, termed an α/β hydrolase fold. The region of highest conservation is the active site, which contains a "classical" Ser-His-Asp catalytic triad. The amino terminal domain of pancreatic lipase has striking similarities to that found in bacterial and fungal lipases, which are single domain enzymes.

However, pancreatic lipase also has a separate, discrete carboxyl-terminal domain that is absent in the other lipases. A high affinity calcium-binding site with dissociation constant of 55 μM is found in lipase from *Staphylococcus hyicus*. The residual activity of the calcium-free enzyme compared to the activity of the calcium-loaded enzyme varies from 65% at 10°C to nearly zero at 40°C (Permyakov 2009; Permyakov and Kretsinger 2010).

Collagenase

Collagenase from the anaerobic spore-forming bacterium, *Histotoxic clostridia*, is responsible for the extensive tissue destruction of gas gangrene. The collagen-binding domain of *Clostridium histolyticum* class I collagenase also binds two Ca^{2+} ions between two loops and have limited solvent access. The coordination by oxygen atoms of Glu899, Glu901, Asp927, and Asp930 side chains, main chain carbonyl of Ser922, and one water is best described as a square antiprism. The water, Glu901, and Glu899 (bidentate) form one face while Ser922, Asp927, and Asp930 (bidentate) form the other face. The peptide bond between residues Glu901 and Asn902 adopts a *cis* conformation that is stabilized by calcium chelation. This dual ion structure is different from those in all other calcium-binding proteins. The apparent K_d(Ca) of the domain is about 4 μM (Permyakov 2009; Permyakov and Kretsinger 2010).

α-Lactalbumin

α-Lactalbumin is homologous to lysozyme of eukaryotes. In spite of the fact that its calcium-binding domain is not an EF-hand, its structure, which includes a helix-loop-helix domain resembles an EF-hand domain. It is the modifier component of lactose synthase, which is synthesized in the lactating mammary gland. It complexes with galactosyl transferase, thereby altering the substrate specificity of the enzyme to favor glucose as the acceptor molecule. A single Ca^{2+} ion-binding site in α-lactalbumin consists of seven oxygens from carboxylates of Asp82, Asp87, and Asp88; carbonyls of Lys79 and Asp84; and two waters. The coordinating ligands form a slightly distorted pentagonal bipyramid. Ca-O distances are from 2.3 to 2.5 Å. The calcium-binding loop in α-lactalbumin is flanked by two helices. Conformation of the backbone chain in the calcium-binding region of α-lactalbumin is similar to the conformation of the corresponding region in hen egg lysozyme but the side chains in this region of α-lactalbumin and lysozyme are different. In contrast to the EF-hand, which has no disulfide bonds, bovine α-lactalbumin has four disulfide bonds, Cys6-Cys120, 28–111, 61–77, and 73–91. The removal of calcium has only minor effects on the structure of the metal-binding site and the largest structural change is observed in the cleft on the opposite side of the molecule. Tyr103 is shifted toward the interior of the cleft and water-mediated interactions with Gln54 and Asn56 replace the direct hydrogen bonds. These changes result in increased separation of the α and β domains, loss of a buried solvent molecule near the calcium-binding site, and the replacement of inter- and intra-lobe hydrogen bonds of Tyr103 by interactions with newly immobilized waters (Permyakov 2005).

Calcium-Buffering Proteins Within the Endoplasmic Reticulum (ER)

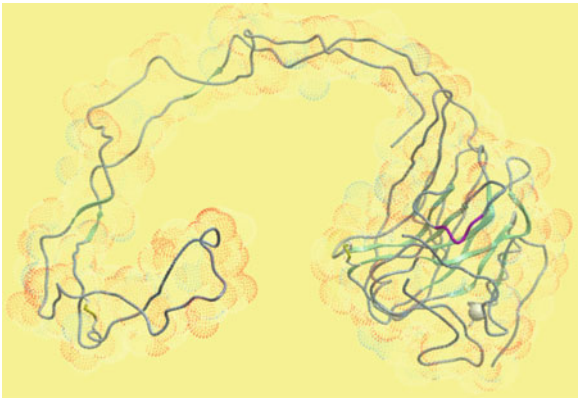
One of the primary functions of the ER is to store calcium either as a result of downregulation within the cytosol or in anticipation of upregulation. The ER is intracellular; however, the lumen of the ER is topologically extracytosolic. The relative advantage to the cell of using extracellular calcium versus ER calcium for cytosolic signaling is not obvious. Proteins that exit the endoplasmic reticulum are, for the most part, properly folded and assembled, owing to the coordinated activities of several folding enzymes, molecular chaperones, and a rigorous quality control system that retains and disposes of misfolded proteins. Some of the proteins that are involved in calcium sequestration are also involved in this protein-folding process.

Calsequestrin is found within the sarcoplasmic reticulum (SR) of skeletal and cardiac muscles; it contains no transmembrane segments and is therefore inferred to be located within the lumen of the SR. The total concentration of calcium in SR is as high as 50 mM, but a large portion of this calcium is bound to calsequestrin, which acts as a luminal buffering system; the concentration of free Ca^{2+} ion within the lumen can be maintained below the inhibitory level (~1.0 mM) of the calcium pump. For the fastest muscles, a limiting step in the contraction, relaxation cycle is pumping calcium into the SR. In this process, calsequestrin plays a key role through buffering the calcium levels within the lumen of the SR. It consists of three homologous domains, each with a thioredoxin

fold, and a five strand β-sheet sandwiched by four α-helices. Each domain has a hydrophobic core with acidic residues on the exterior, forming electronegative surfaces. The connecting loops and the secondary structural elements that fill the interdomain spaces contain mostly acidic residues. Cations are required to stabilize the acidic center of calsequestrin. It is a glycoprotein with 30–50 calcium-binding sites with rather low affinity ($K_d(Ca^{2+}) \sim 10^{-3}$ M). Over 30% of its residues are Asp or Glu; its isoelectric point is 3.75. The binding of calcium makes calsequestrin insoluble. In the absence of calcium, calsequestrin is in near random coil conformation with α-helical content 11%. The binding of calcium increases its helical content up to 20% and changes its shape from elongated (Stokes radius, 45 Å) to much more compact (35 Å).

Calsequestrin has several functions in the lumen of the sarcoplasmic reticulum in addition to its well-recognized role as a calcium buffer. First, it is a luminal regulator of ryanodine receptor activity. In the presence of triadin and junctin, calsequestrin maximally inhibits the Ca^{2+} release channel when the free $[Ca^{2+}]$ in the lumen of the sarcoplasmic reticulum is 1 mM. This inhibition is relieved when the $[Ca^{2+}]$ changes, either because of small changes in the conformation of calsequestrin and/or its dissociation from the junctional face membrane. Calcium, but not magnesium, blocks the binding of calsequestrin to a 26 kDa protein of the junctional SR. It is inferred that calsequestrin is also involved in the regulation of calcium release from the ER (Beard et al. 2009).

Calreticulin and calnexin are the most intensively studied chaperones of the ER because of their unusual modes of substrate recognition, their intimate relationship with the Asn-linked glycosylation system, and the diversity of functions attributed to them. They are lectins that interact with newly synthesized glycoproteins that have undergone partial trimming of their core, N-linked oligosacharides. Simultaneously, they serve as molecular chaperones. Calreticulin, calnexin, and ERp57 (a glycoprotein-specific thiol-disulfide oxido-reductase) are components of the "calreticulin/calnexin cycle" that interacts with partially folded glycoproteins and determines whether the proteins are to be released from the endoplasmic reticulum or, alternatively, whether they are to be sent to the proteosome for degradation (Williams 2006). Accumulation of misfolded protein in the endoplasmic reticulum leads to activation of genes responsible for the expression of these chaperones. When accumulation of misfolded protein becomes toxic, apoptosis is triggered, possibly with membrane kinase, IRE1, involved in signaling via caspase-12 (Michalak et al. 2009). The C-domain of calreticulin is similar to the C-domain of calsequestrin. The C-domain terminates with the endoplasmic reticulum retrieval signal, KDEL.



Calcium-Binding Proteins, Overview, Fig. 5 Structure of the luminal domain of calnexin (PDB file 1JHN): The 89 residue cytoplasmic tail of calnexin (65 kDa, 573 residues) (*left*) is phosphorylated and carries a C-terminal RKPRRE sequence that serves as a signal for endoplasmic reticulum localization. The luminal domain of calnexin binds substrates, (at least) four equivalents of calcium, and Mg-ATP

Calnexin (65 kDa, 573 amino acid residues) is a non-glycosylated, transmembrane protein with an extracellular N-terminus and cytoplasmic C-terminus, so called type I. Its substrate-binding domain is located in the lumen of the ER. The luminal portion of calnexin has two domains: a globular β-sandwich that resembles legume lectins and an extended 140 Å arm consisting of two β-strands folded into a hairpin. Each β-strand is composed of four tandemly repeated, Pro-rich domains. The 89 residue cytoplasmic tail of calnexin is phosphorylated and carries a C-terminal RKPRRE sequence that serves as a signal for endoplasmic reticulum localization. The luminal domain of calnexin (Fig. 5) binds substrates, (at least) four equivalents of calcium, and Mg-ATP.

Possible Modulation of Extracellular Calcium-Binding Proteins

The concentration of free Ca^{2+} ions is usually held constant in the extracellular fluid, or plasma, of multicellular organisms. However, there is some evidence that $[Ca^{2+}]_{out}$ may vary in a controlled manner

over restricted volumes and/or brief times. Calcium may be involved in extracellular signaling (Hofer 2005); these target proteins are considered to be calcium modulated.

Calcium Pump and Calcium Channel Proteins

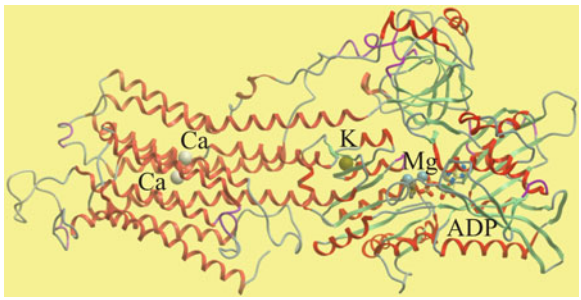
Lipid bilayer membranes surround all cells and organelles, forming barriers that limit the free exchange of polar solutes. A wide variety of proteins responsible for controlling the diffusion or active transport of ions and nutrients are inserted into these membranes. Calcium is pumped out of the cytosols of both eukaryotic and prokaryotic cells and it is pumped out of the matrix of mitochondria and other plastids.

Calcium Pumps

The P-type ATPases, also known as E1-E2 ATPases, are a large group of evolutionarily related ion pumps that are found in bacteria, archaea, and eukaryotes. They are α-helical bundle, primary transporters; they all appear to interconvert between at least two different conformations, denoted by E1 and E2. They are encoded by five main gene families (I, II, III, IV, and V). Those that share specificity for Ca^{2+}, K^+, and Na^+ ions group together in a single clade and are designated as P-Type II ATPases. They include five subfamilies: A, B, C, D, and E; also known as SERCA (sarco/endoplasmic reticulum Ca^{2+}-ATPase), PMCA (plasma membrane Ca^{2+} ATPase), NK/HK (Na^+,K^+- and H^+, K^+-ATPase), ENA (P-type ATPases which are able to extrude Na^+, Li^+, and K^+; and ACU (P-type ATPases which mediate high affinity Na^+ and K^+ ion uptake and are encoded by ACU genes in fungi).

The central event in the activity of this family of P-type ATPases is the formation of an acid stable aspartyl phosphate intermediate (Inesi et al. 2008). This event is initiated by cooperative binding of two cytoplasmic Ca^{2+} ions to transport sites. The energy of this intermediate is used to induce a conformational change that closes the ion gate from the cytoplasm, reduces the affinity of these transport sites for Ca^{2+} ions, and opens the ion gate toward the lumenal, or extracellular, side of the membrane. After releasing calcium, protons bind to the transport sites and the aspartyl phosphate is hydrolyzed to complete the cycle.

The P-ATPase consists of four basic domains (Fig. 6). The transmembrane domain is almost entirely helical (ten helices M1–M10) and has short loops on the lumenal and cytoplasmic surfaces. Four of the transmembrane helices extend into the cytoplasm to form a stalk. The three cytoplasmic domains are built from two large cytoplasmic loops between transmembrane helices M2/M3 and M4/M5. The M4/M5 loop forms the phosphorylation (P) domain and the nucleotide-binding (N) domain, which is inserted within the P domain. The third cytoplasmic loop, forming the transduction or anchor (A) domain, includes the smaller M2/M3 loop as well as the N terminus.



Calcium-Binding Proteins, Overview, Fig. 6 Structure of sarcoplasmic reticulum Ca^{2+}-ATPase in the Ca_2-E_1-ADP state (PDB file 1T5T): ADP is bound in the N domain, to the *right*. The transmembrane domain (helices M1–M10) is to the *left*; the Ca^{2+} ions indicate the channel. The transmembrane domain is almost entirely helical and has short loops on the luminal and cytoplasmic surfaces. Four of the transmembrane helices extend into the cytoplasm to form a stalk

The Ca^{2+}-ATPase pump has to discriminate between Ca^{2+} and Na^+, K^+, and Mg^{2+} ions (Gouaux and Mackinnon 2005). An obvious difference between the Ca^{2+} ion-binding sites and the N^+ and K^+ sites is the greater importance of negatively charged oxygen atoms contributed by Glu and Asp side chains for calcium coordination. A higher charge density is apparently required to compensate for the dehydration of a divalent cation. Part of the selectivity for the Ca^{2+} ion derives from its being seven coordinate, as opposed to six for the Mg^{2+} ion.

Phospholamban, a 52-residue protein spanning the sarcoplasmic reticulum membrane, is an endogenous inhibitor of SERCA ATPase, lowering the apparent calcium affinity of the ATPase.

Calcium Channel Proteins

Calcium channels, like pumps, are located in both cell membranes and organelle membranes of eukaryotes.

Although there is strong evidence that calcium is extruded from the cytosols of bacteria, there have yet to be established channels permitting inflow of calcium from the surrounding medium. Calcium influx in many types of cells is regulated primarily through two types of plasma membrane channels: voltage-dependent calcium channels (VDCCs) and receptor-operated (ligand gated) channels (ROCs). VDCCs transduce changes in transmembrane potential into local cytosolic calcium transients that regulate enzyme activation, gene expression, neurotransmission, and neurite outgrowth or retraction. They are composed of an α1 (190 kDa) 1–10 subunit forming the Ca^{2+} ion-selective channel, and several accessory subunits, α2δ, β1–4, and γ with anchorage and regulatory functions. The α1 subunit contains four repeated domains (I–IV), each of which contains six transmembrane segments (S1–S6) and a membrane associated loop between transmembrane segments S5 and S6. Based on their electrophysiological and pharmacological properties and the type of α1 subunit, VDCCs are divided into five classes: Cav1.1–Cav1.4 (L-type), Cav2.1 (P/Q-type), Cav2.2 (N-type), Cav2.3 (R-type), and Cav3.1–3.3 (T-type). Low resolution structures have been developed from image reconstruction analysis of CaV1.1 channels purified from skeletal muscle membranes; however, no high resolution structures have been determined.

ROCs open in response to the binding of specific ligands, such as neurotransmitters, to the extracellular domain of the receptor. This interaction causes a change in the structure of the protein that leads to the opening of the channel pore and subsequent ion flux across the plasma membrane. Most ROCs are permeable to Ca^{2+} ions and represent an important mechanism for the generation of second messengers. Examples of ROCs include the glutamate (*N*-methyl-D-aspartate), α-amino-3-hydroxy-5-methylisoxazole-4-propionate acid (AMPA), kainite (KARs), nicotinicacetylcholine receptors (nACh), serotonin(5-HT3), and adenosine 5′-triphosphate (ATP) P2X receptors.

Summary

Magnesium and zinc, at physiological concentration, sometimes compete for calcium-binding sites. Given the precedents of known high affinity, high specificity calcium-binding sites, for instance, in the EF-hand proteins, one can safely assume that Nature could have evolved, in other proteins, high specificity calcium-binding sites. These observations pose two challenges: first to determine whether the competing cation is binding to the calcium-binding site or to a different site, second to determine whether the binding of the non-calcium cation exerts some sort of modulatory function on the calcium-binding protein. These possible physiological functions, cytosolic or extracellular, might occur under normal or pathologic conditions.

Calcium-activated photoproteins

Definition

Ca^{2+}-regulated photoprotein is a "precharged" bioluminescent protein from which light emission is triggered by addition of calcium ions. The bioluminescence reaction does not require addition of molecular oxygen or any other cofactors, only the photoprotein and the triggering ion are necessary.

Background

Bioluminescence is widespread in the biosphere. Luminous organisms have been found among bacteria, fungi, protozoa, coelenterates, worms, mollusks, insects, and fish. Although these organisms occupy different places in the evolutionary ladder, the nature of their bioluminescence is always the same. In fact, bioluminescence is a chemiluminescent reaction whereby oxidation of a substrate, luciferin, is catalyzed by a specific enzyme, luciferase. Luciferins and luciferases of different organisms differ in structure; that is, the terms are generic and functional rather than structural and chemical. The many differences suggest that bioluminescence independently arose many times during evolution. Despite the more than 100-year history of studies on bioluminescence, the origin and functional advantage of bioluminescence in most organisms remain obscure.

Calcium-regulated photoproteins are "precharged" bioluminescent proteins that are triggered to emit light by binding Ca^{2+} or certain other inorganic ions. The reaction does not require the presence of molecular

oxygen or of any other cofactors – the photoprotein and the triggering ion are the only components required for light emission. Since the energy emitted as light is derived from the "charged" photoprotein, that molecule can react only once, that is, it does not "turn over" as an enzyme does. In this respect, as well as in the lack of a requirement for molecular oxygen or any other cofactor, the reaction is strikingly different from that of classical bioluminescent systems in which an enzyme (luciferase) catalyzes the oxidation of a smaller organic substrate molecule (luciferin) with the creation of an excited state and the emission of light. This difference prompted Shimomura and Johnson (Shimomura 2006) to coin the term "photoprotein" to describe proteins that serve as the sole organic molecular species in bioluminescent reaction systems. Though other kinds of photoproteins have been described, the great majority of photoproteins now known to exist are stimulated to luminescence by calcium, and the term "calcium-activated photoproteins" was applied to them by Hastings and Morin (1969). Later, the term "calcium-regulated photoproteins" was suggested to refer to this group, first, because these proteins are members of the family of calcium-regulated effector proteins such as calmodulin and troponin C and, second, because calcium regulates the function of these proteins but is not essential for it.

Occurrence and General Features of Calcium-Regulated Photoproteins

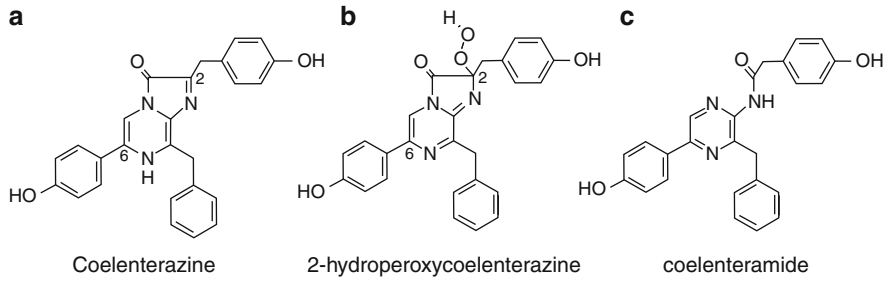
All of the calcium-regulated photoproteins that have been discovered so far have been isolated from luminescent marine coelenterates. A great many luminescent coelenterates are known; calcium-triggered luminescence occurs in more than 25 of these and may eventually be found in all of them. Nevertheless, even at present, only a handful of photoproteins have been isolated and studied. These are aequorin, halistaurin (mitrocomin), and phialidin (clytin) from hydromedusae *Aequorea*, *Halistaura* (*Mitrocoma*), and *Phialidium* (*Clytia*), respectively, obelin from hydroids *Obelia longissima* and *Obelia geniculata*, and mnemiopsin and beroin from ctenophores *Mnemiopsis* and *Beroe* (Shimomura 2006).

The calcium-regulated photoprotein is a complex of a single-chain polypeptide with molecular mass ~22 kDa and a peroxy-substituted coelenterazine (2-hydroperoxycoelenterazine), which is tightly, though noncovalently, bound with the polypeptide (Fig. 1). Bioluminescence initiated by Ca^{2+} results from oxidative decarboxylation of the 2-hydroperoxycoelenterazine. The reaction yields an excited molecule of coelenteramide and CO_2. The transition of coelenteramide from the excited into the ground state is accompanied by light emission.

The bioluminescence spectral maxima of photoproteins are in the range 465–495 nm, the wavelength varying with source organism. For instance, the bioluminescence maximum is at 465 nm in the case of aequorin and 495 nm for obelin from *O. geniculata*. Photoproteins exhibit little fluorescence, but after the bioluminescence reaction, the bound product coelenteramide is brightly fluorescent (Shimomura 2006). With aequorin, for example, the fluorescence spectrum of the discharged protein coincides with the bioluminescence, whereas in case of obelin, the fluorescence is shifted to 25-nm longer wavelength than the bioluminescence (Vysotski and Lee 2004).

Structure of Calcium-Regulated Photoproteins and Mechanism of the Ca^{2+} Trigger

During the past 25 years, cloning and sequence analysis have been achieved for cDNAs coding for five Ca^{2+}-regulated photoproteins: aequorin, phialidin (clytin), halistaurin (mitrocomin), and two obelins from *O. longissima* and *O. geniculata* (Markova et al. 2002). The Ca^{2+}-regulated photoproteins show a high degree of sequence identity (76–63%) and contain three canonic EF-hand Ca^{2+}-binding sites. This places these photoproteins into the EF-hand calcium-binding protein family (Kawasaki et al. 1998), one containing the most numerous and extensively studied members of all the protein families. However, the degree of identity of photoproteins with other calcium-binding proteins, for example, sarcoplasmic calcium-binding protein, caltractin, calmodulin, troponin C, and even calcium-dependent coelenterazine-binding protein from *Renilla*, is significantly low, not more than 25%. The Ca^{2+}-regulated photoproteins are distinctive also in having a primary sequence with many tryptophan, cysteine, and histidine residues, which are not commonly found in other calcium-binding proteins.

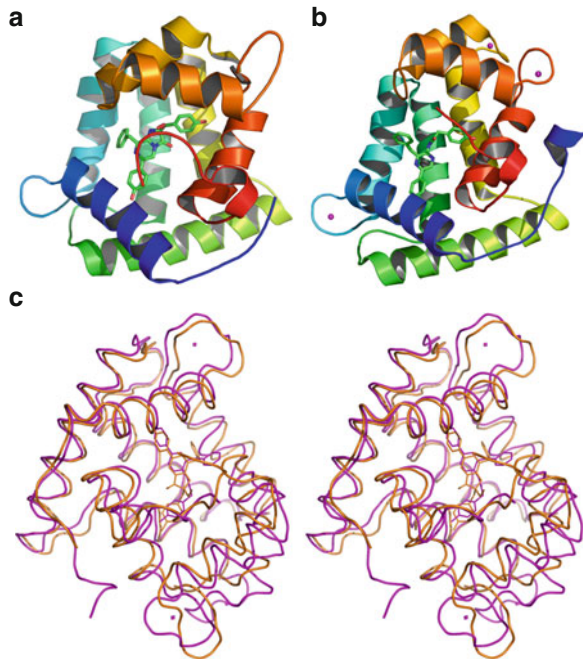


Calcium-Regulated Photoproteins, Fig. 1 Coelenterazine (**a**), 2-hydroperoxycoelenterazine, oxygen preactivated coelenterazine bound within photoprotein molecule (**b**), oxidation product of coelenterazine, coelenteramide (**c**)

The spatial structures of two photoproteins, obelin and aequorin, were determined in 2000 (Vysotski and Lee 2004; Shimomura 2006). As expected from the identity of their primary sequences, these and all subsequent photoproteins determined have the same compact globular structure (Fig. 2a). The spatial structure is formed by two sets of the four α-helices in the N- and C-terminal domains. Each domain can be thought of as a "cup" whose insides are lined with hydrophobic residues. The overall structure of photoprotein can then be considered as two "cups" joined at their rims. The 2-hydroperoxycoelenterazine resides in an internal cavity, which is surrounded by hydrophobic residues from the eight helices.

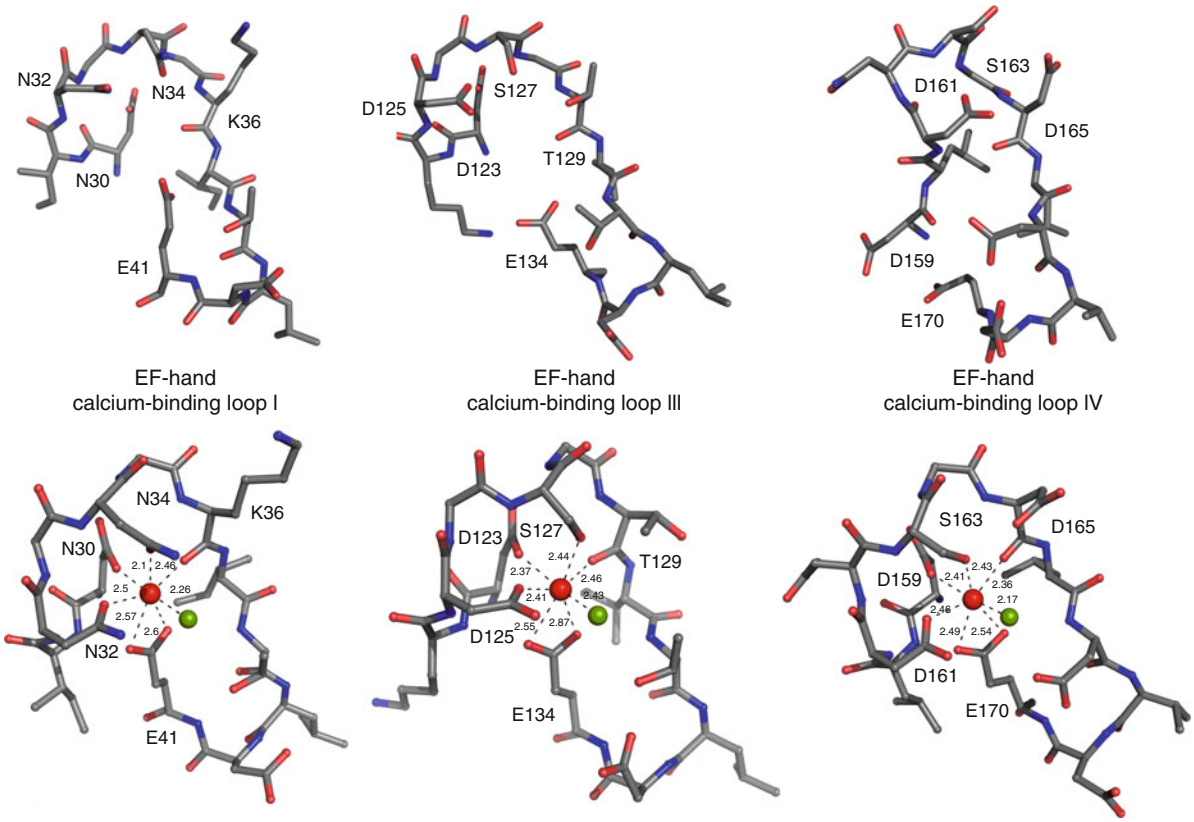
The three-dimensional structure of Ca^{2+}-discharged photoprotein (Fig. 2b) bound with the product of the bioluminescent reaction, coelenteramide, and calcium ions has been determined only for the case of obelin. The overall scaffold is retained and is the same as before bioluminescence discharge (Fig. 2). The RMS deviation from the C-α-atomic positions of Ca^{2+}-discharged obelin versus obelin is only 1.37 Å, which shows the well-conserved structural features between these protein states, the one primed with the 2-hydroperoxycoelenterazine and the other with the bound reaction product, coelenteramide. The coelenteramide is buried in a highly hydrophobic cavity situated at the center of the protein structure in the same place as its precursor 2-hydroperoxycoelenterazine, again surrounded by residues from each of the eight helices of the protein. This solvent-inaccessible cavity apparently provides the necessary environment for efficient generation of the product in the excited state and for its efficient fluorescence.

Since the photoprotein structure hardly changes following its reaction, it indicates that in the EF-hand protein family, the Ca^{2+}-regulated photoproteins belong to the category of Ca^{2+} signal modulators, such as a parvalbumin, rather than to the Ca^{2+} sensors,



Calcium-Regulated Photoproteins, Fig. 2 The three-dimensional structures of obelin (**a**) (PDB code 1QV0) and Ca^{2+}-discharged obelin (**b**) (PDB code 2F8P). The 2-hydroperoxycoelenterazine and coelenteramide molecules are displayed by the stick models in the center of the protein structure; the calcium ions are shown as balls. The 2-hydroperoxycoelenterazine, coelenteramide, and calcium are colored according to the conformation state

of which calmodulin is typical and the best-known representative (Nelson and Chazin 1998). This categorization probably has to do with function where, to be a sensor, protein-protein association is involved, whereas the photoproteins have to operate on the millisecond timescale, enabling just a subtle shift to disturb the hydrogen bond network that triggers bioluminescence.

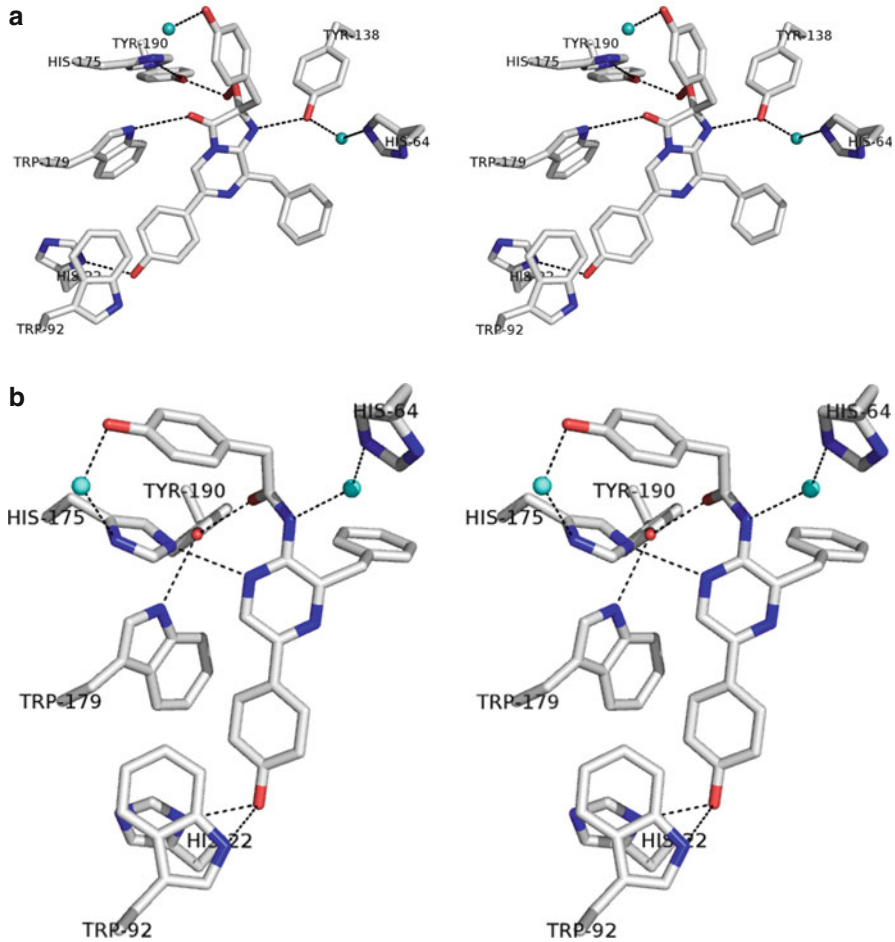


Calcium-Regulated Photoproteins, Fig. 3 Obelin EF-hand Ca^{2+}-binding loops I, III, and IV before bioluminescence reaction (*upper panel*) and after calcium binding (*bottom panel*). The calcium ion and the water molecule are shown as *red* and *green balls*, respectively

A calcium ion is found at each of the expected Ca^{2+}-binding sites, EF-hand loops I, III, and IV. For binding Ca^{2+} into the EF-hand, the 12 residues of the loop shift their positions to accommodate the calcium ion in its preferred configuration (Fig. 3). The typical geometrical arrangement of oxygen atoms in a pentagonal bipyramid is observed with the Ca^{2+} occupying the center of the pyramid. All three Ca^{2+}-binding sites of the photoprotein contribute six oxygen ligands to the metal ion, derived from the carboxylic side groups of Asp and Glu residues, the carbonyl groups of the peptide backbone, or the side chain of Asn, and the hydroxyl group of Ser, all with a coordination distance of ≈ 2.4 Å. The seventh ligand comes from the oxygen of a water molecule. Based on studies of the EF-hand Ca^{2+}-binding proteins from different sources, it has been observed that high-affinity Ca^{2+}-binding sites have either no water or at most one water ligand (Strynadka and James 1989). The three Ca^{2+}-binding sites of the Ca^{2+}-discharged obelin each contain only one water molecule as a ligand, suggesting that they all should have high affinity for calcium.

The residues comprising the binding cavity, that is, within 4 Å of the coelenteramide, after the bioluminescence discharge, essentially remain in place compared to their location in the obelin cavity, except Ile142, Ile111, Phe119, Ile142, Ile144, Trp135, and Tyr138, which are displaced, and Phe28, Gly143, and Thr172, which move into the cavity. As in obelin, there are two water molecules in the cavity of the discharged protein, but they are repositioned.

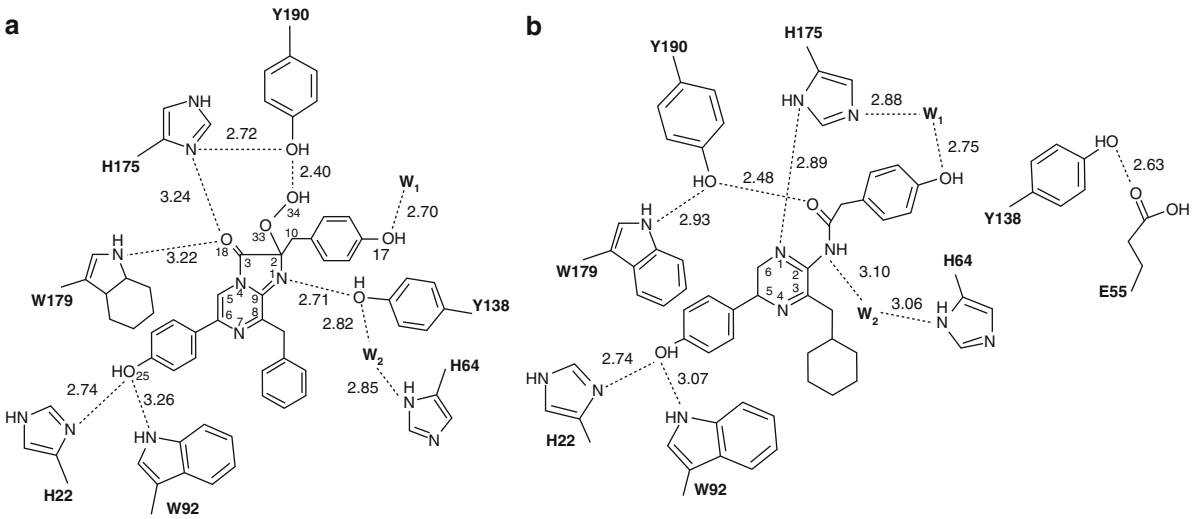
Aside from the loss of CO_2 from the chemical decomposition of coelenterazine, the biggest change in its molecular structure is in the reaction center around the C-2 position (C-2, O-33, and C-10) and C-8, resulting in an obvious deviation of the orientation of the phenol group at the C-10 position and the phenyl group at the C-8 (Fig. 4). Other parts of the



Calcium-Regulated Photoproteins, Fig. 4 Stereoview of the substrate-binding cavity with key residues of obelin before (**a**) (PDB code 1QV0) and after bioluminescent reaction (**b**) (PDB code 2F8P). Hydrogen bonds and the water molecules are shown with *dashed lines* and as *cyan balls*, respectively

molecule also adjust positions a little but not dramatically. His22 and Trp92, which were in hydrogen bond distances with the oxygen of the 6-(*p*-hydroxyphenyl) group of coelenterazine before reaction (Fig. 5a), are at practically the same distances to coelenteramide in the product cavity (Fig. 5b). In obelin, the Nε atom of Trp179 is 3.32 Å from the C3-carbonyl oxygen, but after reaction, this residue is moved in the direction of Tyr190 with formation of a new hydrogen bond to it. The Tyr190 OH group, which apparently stabilizes the 2-hydroperoxy group of coelenterazine in obelin by a hydrogen bond and is also hydrogen bonded to His175, is also slightly repositioned in the Ca^{2+}-discharged protein. The hydrogen bond to His175 is lost, but a new hydrogen bond develops to the carbonyl of coelenteramide. There is a major reorientation of the His175 with its imidazole ring now almost perpendicular to the original orientation (Vysotski and Lee 2007). His175 also forms new hydrogen bonds with the N1 atom of coelenteramide and the water molecule W_1 (Figs. 4b and 5b). Tyr138 is moved out of the binding cavity (Fig. 4a, b). The hydrogen bond from Tyr138 originally to the N1 of coelenterazine (Fig. 5a) now goes to Glu55 (Fig. 5b), and the Tyr138 appears to be replaced by that water molecule (W_2) originally connecting Tyr138 to His64 (Fig. 5a). As a result, the His64 is also slightly shifted toward coelenteramide. The second water molecule (W_1) is also moved, apparently after the change in position of the 2-(p-hydroxybenzyl) group. Thus, only His175 and Tyr138 undergo a noticeable repositioning in the binding cavity after the bioluminescence reaction.

In any protein crystal structure, hydrogen bonds are inferred if the separation of a putative H-donor and acceptor is less than about 3 Å, and in Fig. 5a, these inferred H-bonds are indicated by the dotted lines between the donor atom and the acceptor. The 2-hydroperoxycoelenterazine is not stable in free



Calcium-Regulated Photoproteins, Fig. 5 Two-dimensional representation to illustrate the hydrogen bond (*dashed lines*) network in the binding cavities of obelin (**a**) and Ca^{2+}-discharged obelin (**b**)

solution but in the hydrophobic environment of the binding site, the hydroperoxide group appears to be stabilized by the H-bond to Tyr190. In turn, there is an H-bond from Tyr190 to His175. This same arrangement is seen in other Ca^{2+}-regulated photoproteins: aequorin (PDB code 1EJ3), obelin from *O. geniculata* (PDB code 1JF0), and clytin (PDB code 3KPX).

The H-bond distance between Tyr190 and His175 is 2.72 Å (Fig. 5a), which is indicative of an H-bond with moderately strong electrostatic character. The hypothetical mechanism of the Ca^{2+} trigger (Vysotski and Lee 2004, 2007) is that as a direct result of Ca^{2+} binding, the H-bond between Tyr190 and His175 becomes stronger, increasing the electrostatic contribution, being equivalent to saying that the His175 becomes partially protonated. Because the tyrosine and hydroperoxide have similar p*K*s around 10, there will be a probability that the hydroperoxide will protonate the tyrosinate, and the peroxy anion then has another probability of irreversible nucleophilic addition to the C3-carbon of coelenterazine to form the committed dioxetanone intermediate. The exergonicity of this last step provides the thermodynamic feasibility of the overall process.

In the family of EF-hand calcium-binding proteins, the bound calcium ion is found associated specifically in a consensus sequence in the loop region of the helix-turn-helix motifs. In practice, the identification of the bound Ca^{2+} is by its strong electron density and, as well in almost all cases, by a bipyramidal pentagonal coordination with a bond length close to 2.4 Å, between the central atom and the coordination partner (Strynadka and James 1989; Nelson and Chazin 1998). The recent crystal structures of Ca^{2+}-discharged obelin, apoobelin, and apoaequorin bound with calcium, indicate adherence to these average bond length specifications.

In the published spatial structures of photoproteins, the loop structures are not prepositioned for calcium binding; that is, especially in the C-terminal loop III and IV, some movement of the residues must occur on Ca^{2+} binding to happily accommodate the coordinating atoms to the required 2.4 Å separation. In photoproteins, the first step in the generation of high-intensity bioluminescence must obviously be the binding of Ca^{2+} to the loops within the EF-hands. The Tyr138, His175, and Trp179 within the exiting helices of loops III and IV as well as Tyr190 have critical proximity to the substrate in the reactive center. Therefore, any conformational adjustment in the binding loops accompanying Ca^{2+} binding (or even spontaneous motions of the residues) can be expected to propagate into shifts of the hydrogen bond donor-acceptor separations around the coelenterazine, the ones apparently essential for the hydroperoxide stability, the networks O34, Tyr190, His175, O18, and N1 to Tyr138. Because the p*K*s of the tyrosine hydroxyl and the hydroperoxide are very close, as already noted, and the position of His175 is poised to act as a general base, the destabilization of the substrate is thereby triggered.

To initiate the shift of hydrogen donor-acceptor separations, the small spatial shift of the exiting α-helix of loop IV will be enough, since most of the residues mentioned above, including His175 which is the key residue, are found in this α-helix. The notion that a His residue in this position is very important for photoprotein activity is supported by substitution of this residue in aequorin to Ala, Phe, or Trp which leads to complete loss of activity. The suggestion that His175 can be the key residue for Ca^{2+} triggering of bioluminescence is also supported by the finding that in the crystal structure of Ca^{2+}-discharged obelin, the imidazole ring of this residue changes orientation to become almost perpendicular to its initial state. The process of hydrogen donor-acceptor separation may be fast and will be irreversible because it initiates the chemical reaction of coelenterazine decarboxylation, and its rate would then be independent of calcium concentration.

Applications of Calcium-Regulated Photoproteins

The mainstream applications of Ca^{2+}-regulated photoproteins take advantage of their inherent property to emit light on calcium binding. Owing to this property and because photoproteins are highly sensitive for detecting calcium and harmless when injected into living cells, they have been widely used as probes of cellular Ca^{2+}, both to estimate the intracellular Ca^{2+} concentration under steady-state conditions and to study the role of calcium transients in the regulation of cellular function. To estimate [Ca^{2+}], purified natural photoproteins were delivered into the cell via labor-intensive procedures, such as microinjection or liposome-mediated transfer. Aequorin was more available and consequently has come to be commonly employed in measuring intracellular [Ca^{2+}] notwithstanding its drawbacks.

Figure 6 shows Ca^{2+} concentration-effect curves for the recombinant photoprotein from *O. geniculata*, determined under conditions of pH and ionic strength likely to be encountered inside cells, in the absence and presence of 1 mM Mg^{2+}. The curves are log-log plots in which light intensities have been expressed in terms of a ratio that we have termed the fractional rate of discharge (L/L_{int}) (Markova et al. 2002). Under physiological conditions, the level of photoprotein luminescence rises rapidly as [Ca^{2+}] is increased over the range 0.1–100 μM. The curve spans more than a million-fold range of light intensities. Therefore, in order to use photoprotein in the lower part of its range of sensitivity, one must pay close attention to maximizing the recorded signal. There is a natural limit to the extent to which one can reduce the threshold of detectability for [Ca^{2+}] however, and that is imposed by the fact that the Ca^{2+} concentration-effect curve flattens out at very low [Ca^{2+}]. That is, there is a very low level of Ca^{2+}-independent luminescence. This fact has the obvious practical consequence that, under physiological conditions (Fig. 6), it is virtually impossible to detect calcium below about 10^{-8} M by means of wild-type photoprotein. From the theoretical point of view, it means that calcium ion should not be viewed as an indispensible ingredient in the chemical reaction leading to luminescence but as a factor that greatly accelerates the reaction (Blinks et al. 1982).

Another highly significant feature of the Ca^{2+} concentration-effect curve is the steepness of its midportion. The maximum slope has been found to be approximately 2.5 on log-log plots such as those of Fig. 6. This feature also has important implications from both theoretical and practical standpoints.

The most important theoretical implication is that more than two (i.e., at least three) calcium ions must interact with each photoprotein molecule in the control of the luminescent reaction (Blinks et al. 1982). This early proposition was subsequently confirmed by the spatial structure of Ca^{2+}-discharged photoprotein because calcium ion has been found in each Ca^{2+}-binding site of the photoprotein (Vysotski and Lee 2007). From the practical standpoint, the steepness of the curve means that changes in light intensity will give an exaggerated impression of the changes in $[Ca^{2+}]$ responsible for them. It should also be obvious from the Ca^{2+} concentration-effect curve that the photoproteins are not well suited to the measurement of free calcium concentrations in the range (mM) likely to be encountered in extracellular fluids or secretions, although their use for this purpose has been proposed.

The Ca^{2+}-regulated photoproteins are not uniquely sensitive to Ca^{2+}. A number of other di- and trivalent cations (e.g., Yb^{3+}, La^{3+}, Sr^{2+}) are capable of stimulating luminescence. For instance, all of the lanthanides that have been tested are more potent than Ca^{2+} in stimulating aequorin luminescence, and the maximum light intensity that they produce is either equal to (e.g., Yb^{3+}) or only slightly lower (e.g., La^{3+}) than that observed with Ca^{2+} (Blinks et al. 1982). However, calcium is the only ion likely to be found in living cells in sufficient quantities to trigger luminescence.

From the standpoint of intracellular measurements, free magnesium ion concentration is the most important factor known to influence the sensitivity of photoproteins to Ca^{2+}. In the case of aequorin, Mg^{2+} within the range of concentrations (in the vicinity of 1 mM) that likely might be encountered inside living cells reduces Ca^{2+}-independent luminescence and sensitivity to calcium, that is, shifts the Ca^{2+} concentration-effect curve to the right (Blinks et al. 1982). However, it may be not so critical for other photoproteins because for obelin, for example, the effect of Mg^{2+} is much less pronounced than on aequorin bioluminescence. A concentration of 1 mM Mg^{2+} has no effect on the Ca^{2+}-independent luminescence or the Ca^{2+} sensitivity (Fig. 6); only a nonphysiological concentration of magnesium ion of 10 mM produces a modest rightward shift of the Ca^{2+} concentration-effect curve. Another effect of Mg^{2+} on the luminescence of the obelin is more evident. Magnesium ions, even at 1 mM concentration, produce a decrease in maximum level of luminescence attainable under the influence of Ca^{2+}, and this effect cannot be surmounted by increases in $[Ca^{2+}]$ (Markova et al. 2002).

In fact, the Ca^{2+}-regulated photoproteins were the first intracellular calcium probes, and they were employed for measurement of calcium in cells for more than 40 years. However, the development of fluorescent dyes for detection of intracellular calcium, which have simplified the measurement procedure, essentially supplanted photoproteins. The successful cloning of cDNAs encoding apophotoproteins has opened new avenues for utilizing photoproteins, by expressing the recombinant apophotoprotein intracellularly, then adding coelenterazine externally which diffuses into the cell and forms the active photoprotein. Such cells and whole organisms have, in effect, a "built-in" calcium indicator. This technique is highly valuable because it does not require laborious procedures such as microinjection. To date, various types of cells expressing the apophotoprotein gene have been constructed, including mammalian and insect cells, bacteria, yeasts, plants, and fungi. They are widely employed in the studies of Ca^{2+} homeostasis in cells and the effect of various compounds. The application of such cells takes advantage of the fact that the light emission reports changes in intracellular Ca^{2+}, in particular those mediated by the interaction of various agonists and antagonists with cell receptors. Consequently, these mammalian cell lines are widely employed in high-throughput screening of new drugs, for instance, various chemical compounds affecting G-protein-coupled receptors, tyrosine kinase receptors, and ionic channels (Dupriez et al. 2002).

The most attractive and, probably, the most substantial idea was to selectively direct a photoprotein to individual cell compartments for local measurement of calcium. To direct a Ca^{2+}-regulated photoprotein to a necessary cell compartment, a chimeric DNA is constructed to fuse the apophotoprotein gene to a sequence encoding a molecular address, which might be either short amino acid sequences directing proteins to specific organelles or full-size proteins with known cell localization. For instance, for measurement of calcium in mitochondria, the N-terminus of aequorin has been fused with a cytochrome *c* oxidase fragment, consisting of the cleavable mitochondrial targeting signal and the first six residues of the enzyme. To monitor $[Ca^{2+}]$ in the intermembrane space of mitochondria, aequorin was linked with the

C-terminus of glycerophosphate dehydrogenase, which is located in the inner mitochondrial membrane with its C-terminus directed toward the intermembrane space. Similar approaches have been used to produce probes for measurement of [Ca^{2+}] in the nucleus, sarcoplasmic reticulum, and Golgi apparatus. Since Ca^{2+} concentration varies considerably among cell compartments and the role of local changes of [Ca^{2+}] in regulation of cell events is still not completely understood, the opportunity to measure local calcium concentrations gives unquestionable advantages for photoproteins with respect to fluorescent dyes, which are distributed throughout the cell, consequently allowing only an averaged estimation of [Ca^{2+}].

Assay of intracellular [Ca^{2+}] does not exhaust the applications of Ca^{2+}-regulated photoproteins; in many studies, it has been demonstrated that photoprotein is a very promising label for various in vitro assays. There are several factors accounting for that: (1) The sensitivity of analysis is comparable with that of radioisotope methods because photoprotein can be detected in attomole amounts using modern luminometers. (2) A background signal is practically absent because of the high selectivity of photoproteins to Ca^{2+}. (3) The light signal linearly depends on the photoprotein concentration throughout a virtually unlimited range. At a saturated [Ca^{2+}], the light intensity is in direct proportion to the protein amount because the photoprotein is the only molecule directly involved in the bioluminescent reaction. (4) The bioluminescent reaction is easy for triggering due to a lack of additional substrates and cofactors, and it is fast (reaction ceases within several seconds). (5) Photoproteins are not toxic. (6) Photoproteins are available because *E. coli* strains producing recombinant apophotoproteins have been constructed, and efficient procedures for their purification have been developed. (7) Photoproteins are stable upon storage in solution, lyophilization, and chemical or genetic modifications. These properties of photoproteins are very advantageous for their use in clinical diagnostics, for example, in ELISA and hybridization assays. To date, photoprotein-based reagents have been applied to the assay of numerous analytes of diagnostic value (hormones, proteins, etc.) and, conjugated to oligonucleotides, as a DNA probe for detection of specific nucleotide sequences. Direct comparison of hybridization assays utilizing different labels has shown that the use of a photoprotein increases the sensitivity of an analysis by 2–3 orders of magnitude. In turn, this makes the analysis more sensitive and less time-consuming.

Synonyms

EF-hand superfamily = Calmodulin superfamily = Troponin superfamily

Definitions

EF-hand: Helix-loop-helix motif obeying a 29-residue consensus sequence with hydrophobic and Ca^{2+}-ligating residues in defined positions, typically forming a pentagonal bipyramidal coordination sphere

Ca^{2+}-signaling proteins: Proteins for which Ca^{2+} binding preferentially stabilizes a form that activates other proteins

Domain: Independent folding unit

Chromophoric chelator: A metal-binding dye which changes its optical spectrum upon chelation

Discovery

The discovery of calmodulin (CaM) was reported in 1970 independently by Cheung and by Kakiuchi, Yamazaki, and Nakajima. They found that cyclic nucleotide phosphodiesterase was modulated by a Ca^{2+}-dependent activator protein, which was named calmodulin for *cal*cium-*modul*ated prote*in*.

Prevalence

CaM is a 17-kDa protein ubiquitously expressed in eukaryotic cells constituting at least 0.1% of total cellular protein, with higher abundance in brain and testes. The ubiquitous expression highlights the fundamental role of CaM in calcium homeostasis, further underscored by the observation that gene knockouts are lethal.

Sequence

The amino acid sequence of CaM is extremely conserved; the exact same protein sequence is found in all vertebrates, and the human genome contains three genes that encode an identical CaM sequence characterized by a high prevalence of acidic residues and dominated by four EF-hand motifs connected by linking segments. The vertebrate sequence is shown below with the four EF-hand loops underlined and other residues in consensus sequence positions in bold. The stars indicate positions responsible for the specificity of EF-hand pairing (seebelow).

Highly similar sequences are found also in yeast, drosophila, and plants. Point mutations have been studied in Drosophila but are lethal. Plants, in contrast to mammals, have a number of CaM genes coding for proteins of varying sequence (84–100% identity).

Posttranslational Modifications

Known posttranslational modifications include trimethylation of lysine 115 and oxidation of methionines. The loops of EF2 and EF3 contain classical deamidation sites (NG). There is evidence that

a fraction of cellular CaM is constitutively phosphorylated in vivo. Phosphorylation in vitro by several kinases has been observed at Thr-26, Thr-29, Thr-79, Ser-81, Tyr-99, Ser-101, Thr-117, and Tyr-138.

The EF-Hand

The EF-hand and C2 motifs are the two most common motifs found in Ca^{2+}-binding proteins. The Ca^{2+} ion is rather flexible in its requirements for the geometry and number of coordinating oxygens. In the EF-hand, there are seven coordinating oxygens arranged as a pentagonal bipyramid. Receiving its moniker from the E and F helices in parvalbumin, the first EF-hand protein for which a high-resolution structure was solved by Kretsinger, the motif consists of a helix followed by a loop and then another helix. The EF-hand loop comprises 12 residues, although residues 1 and 12 are part of the entering and exiting helices. In the bound state, Ca^{2+} is coordinated by side-chain carboxyl or amide oxygens of residues 1, 3, 5, and 12 and the main-chain carbonyl oxygen of residue 7. Position 1 is most strictly conserved as an aspartate. Positions 3 and 5 are typically aspartate or asparagine but sometimes serine. The side-chain carboxylate in position 12 (glutamate or aspartate) acts as a bidentate Ca^{2+} ligand providing both its oxygens to Ca^{2+} chelation. The side-chain in position 9 may complete the Ca^{2+} coordination sphere, but more often, this residue is hydrogen-bonded to a water molecule which coordinates Ca^{2+}. The highly conserved glycine at position 6 allows for a turn to assemble the two halves of the loop in tight Ca^{2+} coordination. Proteins with EF hands constitute the EF-hand superfamily, also called the calmodulin superfamily or troponin superfamily. Whereas some proteins contain variant EF hands, CaM has four canonical EF hands that fulfill the consensus sequence at nearly all positions (see above).

EF-Hand Pairing

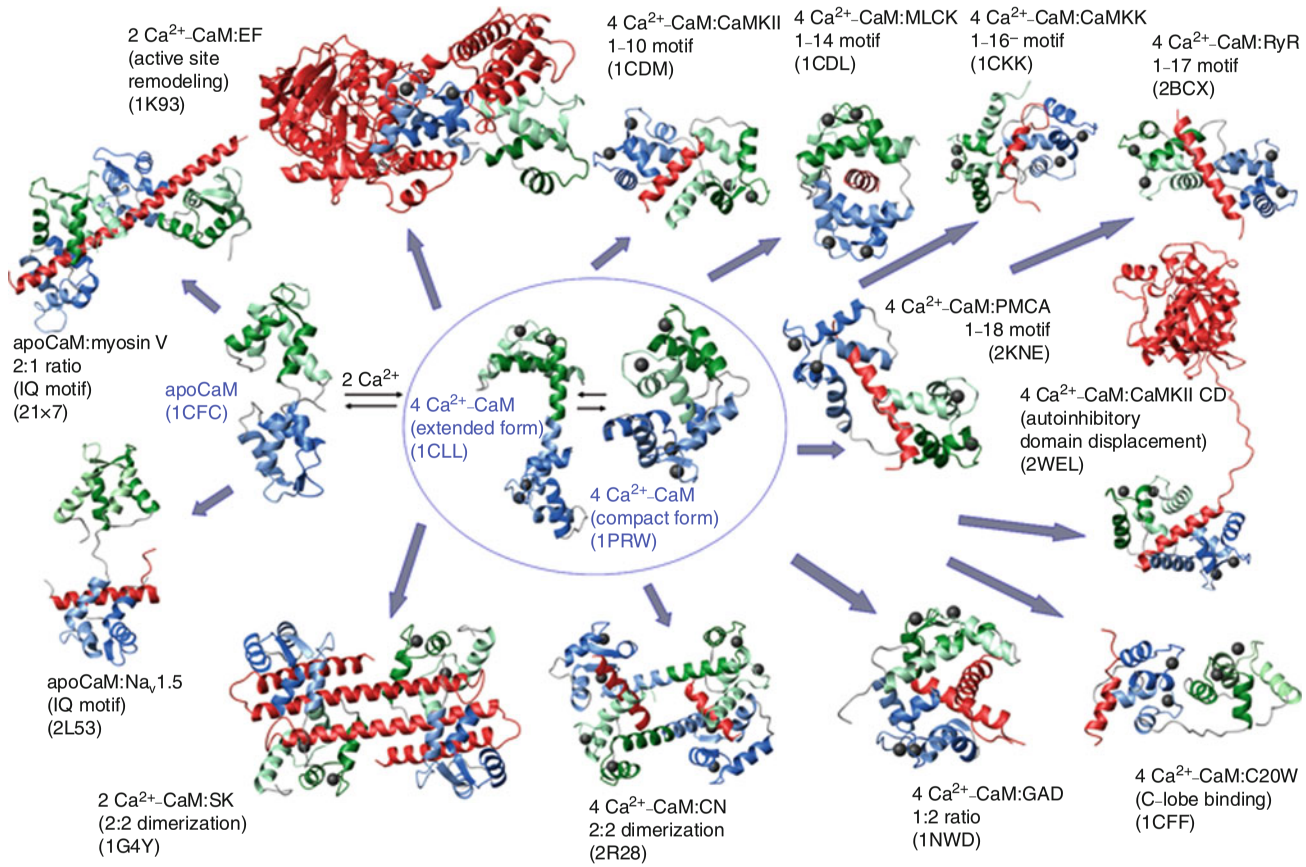
While some proteins contain a single or an odd number of EF hands, the most common structural feature is the EF-hand pair which may form a two EF-hand domain or be part of a larger domain with more EF hands. A significant hydrophobic surface area is buried in the interface between the two EF hands in each pair. A short two-stranded β-sheet connects the paired loops centered around their respective residue 8 with their bulky hydrophobic side chains interacting in the hydrophobic core. When excised from the protein, an EF hand may form homodimers, but with many orders of magnitude lower affinity (e.g., EF3-EF3 and EF4-EF4 of CaM versus EF3-EF4). The heterodimer over homodimer specificity is governed by electrostatic repulsion within one homodimer (EF4-EF4) and three hydrophobic positions which form one aromatic (F89, Y138, F141) and one aliphatic (A102, L105, I125) cluster (Linse et al. 2000; Fig. 3).

Structure

Since the late 1970s, a wealth of biochemical evidence demonstrated that CaM contains two independent folding units, each containing two EF hands. The first crystal structure of Ca^{2+}-loaded CaM revealed a dumbbell-shaped protein in which two globular domains are separated by a central helix (Babu et al. 1988; Fig. 1). The four EF hands are in a helix-loop-helix conformation, and a number of hydrophobic side chains are exposed at the base of each globular domain. The structure of vertebrate CaM was subsequently confirmed and refined by several investigators. NMR studies have revealed that in solution, the central helix is interrupted in the middle with a short flexible linker which allows the two globular domains to move relative to one another. In one crystal form, a compact conformation of CaM was selected by the crystallization procedure, indicating a conformational heterogeneity of the relative domain orientation in solution, supported by single-molecule Förster resonance energy transfer (FRET) studies. With the data available today, it seems most likely that the linker between the domains is flexible and samples multiple conformations including both extended and collapsed overall structures.

Stability Toward Denaturation

CaM has been optimized by evolution for stability and solubility to allow for high concentration in the cell. The highly negative net surface charge prevents aggregation and keeps the protein soluble at concentrations up to 5 mM (90 g/L). The Ca^{2+}-bound state is so stable that thermal denaturation occurs above 100°C; thus, boiling is used as an efficient purification step. The globular domains can be produced by proteolysis or cloning as separate fragments which are also very stable and do not denature upon boiling in the Ca^{2+} state. The stability toward thermal and chemical denaturation is substantially reduced upon Ca^{2+} release. In the apo state, the domains have similar midpoints for



Calmodulin, Fig. 1 Structural models of calmodulin in its apo, calcium-bound, and target-complexed states. In each structure, the N-terminal domain of CaM is green (EF1 in *light green*), the C-terminal domain is blue (EF3 in *light blue*), Ca^{2+} ions are grey, and target peptides and proteins are *red*. The apo-CaM structure presented is one model from an ensemble of NMR structures, in which the two domains are found in variable relative orientations. Two forms of Ca^{2+}-bound CaM are shown, which likely exist in equilibrium. On the left are Ca^{2+}-independent complexes of apo-CaM with IQ motifs from myosin V and the voltage-gated sodium channel ($Na_V1.5$), followed by Ca^{2+}-dependent target complexes in which CaM is not fully saturated with Ca^{2+}, including *Bacillus anthracis* edema factor (EF), and a peptide from the small conductance Ca^{2+}-activated potassium channel (SK). Target complexes in which CaM is fully Ca^{2+}-bound include (clockwise from top) peptides from calmodulin-dependent kinase II (CaMKII), myosin light-chain kinase (MLCK), CaM-dependent kinase kinase (CaMKK), ryanodine receptor (RyR), plasma membrane Ca^{2+} ATPase pump (PCMA), plasma membrane calcium pump (C20W), petunia glutamate decarboxylase (GAD), and calcineurin (CN). The catalytic and regulatory domain of CaMKII in complex with Ca^{2+}/CaM is shown on the right. The Protein Data Bank (PDB) code for the structural coordinate file is given next to each structure, along with the type of motif and/or mechanism of target activation. More information on these structures and literature references can be obtained from www.rcsb.org/pdb

thermal denaturation as the intact protein, with the N-terminal domain (thermal denaturation midpoint $T_m = 49°C$) slightly more stable than the C-terminal domain ($T_m = 46°C$) (Brzeska et al. 1983; Fig. 2).

Structural Transitions Due to Ca^{2+} Binding

Ca^{2+} binding leads to a large conformational change in each globular domain of CaM. This conformational change is key to the biological role of CaM and reveals the binding sites for target proteins (Zhang et al. 1995). The bidentate Ca^{2+}-coordinating carboxylate in position 12 of the EF-hand loop plays an important role in this transition from a closed apo state to a more open Ca^{2+}-bound state. The structural switch propagates from small alterations in the loop to a change in interhelical angles. In each domain, there is also a change in the angle between the two EF hands in the pair. The key feature is the exposure of a number of methionine and other hydrophobic residues at the base of each domain, providing an anchoring site for the large hydrophobic residues in target proteins. CaM is a dynamic system, and detailed NMR studies have revealed that the apo state conformational ensemble includes conformations similar to the Ca^{2+}-bound state and that Ca^{2+} binding shifts the ensemble toward those conformations (Evenäs et al. 2001).

Ca^{2+}-Binding Properties

CaM contains four Ca^{2+}-binding sites of physiological relevance. Each EF hand provides one of these sites. The Ca^{2+} affinity is ca. sixfold higher for the C-terminal compared to N-terminal domain (Linse et al. 1991; Fig. 2). At physiological KCl concentration, the average dissociation constant is $K_D = 3.5$ µM

for the C-terminal sites and 22 μM for the N-terminal sites. Within each domain, the two Ca^{2+} ions are bound with positive cooperativity. Moreover, the Ca^{2+}-binding properties of each domain fragment is essentially the same as when the domain is part of the intact protein. In the presence of a bound target protein or peptide, the affinities are significantly increased, and the saturation curve is shifted toward lower Ca^{2+} concentration (Bayley et al. 1996).

CaM is optimized not for the highest possible Ca^{2+} affinity but for the most suitable affinity for its cellular functions. At physiological salt concentration, the enthalpy of Ca^{2+} binding is positive, thus unfavorable. Exposure of hydrophobic surface gives an unfavorable entropic contribution from ordering of water molecules. The free energy of Ca^{2+} binding is in fact dominated by the entropic gain from the release of water molecules that hydrate the Ca^{2+} ion in the unbound state. CaM is an intricate example of a protein that "uses" part of the available free energy for binding a small cofactor (metal ion) to drive a conformational change, which lowers the overall Ca^{2+} affinity but gives the system a regulatory capacity with huge biological impact. Proteins with higher Ca^{2+} affinity, for example, calbindin D_{9k}, parvalbumin, and the amylases, have a larger degree of preorganization of the protein, smaller conformational change, and/or fewer water molecules in the Ca^{2+} coordination sphere.

The rate of Ca^{2+} association is close to diffusion controlled, but the dissociation rates are relatively low, especially for the C-terminal domain with $k^{off} = 24\ s^{-1}$ while for the N-terminal domain $k^{off} = 240\ s^{-1}$, at 0.1 M KCl. (Martin et al. 1985). Because of the high positive cooperativity within each domain, dissociation of the first ion from each domain becomes rate limiting, and the two ions appear to dissociate together.

Mg^{2+} Binding

The EF hand is flexible enough to adapt to coordination of Mg^{2+}, but the affinity is 10^3–10^4-fold lower for Mg^{2+} binding compared to Ca^{2+} binding (Malmendal et al. 1989). Nevertheless, Mg^{2+} is still a relevant intracellular competitor because it is abundant. $[Mg^{2+}]$ is relatively constant around 1–2 mM, while $[Ca^{2+}]$ changes from ca. 100 nM in the resting state to 1–10 μM upon cellular activation. Indeed, in the resting cell, Mg^{2+} does bind to CaM, and the rate of Mg^{2+} dissociation may become rate limiting for Ca^{2+} binding to the regulatory sites.

Other Metal Ions

CaM has high affinity for many other divalent metal ions but also binds mono- and trivalent metal ions like Na^+, K^+, and the lanthanides. The fluorescent ions Tb^{3+}

and Eu^{3+} bind CaM with opposite domain preferences compared to Ca^{2+} and can be used to study ion competition, as well as structural transitions monitored by FRET to the metal ion sites from the tyrosine residues in the C-terminal domains. $^{113}Cd^{2+}$ is a sensitive NMR probe to study structural transitions in CaM. This spin-1/2 nucleus produces narrow NMR lines and superior spectroscopic properties compared to the quadrupolar $^{43}Ca^{2+}$ or $^{25}Mg^{2+}$ ions with very broad signals. ^{113}Cd NMR studies revealed cooperation of the globular domains in target binding (Linse et al. 1986), which was later confirmed by high-resolution structures (below).

Ca^{2+} Signaling Via Calmodulin

Ca^{2+} signaling is fundamentally important in regulating eukaryotic cellular homeostasis. The dynamics of Ca^{2+} signaling are governed by a very steep gradient between extracellular (mM) and intracellular (~100 nM) Ca^{2+} concentration. This gradient allows intracellular Ca^{2+} to fulfill a critical role as a second messenger. The cytosolic Ca^{2+} concentration is exquisitely regulated by the operation of transport systems responsible for its increase and decrease. Influx is through Ca^{2+} channels and $Na^{+}(H^{+})/Ca^{2+}$exchangers in the plasma membrane (PM), the endo(sarco)plasmic reticulum (ER), and/or the mitochondria. Decrease after a Ca^{2+} pulse is due to intracellular Ca^{2+} buffer proteins that bind with higher affinity but lower on rate compared to CaM and to extrusion transport systems represented by Ca^{2+} ATPases in PM and ER and Na^{+}/Ca^{2+} exchanger in PM. These transporter systems give rise to oscillations in the concentration of Ca^{2+} not only in the cytosol but also in the nucleus and intracellular organelles. These oscillations in $[Ca^{2+}]$ are recognized by CaM to mediate changes in gene expression, cell growth, development, cell survival, and cell death.

Target Repertoire

CaM binds to and regulates a very large number of proteins. Several hundred binding targets of CaM are currently known in a fantastic range of organisms spanning the natural kingdom from yeast, insects, plants to mammals based on classical biochemical experiments, affinity chromatography (Berggård et al. 2006; mouse), and more lately protein array screens (O'Connell et al. 2010). The target repertoire includes proteins from all compartments in the cell: cytosolic enzymes, proteins at the cell membrane, intracellular membrane proteins, organellar proteins, and proteins in the nucleus.

There is an entire family of cytosolic enzymes such as the CaM kinases whose activity is controlled by Ca^{2+} CaM. Upon increase in intracellular Ca^{2+}, Ca^{2+} CaM binds to and activates the kinases myosin light-chain kinase (MLCK), calmodulin-dependent kinases I, II, and IV (CaMKI, CaMKII, and CaMKIV), and CaM-dependent kinase kinase (CaMKK). Primary targets of CaMKK are CaMKI (cytosolic) and CaMKIV (nuclear), requiring binding of Ca^{2+} CaM to both CaMKK and CaMKI/CaMKIV (Wayman et al. 2008).

CaM has a large number of membrane protein targets, for example, subunits of the glutamate (NMDAR) receptor and voltage-gated potassium channel receptors (O'Connell et al. 2010; Pitt 2007). The role of these receptors in excitatory activity is fundamentally important in development of learning and memory and provides an excellent example of the regulation and propagation of a Ca^{2+} signal into the cell to achieve higher-order effects. NMDAR activity leads to an increase in intracellular $[Ca^{2+}]$, and binding of CaM to motifs in the cytoplasmic tails of the receptor regulates channel activity.

In several membrane proteins, including sodium and potassium channels, CaM has more than one interaction site in the cytoplasmic domain. One binding site is Ca^{2+} independent, serving to prelocalize CaM to the receptor, and the Ca^{2+} signal leads to binding of an additional receptor motif resulting in translocation and regulation. The voltage-gated potassium channel KCNQ1 is the pore-forming subunit regulating cardiac muscle function. CaM interacts with multiple sites in the cytoplasmic region of KCNQ1, including two IQ motifs (Pitt 2007), and is critical for the current through the channel.

CaM regulation of ion channels in the cell membrane underpins learning and memory, and nuclear CaM is critical in the formation of long-term memory in several animal species. The phosphorylation of Ser 133 of the transcription factor CREB is critical for its activation and is rapidly induced by brief synaptic activity in hippocampal neurons. A highly local rise in Ca^{2+}-ion concentration near the cell membrane causes a swift (~1 min) translocation of CaM from the cytoplasm to the nucleus, which culminates in activation of CaMKIV and phosphorylation of CREB. Translocation of CaM provides a form of

cellular communication that combines the specificity of local Ca^{2+} signaling with the ability to produce action at a distance (Deisseroth et al. 1998).

Especially intriguing is the interaction of CaM with proteins that control cellular Ca^{2+} flux and refilling of the internal stores through which CaM regulates its own activity. In store-operated calcium entry (SOCE), ER luminal Ca^{2+} store depletion leads to the formation and opening of highly selective PM Ca^{2+} channels that facilitate a sustained increase in cellular [Ca^{2+}] crucial for stimulating a cellular response (e.g., transcription activation) and for replenishing the ER stores. CaM is repeatedly identified to interact with the ER membrane proteins stromal interaction molecule 1 and 2 (STIM1 and 2). ER luminal Ca^{2+} depletion results in significant redistribution of STIM1 from homogeneous dispersion on the ER membrane to specific cluster sites at ER–PM junctions. The movement of STIM1 to the discrete ER–PM cluster sites facilitates the recruitment of the Orai1 component of the CRAC channel (Ca^{2+} release-activated Ca^{2+} channel) to the same junctions, a requisite for the sustained SOCE/CRAC entry. A lysine-rich region of STIM1 at the carboxyl terminal region may communicate with the Orai1 N-terminal pro-rich region, permitting the interactions which activate SOCE/CRAC entry while also targeting STIM1 to ER–PM junctions. This lysine-rich region of both STIM1 and STIM2 binds to CaM in a Ca^{2+}-dependent manner with dissociation constant in the nanomolar range (Bauer et al. 2008). This may implicate CaM in regulating STIM action in the ER–PM cooperation during SOCE.

Regulation and Competition

One of the most intriguing problems regarding CaM action is how one signal, the intracellular Ca^{2+} concentration, can be translated into the regulation of numerous targets in vivo. One possible mechanism relies on the frequencies of Ca^{2+} oscillations (Dolmetsch et al. 1998). Since Ca^{2+} oscillations occur on a rather fast time scale (seconds or faster), CaM binding of targets does not reach equilibrium during or between pulses. Thus, the binding kinetics and the local concentration of CaM and targets will determine the outcome of a Ca^{2+} oscillation train. To fine-tune the response to an oscillation, the concentration of target proteins is controlled spatially and temporally, while affinities and kinetics can be modified by phosphorylation of binding sequences. Another possible mechanism relies on "prelocalization" of CaM to Ca^{2+}-independent IQ motifs of certain targets such that they compete more effectively for CaM against the manifold of targets upon Ca^{2+} influx.

Electrostatic Interactions

CaM is a highly charged protein. At neutral pH, the apo protein has a net charge of −24, evenly distributed over the two globular domains, which changes to −16 when four Ca^{2+} ions are bound. The net negative charge makes the Ca^{2+} affinity and exchange rates strongly dependent on ionic strength and gives upshifted pKa values of ionizable side chains. Within each domain, there is marked charge separation between the two EF hands, as seen in several other proteins (Linse et al. 2000). In the Ca^{2+}-bound C-terminal domain, EF3 has zero net charge, whereas EF4 has net charge −7. This minimizes electrostatic repulsion between the EF hands, governing domain stability. Charge separation also governs the specificity of EF-hand pairing (EF3–EF4) due to electrostatic repulsion within the EF4–EF4 pair.

Anomalous Electrostatic Effects and Charge Regulation Mechanism

CaM–target interactions occur between two highly and oppositely charged species. CaM-binding segments typically carry a net positive charge, often as high as +6 to +8 over some 20 residues. High-resolution structures reveal a number of close contacts in which negatively charged side chains of CaM are in close proximity of positively charged residues in targets. However, addition of salt to screen electrostatic interactions actually increases the affinity between CaM and target peptide (André et al. 2006; Fig. 2), and disruption of ionic interactions by mutation or pH variation has very little effect on the affinity between CaM and peptide (André et al. 2004; Fig. 2). Peptides with +4 and +8 net charge have the same affinity, and a large change in the net charge of Ca^{2+}-loaded CaM is required for any measurable effect on peptide affinity. Thus, in this highly charged system, individual charges lose importance. This insensitivity is due to a charge regulation mechanism, which involves pKa-value modulation upon complex formation. The pKa values of ionizable groups in CaM shift closer to normal values upon target binding. Likewise, the downshifts of pKa values in the positive target are reduced upon CaM binding. In a more moderately charged system

(e.g., CaM at pH 5 and a +4 peptide), electrostatic effects are normalized, and a monotonous decrease in affinity is observed upon increased ionic strength (Fig. 2).

Ca^{2+}-Dependent Target Motifs

Ca^{2+}-dependent targets can be classified according to the relative position of two hydrophobic residues that anchor the two lobes of CaM. The first high-resolution structures of CaM complexed with peptides derived from skeletal and smooth muscle MLCK revealed helical peptides with two hydrophobic side chains spaced by 14 residues bound by the N- and C-terminal lobes of CaM (Ikura et al. 1992, Meador et al. 1992). This CaM-binding motif called "1–14" (Rhoads and Freidberg 1997) has been found in several other CaM targets, including CaMKIV, calcineurin A, death-associated protein (DAP) kinase, and endothelial nitric oxide synthase (NOS), and may include additional hydrophobic residues in position 5 or 8. In complex with a CaMKII peptide, the two lobes of CaM are bound to more closely spaced hydrophobic residues (10-a.a. apart). This structure identified a class of 1–10 CaM targets, including synapsins and heat-shock proteins, which may have an additional hydrophobic residue in position 4 or 5. The structural plasticity of CaM is further illustrated by the complex with a CaMKK peptide which is bound in opposite orientation, is not entirely helical, and has more widely spaced hydrophobic anchors (1–16). The anchor for the N-lobe is a Trp residue on an 11-residue helix, whereas the C-lobe is anchored by a Phe residue found on a hairpin structure that folds back on the helix. This mode of 1–16 binding has only been observed for CaMKK homologues. The plasma membrane calcium pump has a 1–14 motif but is unusual in that it can be activated by an isolated C-lobe fragment of CaM. A peptide from the N-terminal portion of the CaM-binding region ("C20W") representing a splice variant of the pump binds to the C-terminal lobe of CaM while the linker and N-lobe remain flexible.

Two recent structures illustrate that CaM can extend considerably to accommodate long helical targets. A peptide derived from the ryanodine receptor is bound with hydrophobic anchor residues with "1–17" spacing, and a plasma membrane ATPase (PMCA) pump peptide interacts with CaM through a "1–18" motif. Because these targets are completely helical, the CaM lobes adopt similar relative orientations in the 1–18, 1–14, and 1–10 conformations, although the spacing between the lobes varies by 1–2 helical turns. As a result of the longer spacing in 1–17 and 1–18 motifs, there are few contacts between the two bound lobes of CaM, and much of the target sequence remains exposed to solvent.

The plasticity of CaM in binding to variably spaced anchors in single helices is due to the flexibility of the linker connecting the globular domains. CaM is also capable of simultaneous engagement of multiple helices. Ca^{2+}/CaM interacts with the C-terminal domain of plant glutamate decarboxylase (GAD) in a novel mode, simultaneously binding two GAD peptides leading to activation through dimerization. Each lobe of CaM binds a helical GAD peptide, and the two lobes are in close proximity making several contacts. The two GAD peptides are perpendicular to each other with two anchors separated by only two residues (1–4). Most CaM targets form helices that engage both lobes of CaM; however, the myristoylated alanine-rich C kinase substrate (MARCKS) is a notable exception. An elongated peptide has a single helical turn bearing a Phe residue that is grasped by the C-lobe hydrophobic pocket. The N-lobe forms a hydrophobic surface interacting with a Leu two residues away from the C-lobe anchor. Plasticity of CaM–target complexes is further highlighted by a 25-residue calcineurin (CN) peptide, which can form both a 1:1 complex with CaM and a domain swapped 2:2 complex in which each CN peptide interacts with the N-lobe of one CaM and the C-lobe of the other.

Ca^{2+}-Independent (Including IQ) Target Motifs

A large number of proteins interact with Ca^{2+}-free (apo) CaM, including myosin, nitric oxide synthase, cyclic nucleotide phosphodiesterase (PDE), phosphorylase kinase, neuromodulin, neurogranin, and IQGAPs. Many of these proteins contain a so-called "IQ motif" comprised of the sequence IQXXXRGXXXR. Apo-CaM binds some target proteins such as neuromodulin only in the absence of Ca^{2+}, whereas others remain associated with CaM in the presence and absence of Ca^{2+}. The CaM-binding region of PDE contains an "atypical" motif, which forms a helix that interacts with both lobes of Ca^{2+}/CaM. In the absence of Ca^{2+}, this peptide is less helical and binds with lower affinity to apo-CaM through the C-lobe only.

Two apo-CaM molecules bind to tandem IQ motifs from myosin V in the absence of Ca^{2+}, and the C-lobe is partially open with a shallow groove that binds the conserved N-terminal IQXXXR portion of the helical IQ motif. The N-lobe remains closed and forms weak interactions with the C-terminal portion of the IQ motif. By contrast, only the C-lobe of apo-CaM binds to an IQ motif from the $Na_V1.5$ channel in a semiopen conformation, and the N-lobe is fully closed and does not interact with target. Complexes of Ca^{2+}/CaM with voltage-activated calcium channel (Ca_V) IQ motifs highlight the remarkable plasticity of CaM, which binds similar IQ domains from Ca_V1 and Ca_V2 with opposite binding orientations.

Structural Plasticity

Several key features underlie the plasticity of CaM in target binding (Yamniuk and Vogel 2004, Ikura and Ames 2006). The C-lobe of apo-CaM samples both closed and open conformations in the absence of Ca^{2+} and is able to bind a subset of target motifs. In the Ca^{2+} state, each hydrophobic pocket is lined by four flexible and polarizable methionines and is structurally adaptable to accommodate a variety of hydrophobic side chains from diverse targets. The flexible interlobe linker allows the two lobes to simultaneously engage hydrophobic anchor residues with widely varied spacing. The remarkable intrinsic plasticity of CaM allows it to recognize a diverse set of target proteins through varied binding modes. This enables a number of fundamentally distinct mechanisms by which CaM can activate its targets, as exemplified below (Fig. 1).

Mechanisms of Target Protein Activation

How can the relatively small protein CaM regulate catalytic activity of a large enzyme by binding to a single helix? Many CaM-regulated enzymes are constitutively regulated by autoinhibitory domains, which are displaced upon CaM binding, activating enzymatic activity. The catalytic domains of CaM-regulated kinases are blocked by pseudosubstrate sequences followed closely by a CaM-binding site. In the resting state, the target motif of CaMKII is unstructured while the inhibitory domain forms a helix that occludes the substrate-binding pocket. Upon binding Ca^{2+}/CaM, the inhibitory domain becomes unstructured and dissociates from the substrate site while the target motif becomes helical. These changes expose the inhibitory region to autophosphorylation, which prevents it from rebinding and generates significant autonomous activity in neuronal cells. In the case of death-associated protein kinase 1(DAPK1), CaM binds its target helix and makes additional interactions with the catalytic domain and blocks the substrate binding site, suggesting that activation of this kinase may require more steps. Furthermore, CaM bound to the catalytic domain construct is significantly more extended than CaM bound to an isolated DAPK1 target peptide. The phosphatase CN also contains an autoinhibitory domain that is displaced by CaM binding, although the arrangement of domains differs from the kinases in that the autoinhibitory domain is C-terminal to the CaM-binding site. Some NOS isoforms are regulated by an autoinhibitory control element (ACE) that blocks the flow of electrons from flavins to heme. CaM binding activates the enzyme by displacing this inhibitory element.

In addition to relieving autoinhibition, CaM can activate target proteins by allosteric mechanisms. *Bacillus anthracis*, the cause of anthrax, secretes a toxic protein called edema factor (EdF), which is an adenylyl cyclase (AC) that converts the host cell's ATP to cAMP. EdF is activated by CaM, which is absent in the bacterium, thus ensuring no toxicity until EdF is released into an infected cell. EdF is activated by a novel mechanism termed "active site remodeling." The lobes of CaM recognize noncontiguous EdF sequences causing a large reorientation of the domains (Drum et al. 2002). The C-terminal lobe is Ca^{2+}-bound and grips a helix of EdF in the canonical manner, whereas the N-lobe is Ca^{2+} free and interacts with EdF in the closed conformation. CaM binds distal to the substrate-binding site of EdF and does not dramatically alter its structure but rather stabilizes the active conformation. *Bordetella pertussis*, the cause of whooping cough, also secretes an AC toxin, called CyaA, which has higher affinity than EdF for CaM and can be activated by the CaM C-lobe alone through a similar mechanism involving stabilization of the catalytic site.

CaM binding to ion channels modulates their gating by inducing dimerization. Small conductance Ca^{2+}-activated potassium (SK) channels are opened by intracellular Ca^{2+} via CaM associating with a cytoplasmic domain C-terminal to the pore. This triggers channel opening in a 2:2 complex. The 96-residue CaM-binding region of SK contains no recognizable CaM target motifs and forms two interacting helices

connected by a loop. Two SK peptides interact through the longer helix to form an antiparallel dimer with a three-helix bundle at each end. In a previously unknown binding mode, the N- and C-lobes of an extended CaM contact different monomers, and each CaM interacts with a total of three helices. Each C-lobe binds one helix in a Ca^{2+}-independent manner while each N-lobe forms Ca^{2+}-dependent interactions with two helices, one from each subunit. It is proposed that through this N-lobe interaction, CaM stabilizes SK dimerization in response to Ca^{2+}, resulting in channel opening.

In contrast to SK channels, Ca_V channels respond to membrane potential, but their opening is modulated by CaM. A 77-residue peptide comprising "pre-IQ" and IQ motifs of the L-type $Ca_V1.2$ channel crystallized as a dimer in complex with four Ca^{2+}-bound CaM molecules. While Ca^{2+}/CaM bound the IQ motifs in a manner observed before, the pre-IQ regions formed a long coiled coil bridged by two Ca^{2+}/CaM molecules, each of which bound one subunit with its C-lobe and the other with its N-lobe, providing another example of channel dimerization. Other Ca^{2+} channels including the IP_3 and ryanodine receptors also bind CaM, yet the mechanisms by which CaM modulates their gating remain elusive.

Calmodulin in Protein Engineering and Biosensor Applications

CaM-GFP-based Ca^{2+} indicators have many advantages over synthetic fluorescent dyes in measuring free Ca^{2+} concentrations in living cells including the onset and termination of Ca^{2+} signaling in specific cellular compartments, such as cytoplasm, nucleus, or endoplasmic reticulum (Miyawaki et al. 1997). In the traditional yellow "cameleon" (YC), cyan fluorescent protein is fused to CaM, the CaM-binding peptide of MLCK and a yellow fluorescent protein. Upon increasing the free Ca^{2+} concentration, the CaM module binds Ca^{2+} and wraps around the fused peptide bringing the GFP variants closer together resulting in increased FRET. The dynamic range is improved by the cameleon YC6.1, in which a peptide from CaMKK is placed between the globular domains of CaM. The high affinity and Ca^{2+} dependence of CaM binding to kinase peptides is also exploited in affinity purification approaches using MLCK peptide as a fusion tag and calmodulin resin for purification.

Calmodulin Literature

Since its discovery in 1970, CaM has been extensively studied resulting in over 34,000 publications by several prominent groups. Only a small fraction is included in the reference list of this chapter.

Synonyms

Calcium-binding proteins; Lectins; Molecular chaperones

Definition

Both of these proteins are present in endoplasmic reticulum that bind to misfolded proteins and assist in their folding and posttranslational modification. Calnexin is an integral membrane protein and endoplasmic reticulum–associated molecular chaperone. Calreticulin is known as a multifunctional Ca^{2+}-binding/buffering endoplasmic reticulum resident chaperone. The protein is responsible for buffering of over 50% of endoplasmic reticulum luminal Ca^{2+} and assisting in folding of newly synthesized glycoproteins.

Background

The endoplasmic reticulum (ER) is a multifunctional organelle responsible for many vital processes in the cell including the synthesis, intracellular transport, and quality control of membrane-associated and secreted proteins; lipid and steroid synthesis; Ca^{2+} signaling and homeostasis; communication with other intracellular organelles including the mitochondria and plasma membrane and ER stress responses. To perform these diverse functions, the ER contains a number of multifunctional integral and resident molecular

chaperones and folding enzymes. Two important proteins in the ER are the key multifunctional lectin-like chaperones calnexin, an integral ER membrane protein, and calreticulin, a resident ER protein.

Calnexin

Calnexin was identified over 20 years ago as a Ca^{2+}-binding phosphoprotein and an ►ER lectin-like molecular chaperone. The amino acid sequence of calnexin is highly conserved between many species, for example, human, rat, mouse, and dog calnexin share 93–98% amino acid sequence identity (Jung et al. 2006). Calnexin homologs are also known in *Saccharomyces cerevisiae, Schisosaccharomyces pombe, Caenorhabditis elegans, Dictyostelium discoideum, Drosophila melanogaster, Ciona savignyi, Ciona intestinalis, and Arabidopsis thaliana* (Jung et al. 2006). The human gene of calnexin is localized on chromosome 5 (5p35) (Jung et al. 2006).

Structure

Calnexin is a 90-kDa type 1 integral membrane protein with a cytoplasmic C-terminal RKPRRE ER retention signal and an N-terminal signal sequence (Jung et al. 2006). The protein consists of four structural and functional domains: the N-globular domain, the P-arm domain, a short transmembrane domain anchors calnexin, and the C-terminal domain extends into the cytoplasm (Fig. 1). The crystal structure of the luminal portion of calnexin has been solved providing important insights into the function of the protein. The N-terminal globular domain of calnexin comprises two regions (residues 1–270 and 418–482) where a concave β-sheet with six strands and a convex β-sheet with seven strands are arranged antiparallel forming a hydrophobic core through interactions between hydrophobic residues (Fig. 1) (Schrag et al. 2001). There is also a disulfide bond within the luminal portion of calnexin formed between C^{161} and C^{195}. This region contains a glucose-binding site which is responsible for the lectin-like properties of calnexin. The carbohydrate-binding site has been mapped, and structural studies have suggested that amino acids M^{189}, Y^{165}, K^{167}, Y^{186}, E^{217}, C^{161}, and C^{195} are involved in substrate binding (Schrag et al. 2001). Recent mutagenesis studies showed that the W^{428}, within the N-terminal region protein, may also affect binding of the glycosylated substrate. The Ca^{2+}-binding site is also localized within the globular domain of calnexin. Ca^{2+} binding to the ER luminal portion of calnexin may play a structural role as the ion-binding site is located at a distance from the carbohydrate site and calnexin is known to undergo Ca^{2+}-dependent conformational changes (Williams 2006). There are also Zn^{2+}-binding sites localized to amino acid residues 1–270, and ion binding results in conformational changes thought to expose hydrophobic substrate binding amino acid residues of the protein. Calnexin also binds ATP which might be required for substrate-calnexin interactions although the binding site of this nucleotide has not yet been identified (Williams 2006). The P-arm domain of calnexin (residues 270–414) forms a structure that consists of an extended and flexible arm (Fig. 1). The P-domain contains four copies of two proline-rich motifs arranged in a linear pattern of 11112222, where motif 1 is PxxIxDPDAxKPEPWDE and motif 2 is GxWxPPxIxNPxYx (Fig. 1). The extended arm forms a long hairpin composed of head-to-tail interactions between a copy of motif 1 and a copy of motif 2. Each of the two repeat motifs has a three residue long β-strand (Schrag et al. 2001). The P-domain of calnexin might be involved in the interaction with other chaperones in the lumen of the ER. One of the best known binding partners of calnexin is oxidoreductase ERp57. Mutagenesis studies have shown that residues located at the tip of the P-domain (W^{343}, D^{344}, G^{349}, E^{352}, and E^{351}) are involved in binding to ERp57 (Coe and Michalak 2010). Although the P-arm domain of calnexin is not directly involved in substrate binding, the P-arm domain enhances the protein folding function of the globular domain. In addition, the P-arm domain may have a role in physically constraining the glycoprotein when bound to the N-domain (Williams 2006).

Amino acid residues 482–502 of calnexin form a transmembrane domain that anchors calnexin to the ER membrane and localizes the whole molecule to the immobile phase of the ER environment. It is unclear as to whether the transmembrane domain may have a role outside of its anchoring function. It has been suggested that the transmembrane domain may promote association of calnexin with membrane proteins by holding calnexin at the ER membrane, or the calnexin transmembrane domain may directly bind the transmembrane domains of substrates (Jung et al. 2006).

The C-terminal domain of calnexin (residues 502–593) forms an acid and charged tail oriented to the cytoplasm (Fig. 1). The function of the charged tail is not well established, but it is known that highly acidic sections of calnexin are high-capacity Ca^{2+}-binding sites. The C-domain of calnexin is phosphorylated at S^{552} and S^{562} by casein kinase II (CDK) and at S^{581} by protein kinase C (PKC) or proline-directed kinase (PDK) (Fig. 1) (Chevet et al. 2010). Phosphorylated calnexin is known to interact with major histocompatibility complex (MHC) class I molecules and affects the transport of MHC class I molecules through the ER (Chevet et al. 2010). The cytoplasmic tail has also been shown to interact with membrane-bound ribosomes, and it has been speculated that this binding may regulate the chaperone activity of calnexin (Jung et al. 2006).

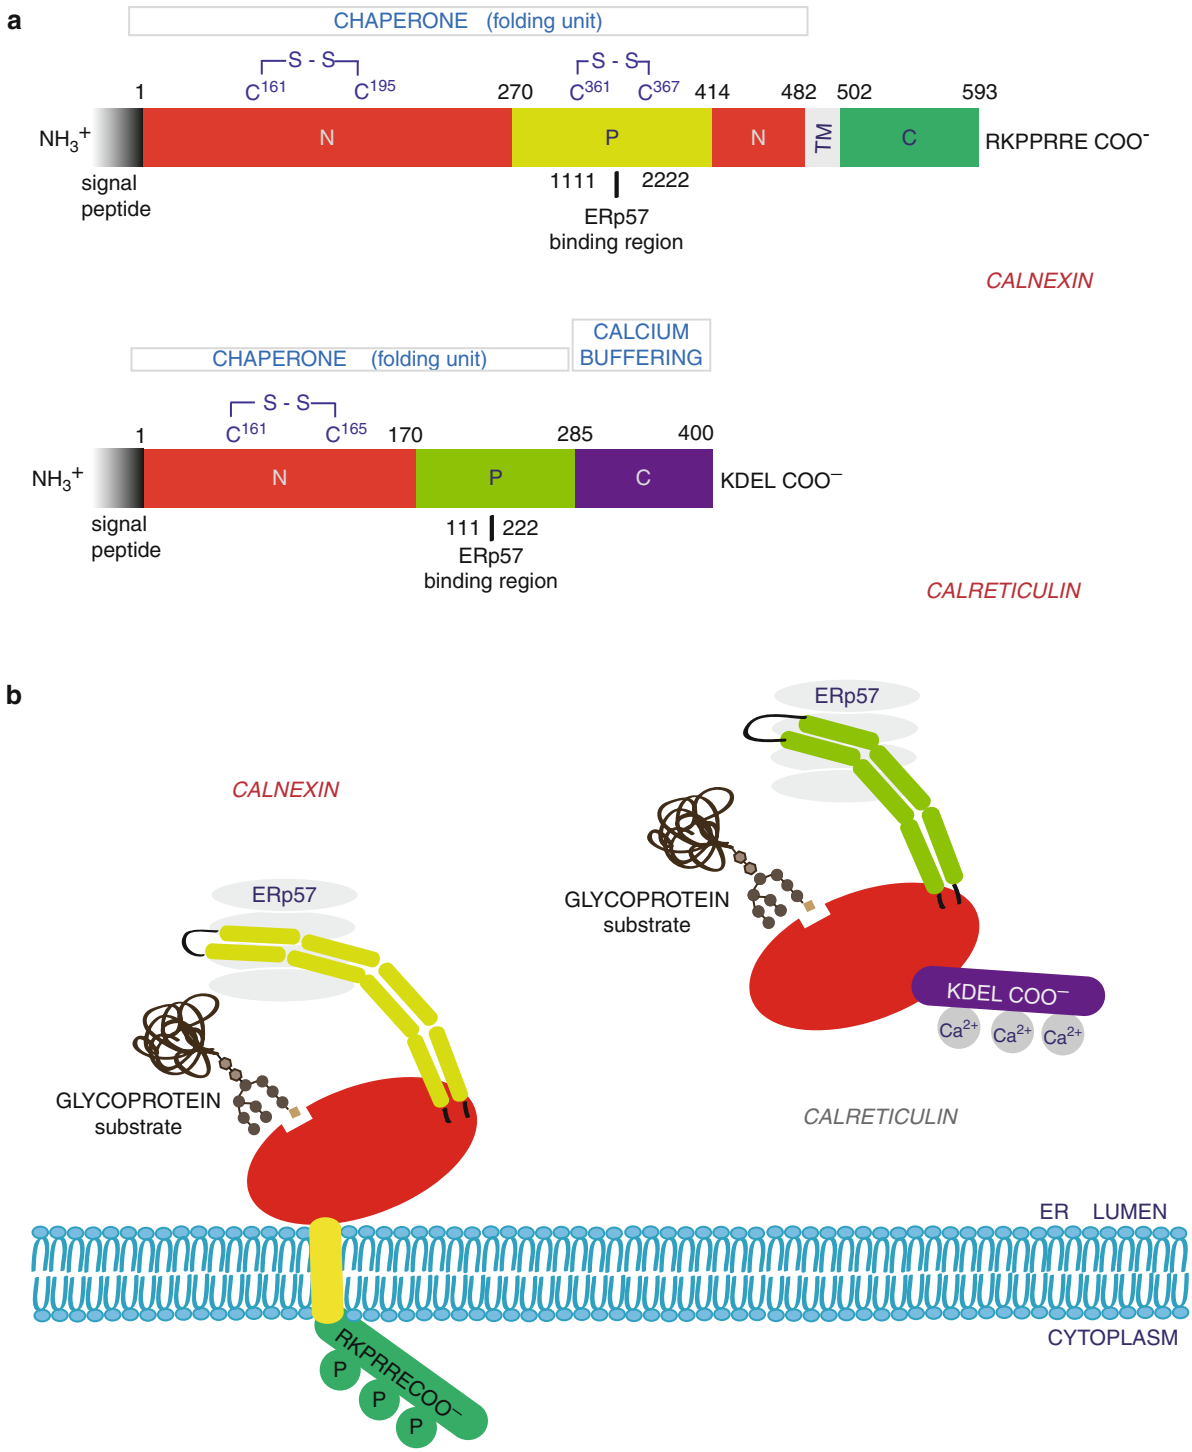
Function

The best established role of calnexin is its chaperone function in ER. The protein, along with calreticulin, is a lectin-like molecular chaperone that recognizes glycosylated and nonglycosylated proteins and participates in the folding and quality control of newly synthesized glycoproteins (Maattanen et al. 2010). The addition of N-glycans to nascent proteins is a common posttranslational modification that occurs within the ER lumen. Both calnexin and calreticulin bind, in a Ca^{2+}-dependent manner, monoglucosylated carbohydrate intermediates (Williams 2006). Upon release of the terminal glucose by glucosidase II, calnexin-substrate interaction is broken, and if the protein is incorrectly folded, it is reglucosylated by UDP glucose: glycoprotein glucosytransferase (UGGT) to reassociate with calnexin for an additional folding cycle. Calnexin deficiency affects the maturation and cell surface targeting of some of its substrates and impacts quality control in the protein secretory pathway. Misfolded glycoproteins may also be substrates for ER-associated degradation (ERAD). In ERAD, a slow-acting enzyme, alpha-1,2-mannosidase, removes a mannose residue at Man_9, allowing the protein to reach Man_8. Exposure of Man_8 allows the misfolded protein to interact with ER degradation enhancing alpha-1,2-mannosidase-like protein (EDEM) (Maattanen et al. 2010).

The lumen of the ER is the main storage site of Ca^{2+} ions that are involved in a universal signaling role in the cell. The concentration of total (free and bound) Ca^{2+} within the ER is estimated to be about 2 mM, while the free ER Ca^{2+} varies from 50 to 500 μM (Williams 2006). Fluctuations of the ER luminal Ca^{2+} concentration result in impact on numerous cellular functions including motility; protein synthesis, modification and folding, and secretion; gene expression; cell-cycle progression; and apoptosis. Thus, changes in Ca^{2+} concentration may play a signaling role in both the lumen of the ER as well as in the cytosol. The enormous capacity of the ER for Ca^{2+} is mediated by the Ca^{2+} buffering capacity of the resident protein. Calnexin may also influence ER ▶ Ca^{2+} homeostasis. Calnexin interacts with SERCA2b (sarcoplasmic-endoplasmic reticulum Ca^{2+} ATPase) and inhibits SERCA function in *Xenopus* by interacting with D^{1036} in the COOH terminus of SERCA2b. Phosphorylated calnexin interacts with SERCA2b, but the interaction is lost upon dephosphorylation of the calnexin. In *Drosophila,* the calnexin homolog is required for rhodopsin maturation, and calnexin affects Ca^{2+} entry to photoreceptor cells during light stimulation. Deletion of the calnexin gene (calnexin 99A) leads to severe defects in rhodopsin expression, whereas other photoreceptor cell proteins are expressed normally (Rosenbaum et al. 2006). Mutations in calnexin also impair the ability of photoreceptor cells to control cytosolic Ca^{2+} levels following activation of the light-sensitive channels and finally lead to retinal degeneration that is enhanced by light (Rosenbaum et al. 2006). Altogether, the results suggest that calnexin deficiency may also affect visual pigments and illustrate a critical role for calnexin in rhodopsin maturation and Ca^{2+} regulation (Rosenbaum et al. 2006).

Through the interaction with integrins in the ER, calnexin is involved in cell adhesion. Heterodimers of α-β integrins mediate cell-cell adhesion and also adhesion of proteins to the cellular matrix and plasma membrane. The largest subgroup of the β-chain family, β1-integrins, are known to bind many adhesion proteins such as collagen, laminin, fibronectin, vitronectin, and VMCAM-1. Calnexin associates with the β1 subgroup of integrins and is involved in their assembly and retention of their immature form in the ER. Thus, calnexin provides a steady supply of β1-integrins to associate with α-chains and form functional heterodimers (Jung et al. 2006).

Additionally, using cell lines deficient in calnexin, it was possible to demonstrate that calnexin is a component of apoptotic pathways involving the ER.



Calnexin and Calreticulin, Fig. 1 Linear models and schematic structures of calnexin and calreticulin. (**a**) In the upper panel the linear model of calnexin domains is shown. The N – terminal signal sequence (*grey box*), N domain (*red box*), P-domain (*light green box*) TM-transmembrane domain (*yellow box*) and a C-domain (*dark green box*) with the C-terminal ER retention sequence (RKPRRE). Repeats 1 (amino acids sequence PxxIxDPDAxKPEPWDE) and 2 (amino acids sequence GxWxPPxIxNPxYx) are indicated as 1111 and 2222 within the P-domain. The amino acids involved in the thiol

Although calnexin-deficient cells are resistant to ER stress-induced apoptosis, the absence of calnexin results in a decrease in caspase 12 expression as well as inhibition of Bap31 cleavage. Calnexin deficiency does not affect caspase 3, caspase 8, or cytochrome c release and may suggest that calnexin is not important in initiating apoptosis but rather has role in the induction of the latter stages of apoptosis. Moreover, calnexin itself is known to be cleaved by ER stress-inducing and noninducing conditions, and this cleavage is known to attenuate apoptosis.

Calnexin-Deficient Mouse Models

Two calnexin-deficient mouse models have been generated. Although calnexin-deficient mice are viable, they have a severe ataxic phenotype. Calnexin-deficient mice are 30–50% smaller than wild-type and show gait disturbance and splaying of the hindlimbs. Electron micrographs of the spinal cord and sciatic nerve indicate that there is severe dysmyelination in the peripheral nervous system (PNS). Thus, it is not surprising that reduced nerve conduction velocity is observed in calnexin-deficient mice (Kraus et al. 2010). A different strain of mouse with a disrupted calnexin gene expressing a truncated (15-kDa smaller) form of calnexin was also reported. Truncated calnexin possesses disruptions in amino acid residues within the carbohydrate pocket in the N-globular domain (C^{161}, C^{195}, Y^{165}, and K^{167}). This mutant mouse is phenotypically similar to the calnexin-deficient mouse suggesting that the chaperone function of calnexin is likely responsible for the observed neurological phenotype. Interestingly, there is no significant impact of calnexin deficiency on the development of immune system (Kraus et al. 2010).

Calreticulin

Calreticulin was discovered over 30 years ago as a Ca^{2+}-binding protein of the sarcoplasmic reticulum with high homology to calregulin. Calreticulin is differentially expressed under a variety of physiological and pathological conditions. A reduced level of calreticulin is observed in heart and brain in differentiated cells, while in highly differentiated cells or upon induction of ER stress, calreticulin is upregulated (Michalak et al. 2009).

Structure

Calreticulin is a 46-kDa ER resident protein involved in Ca^{2+} binding and is a well-known molecular chaperone. Calreticulin has an N-terminal cleavable signal sequence and an ER retention sequence KDEL at the C-terminus (Fig. 1). Similar to calnexin, calreticulin is composed of distinct structural and functional domains: the N-globular domain, the P-arm domain, and the C-domain (Maattanen et al. 2010). Based on the secondary structure, the N-terminal domain (residues 1–170) is predicted to be comprised of eight antiparallel β-strands (Fig. 1). The N-terminal domain of calreticulin contains the oligosaccharide- and polypeptide-binding sites. Although little is known about molecular features of substrate binding to calreticulin, a significant portion of the oligosaccharide domain has been mapped. Mutations to residues Y^{109} and D^{135} were identified to abolish interactions between calreticulin and oligosaccharides. Additionally, other amino acids were identified as responsible for sugar binding: K^{111}, Y^{128}, and D^{127} (Michalak et al. 2009). W^{302} and H^{153} in the N-domain have been shown to be critical for chaperone function and also affect the structure of calreticulin. Disruption of the

Calnexin and Calreticulin, Fig. 1 (continued) linkages are connected with an S-S, with the numbers delineating the amino acid residues at the transition between the various domains. In the lower panel the linear model of calreticulin domains is shown. The N-terminal signal sequence (*grey box*), N domain (*red box*), and P-domain (*green box*) and a C domain (*purple box*) with the C-terminal ER retention sequence (KDEL). Repeats 1 (amino acid sequences IxDPxA/DxKPEDWDx) and 2 (amino acid sequences GxWxPPxIxNPxYx) are indicated as 111 and 222 within the P-domain. The amino acids involved in the thiol linkage are connected with an S-S, with the numbers delineating the amino acid residues. (**b**) On the left, schematic structure of calnexin, transmembrane ER protein is shown. The P-domain (*light green*) contains residues involved in ERp57 binding (*grey*). The N-globular domain (*red*) contains residues involved in carbohydrate substrates binding. The TM domain (*yellow*) anchors calnexin to the ER membrane. The C-domain (*dark green*) is oriented to the cytoplasm and possesses three phosphorylation sites (*dark green spheres*). On the right schematic structure of calreticulin, soluble in ER lumen, is shown. The P-domain (*green*) contains residues involved in ERp57 binding (*grey*). The N-globular domain (*red*) contains residues involved in carbohydrate substrates binding. The C-domain (*purple*) has high capacity for binding Ca^{2+} (*grey spheres*)

disulfide bridge between C^{88} and C^{120} only partially affected the structure of calreticulin. The N-domain also binds Zn^{2+}, and this ion binding may have structural effects on the whole protein and thus affect protein function (Williams 2006). A proteolysis stable N-domain core is formed in the presence of Ca^{2+}, and development of this stable core may have specific pathophysiological implications. The P-domain is located in the middle of calreticulin's amino acid sequence (residues 170–285) and forms an extended, flexible arm (Fig. 1). The P-domain is a proline-rich region similar to the one found in calnexin and is composed of three copies of two repeat amino acid sequences (motif 1: IxDPxA/DxKPEDWDx and motif 2: GxWxPPxIxNPxYx). The repeat sequences are arranged in a 111222 pattern and are thought to be involved in oligosaccharide binding, together with N-domain. Based on NMR studies, it is known that the structure of the P-domain of calreticulin contains an extended region which is stabilized by three antiparallel β-sheets (Williams 2006). ERp57 can dock onto the tip of the P-domain, and mutational analysis showed that amino acids, E^{239}, D^{241}, D^{243}, and W^{244}, are involved in this interaction (Coe and Michalak 2010). The P-domain has also been found to bind Ca^{2+} with a high affinity ($K_d = 1$ μM) and low capacity (1 mol of Ca^{2+} per 1 mol of protein). The binding site appears to possess a potential ▶ EF-hand-like helix-loop-helix motif. The C-domain of calreticulin (residues 285–400) is mainly composed of negatively charged residues interrupted, at regular intervals, with one or more basic K or R residues (Fig. 1). It was found that disruption of these basic residues results in decreased in Ca^{2+}-binding capacity, and the binding can be directly attributed to the lysine amino group side chains. The C-domain is responsible for the Ca^{2+} buffering function of the protein and binding (Michalak et al. 2009). It is known that the C-domain is responsible for binding 50% of ER Ca^{2+} with a low affinity ($K_d = 2$ M) and high capacity (25 mol of Ca^{2+} per mol of protein), opposite to Ca^{2+} binding by the P-domain (Michalak et al. 2009).

Function

Many functions of calreticulin are related to the protein's ability to bind Ca^{2+} with high affinity through the C-domain. Thus, it is not surprising that calreticulin is known as a major ER Ca^{2+} buffer and similar to calnexin's function as a molecular chaperone (Michalak et al. 2009). Other functions within the cell are extensions of calreticulin's roles as a Ca^{2+} buffering and chaperone protein.

Being able to bind Ca^{2+} with high capacity and low affinity, calreticulin is classified as a class I Ca^{2+}-binding protein. In order to understand the Ca^{2+} binding and buffering properties of calreticulin, it is important to describe the cellular and animal models with calreticulin deficiency and overexpression. Calreticulin-deficient cells have reduced Ca^{2+} storage capacity in the ER, while overexpression of calreticulin leads to an increased amount of Ca^{2+} in the cell's intracellular stores (Williams 2006). For example, in calreticulin-deficient mouse embryonic fibroblasts (MEFs), a significant decrease in Ca^{2+} storage was observed. However, when the P + C-domains involved in Ca^{2+} binding were expressed in the calreticulin-deficient cells, there was a full recovery of ER Ca^{2+} storage capacity. Expression of the N + P-domains of calreticulin did not recover Ca^{2+} storage capacity in the ER of calreticulin-deficient cells. Taken together, these results both suggest that the main role of the C-domain is in Ca^{2+} binding. Moreover, the impact of Ca^{2+} fluctuations on the conformation and function of calreticulin was demonstrated by studies involving limited proteolysis of calreticulin by trypsin. These digestion studies showed that when the ER Ca^{2+} level was low (<100 μM) calreticulin was rapidly degraded by trypsin, while under high ER Ca^{2+} concentrations (500 μM–1 mM), the protein forms an N-domain protease-resistant core. The ability to regulate ER luminal Ca^{2+} concentrations affects other biological functions of calreticulin within the cell (Michalak et al. 2009). For example, cytotoxic T-lymphocytes release Ca^{2+}-activated perforin, granzymes/proteases, and calreticulin that, upon interaction with a target cell, cause lysis and apoptosis. Calreticulin regulates this process through Ca^{2+} binding. It has been found that increased levels of calreticulin result in increased amounts of chelated Ca^{2+} and a decrease in activated perforin involved in penetration of the plasma membrane of the targeted cell (Michalak et al. 2009). Calreticulin has also been found outside the ER lumen, in the nucleus, cytoplasm, and on the cell surface, where it may be involved in other biological functions within the cell. Cell surface calreticulin is

involved in the immune system where it functions in antigen presentation and complement activation (Michalak et al. 2009). Calreticulin translocates to the cell surface with ERp57 allowing for presentation to T cells, initiation of the immune response, and apoptosis of the target cell. It is also an important protein for focal adhesion assembly and impacts phagocytosis and the proinflammatory response. Moreover, calreticulin induces the migration and motility of cells involved in wound healing such as keratinocytes, fibroblasts, monocytes, and macrophages.

Translocation of calreticulin to the cytoplasm is still controversial. There are three proposed mechanisms leading to the cytoplasmic localization of calreticulin: (1) the protein is not efficiently targetted to the ER, and this leads to accumulation of the calreticulin precursor in cytoplasm; (2) redistribution of calreticulin is a result of the protein leaking out of the ER; and (3) retrieval from the ER by reverse movement after processing (removal of the signal peptide) (Michalak et al. 2009). The functions of calreticulin in the cytoplasm are not well understood. It has been suggested that calreticulin is a cytoplasmic activator of integrins and is a signal transducer between integrins and Ca^{2+} channels in the plasma membrane. Other groups established that calreticulin could interact directly with the glucocorticoid and androgen hormone receptors and could inhibit steroid-sensitive gene transcription (Michalak et al. 2009).

There are only few studies that have shown calreticulin in the nuclear matrix in hepatocellular carcinomas and binding to core histones. It has also been suggested that calreticulin may act as a nuclear import protein (Michalak et al. 2009).

Calreticulin has been implicated in the cellular response to apoptosis. Modulation of ER Ca^{2+} stores impacts apoptosis as ER Ca^{2+} release is required for activation of transcriptional cascades. It was shown that an increase level of calreticulin results in a sensitivity to apoptosis, while calreticulin-deficient cells are resistant to apoptosis. Further studies showed that calreticulin, intraluminal Ca^{2+}, and disruption in Ca^{2+} regulation influence apoptosis events in cardiomyocytes. Cell-surface calreticulin seems to also play a role in apoptosis. It was shown that in RK3 cells, cell surface calreticulin mediates apoptosis through activating the tumor necrosis factor receptor type 1 (TNFR1). Many forms of cancer display cell surface calreticulin which invites immune cells to destroy them. Moreover, calreticulin was identified as a pro-phagocytic signal highly expressed on the surface of several human cancers, but minimally expressed on most normal cells. Increased calreticulin expression was an adverse prognostic factor in diverse tumors including neuroblastoma, bladder cancer, and non-Hodgkin's lymphoma. Preapoptotic translocation of calreticulin to the cell surface occurs with ERp57 and allows presentation to T cells, triggering the initiation of the immune response and subsequent apoptosis of the immunogenic cell, preventing organism damage. Disruption of the interaction of calreticulin with ERp57 as well as disruption of calreticulin not only prevents surface exposure of calreticulin but also renders the cell resistant to T-cell attack (Coe and Michalak 2010). Exogenous application of calreticulin is able to overcome this resistance. It was also shown that anthracyclines induce the rapid preapoptotic translocation of calreticulin to the cell surface. Blockade or knockdown of calreticulin suppresses the phagocytosis of anthracycline-treated tumor cells by dendritic cells and abolishes their immunogenicity in mice (Michalak et al. 2009).

Mouse Models

Unlike the calnexin-deficient mice described above, calreticulin deficiency is embryonic lethal. This indicates that calnexin and calreticulin, although having similar domain structure and sharing some common functions, may have fundamentally different roles in vivo. During development, calreticulin is expressed at a high level in central nervous system, liver, and heart, and embryonic lethality of calreticulin-deficient mice is due to impaired cardiac development, specifically a marked decrease in ventricular wall thickness. Embryonic fibroblasts derived from calreticulin-deficient mouse embryos show a significant decrease in ER Ca^{2+} capacity, but free ER Ca^{2+} remains unchanged (Williams 2006). Further studies on the embryonic stem cell demonstrated how critical the Ca^{2+} buffering function of calreticulin is to cardiac development as well as for mice survivability. Molecular studies indicate that calreticulin deficiency leads to impaired myofibrillogenesis. Moreover, deficiency of calreticulin leads to deficient intercalated disc formations in the heart, which are adherens-type

junctions of cardiac muscle that contain vinculin, N-cadherin, and catenins (Michalak et al. 2009).

Studies examining the molecular level and functional consequences of overexpression of calreticulin have demonstrated a significant increase in Ca^{2+} capacity of the ER. Transgenic mice overexpressing calreticulin in the heart display bradycardia, complete heart block, and sudden death (Michalak et al. 2009).

Calsequestrin

ChulHee Kang
Washington State University, Pullman, WA, USA

Synonyms

CASQ; CSQ

Definition

Calsequestrin, a ~40 kD protein, binds Ca^{2+} with high capacity (40–50 mol Ca^{2+} mol^{-1} calsequestrin) but with moderate affinity ($K_d = 1$ mM) over a Ca^{2+} concentration range between 0.01 and 1 M and releases it with a high off-rate (10^6 s^{-1}). A high concentration of calsequestrin (up to 100 mg mL^{-1}) is present in the lumen of the junctional terminal cisternae of the sarcoplasmic reticulum (SR) (MacLennan and Chen 2009; Royer and Ríos 2009). In humans, there are two major isoforms; the skeletal muscle calsequestrin (Casq1) and the cardiac muscle calsequestrin (Casq2). They are encoded by *casq1* and *casq2* located on chromosomes 1q21 and 1p13.3-p11 and are the only isoforms in fast-twitch skeletal muscle and cardiac muscle, respectively. In slow-twitch skeletal muscle, Casq1 is the major isoform with Casq2 as minor. In general, the Ca^{2+}-binding capacity of Casq2 is higher than that of Casq1. Isoforms of calsequestrin are also present in the endoplasmic reticulum (ER) vacuolar domains of some neurons and smooth muscles (Dulhunty et al. 2009; MacLennan and Chen 2009; Knollmann 2009). In addition, the ER from plant cells contains very similar proteins that bind Ca^{2+} with a relatively high capacity and low affinity.

Biological Function

The regulation and ▶ transport of Ca^{2+} by the SR controls the state of the actin–myosin fibrils of muscle. Release of Ca^{2+} from the terminal cisternae (TC) of the SR brings about muscle contraction, and uptake of Ca^{2+} by the SR establishes relaxation. In this pump-storage release of Ca^{2+}, the ratio between total and free [Ca^{2+}] in the TC is approximately between 100 and 500.

Thus, a Ca^{2+}-binding/storage motif of large capacity must exist inside the SR. At the same time, the same motif must have a relatively low affinity for Ca^{2+} to allow for its rapid release from the SR. Calsequestrin was suggested as this Ca^{2+} buffer inside the SR, lowering free Ca^{2+} concentrations and thereby facilitating further uptake by the ▶ Ca^{2+}-ATPase (SERCA). In addition, calsequestrin might participate in the Ca^{2+} release process by localizing Ca^{2+} at the release site, sensing the SR Ca^{2+} concentration and regulating the amount of Ca^{2+} released in response to an electrical signal from the motor nerve (Györke et al. 2009). A network of interacting proteins in the junctional face region of the SR such as junctin and triadin are implicated in the regulation of calsequestrin's interaction with the calcium channel known as the ryanodine receptor (RyR). Details of this association remain uncertain. Distribution of calsequestrin is uneven within the SR lumen with a markedly high concentration in close proximity to the RyR, possibly mediated by those calsequestrin-anchoring proteins. By localizing calsequestrin in the vicinity of the RyR during Ca^{2+} uptake and release, diffusion time for Ca^{2+} release could be drastically reduced.

Structure of Calsequestrin

The amino acid sequences of both Casq1 and Casq2 from several species have been characterized. In general, those isoforms exhibit 60–70% sequence identity (Fig. 1). Consistent with their high Ca^{2+}-binding capacity, the sequence of calsequestrin has a large proportion of negatively charged amino acids. Especially, the residues in the carboxyl terminus are the most acidic, which is also most variable area in terms of amino acid sequence among different isoforms. The sequence of calsequestrin does not show a typical KDEL tetrapeptide retrieval signal, thus the targeting mechanism for calsequestrin should be unique.

The crystal structures of both Casq1 and Casq2 show that it is made up of three, nearly identical tandem domains (Wang et al. 1998; Park et al. 2004; Kim et al. 2007). Each of those has the thioredoxin protein fold, although there is no apparent sequence similarity among the three domains (Fig. 2). Each thioredoxin-like domain is made up of a five stranded β-sheet with two α-helices on both sides and has a hydrophobic core with acidic residues on the exterior, generating highly electronegative potential surfaces (Fig. 3). The individual domains contain a high net negative charge, ranging from about −13 to −32, and also have high aromatic amino acid content, ranging from 9% to 13%. The highly negative C-terminal of both Casq1 and Casq2 are completely disordered.

Posttranslational Modification

The posttranslational modifications for calsequestrin have been reported, although their significance is not fully understood (Milstein et al. 2009; Sanchez et al. 2011). From the amino acid sequence, several potential phosphorylation and glycosylation sites were detected. Three serine residues (Ser378, 382, 386) in the canine cardiac isoform were shown to be phosphorylated, whereas the rabbit fast-twitch isoform is phosphorylated on Thr373. In addition, in vitro studies show that both Casq1 and Casq2 can be phosphorylated by casein kinase II. Posttranslational modifications of calsequestrin are associated with its complex cellular transport and physiological Ca^{2+} regulation (McFarland et al. 2010; Sanchez et al. 2011). By in vitro phosphoprylation of human recombinant Casq2, two phosphorylation sites, Ser^{385} and Ser^{393} were identified (Sanchez et al. 2011). Phosphorylation at those two positions produces a disorder-to-order transition of the C-terminus. This phosphorylation-induced extra α-helix and subsequent interaction with nearby electropositive patches lead to increased Ca^{2+}-binding capacity. Calsequestrin undergoes a unique degree of mannose trimming as it is trafficked from the proximal endoplasmic reticulum to the SR. The major glycoform of calsequestrin ($GlcNAc_2Man_9$) found in the proximal endoplasmic reticulum can severely hinder formation of the back-to-back interface, potentially preventing premature Ca^{2+}-dependent polymerization and ensuring its continuous mobility to the SR. Only trimmed glycans can stabilize both front-to-front and the back-to-back interfaces of calsequestrin through extensive hydrogen bonding and electrostatic interactions. Therefore, the mature glycoform of calsequestrin ($GlcNAc_2Man_{1–4}$) within the SR can be retained upon establishing a functional high-capacity Ca^{2+}-binding polymer (Sanchez et al. 2012).

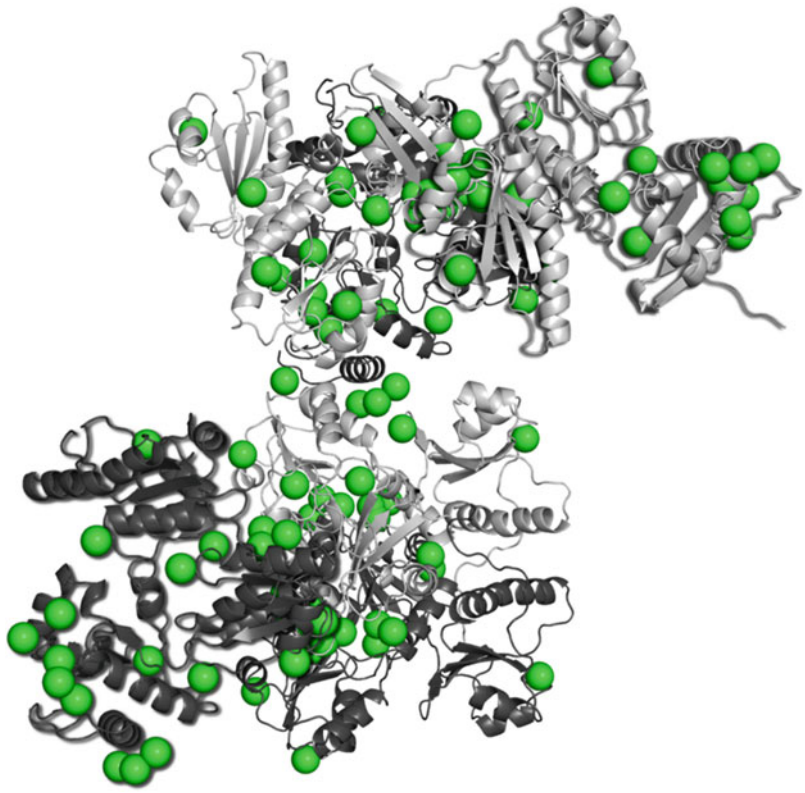
High-Capacity and Low-Affinity Ca^{2+} binding of Calsequestrin

Crystal structures of Ca^{2+}-complexes for both human and rabbit skeletal calsequestrin are determined (Fig.4), clearly defining its Ca^{2+}-sequestration capabilities through resolution of high- and low-affinity Ca^{2+}-binding sites (Sanchez et al. 2012). Three high-affinity Ca^{2+} sites are in trigonal bipyramidal, octahedral, and pentagonal bipyramidal coordination geometries. However, instead of a typical ▶ EF-hand motif that is present in the high-affinity ▶ Ca^{2+}-binding proteins, most of the low-affinity sites, some of which are μ-carboxylate-bridged, are established by the pairs of acidic residues and solvent molecules on the surface through the net charge density. Major portion of those low affinity sites are established by the rotation of dimeric interfaces, indicating cooperative Ca^{2+}-binding that is consistent with the atomic absorption spectroscopic data (Sanchez et al. 2012). The low-affinity Ca^{2+} binding of calsequestrin is likely driven by the entropy gain from the liberation of many water molecules from the hydrated cations. Due to its large negative charge, calsequestrin is mostly unfolded random coil in low ionic strength but folds into a compact structure as the concentration of ions is increased. As folding progresses, cooperative interactions bring acidic surface residues together, literally creating new Ca^{2+}-binding sites. Cations such as Zn^{2+}, Sr^{2+}, and Tb^{2+} also bind to calsequestrin and cause changes



Calsequestrin,
Fig. 4 Asymmetric unit of CASQ in P1 unit cell is shown in gray and black ribbon representations, with the Ca^{2+} ions shown as green spheres (Sanchez et al. 2012)

analogous to those caused by Ca^{2+}. Raising the concentration of Ca^{2+} leads to concomitant low-affinity binding of large numbers of Ca^{2+} and Ca^{2+}-induced calsequestrin aggregation. This strong cooperative Ca^{2+} binding accompanies the polymerization of calsequestrin, thus the Ca^{2+}-induced polymerization/aggregation likely contributes to the function and localization of calsequestrin. On the contrary, monovalent ion-induced folding does not lead to aggregation and precipitation and Ca^{2+}/calsequestrin aggregates are even dissociated by K^+. It has been suggested that K^+ lowers the affinity of Ca^{2+} for calsequestrin from both cardiac and skeletal SR in vivo.

In the crystal lattices of both Casq1 and Casq2, individual molecules form a continuous, linear polymer of ~90 Å thick through two types of dimer interfaces (Wang et al. 1998). The first type of interface, the front-to-front interface, involves the fitting of the convex globule from domain II on one subunit into a concave depression on the other. This interface involves "arm exchange or domain swapping" between the extended amino terminal ends of the two adjacent molecules. Each extended arm comprises ten N-terminal residues from domain I. This extended arm binds along a groove between two β-strands of domain II in the neighbor. Also, the front-to-front interface contains a number of negatively charged groups. The second type of interface, the back-to-back interface, involves bringing together two jaw-like openings between domains I and III, thus creating a substantial and electronegative pocket within this interface (Park et al. 2004). Since both interfaces involve cross-bridging as acidic groups are brought into proximity, on-rates are likely to be close to the diffusion limit ($\sim 10^9$ M^{-1} s^{-1}), and off-rates to be approximately 10^6 s^{-1} for a binding constant of 10^3 M^{-1}. On the basis of the much greater negative charge of the back-to-back interface, the front-to-front type dimer forms before back-to-back type dimer. The residues involved in those interfaces are the most highly conserved residues in the entire sequence. This situation is reminiscent of the higher conservation of active site residues of other proteins, and thus strongly indicates that those two interfaces are the functional contacts involved in the coupled polymerization and low affinity Ca^{2+} binding (Park et al. 2003, 2004). Therefore,

any disruption or interference of this critical intermolecular interaction by either mutation or small molecule binding could disrupt the functional integrity of the calsequestrin molecules (Kang et al. 2010).

The calsequestrin polymer, especially the highly charged disordered tail, provides an acidic and extended surface onto which Ca^{2+} can be adsorbed. The attractive forces exerted by such an extended surface would have a longer range than those from an isolated molecule. A sparingly soluble ion such as Ca^{2+} would tend to spread over the surface of this polymer forming a readily exchangeable film. An array of such polymers would create long, narrow, negatively charged channels leading to the calcium-release channel (RyR). One-dimensional diffusion of Ca^{2+} along the surface of the linear polymer would speed up the diffusion of Ca^{2+} to its release channel compared to random walk diffusion through liquid. Therefore, the calsequestrin polymer located near the RyR can act as a Ca^{2+} wire using a huge Ca^{2+} gradient ($\sim 10^4$) maintained between the cytosolic and the lumenal spaces. In addition, the lack of a fixed or stable structure of the Ca^{2+}-binding sites dictates that binding affinities would be low, and diffusion-limited on and off rates would be as fast as possible (MacLennan and Chen 2009). That is, the use of Ca^{2+} as a cross linker rather than as a tightly bound form speeds up its dissociation.

Related Human Disease

Both mutation and improper levels of calsequestrin have been implicated in several human diseases. Catecholaminergeic polymorphic ventricular tachycardia (CPVT) is a familial arrhythmogenic cardiac disorder characterized by syncopal events, seizures, or sudden cardiac death at a young age (Knollmann 2009). The corresponding arrhythmogenic events are usually triggered in response to intensive exercise or emotional stress. Mutations of *casq2* have been found as the cause of autosomal recessive forms of CPVT. In addition, mutations in the cardiac RyR gene, *ryr2*, have been associated with the autosomal dominant forms of this CPVT. A typical CPVT phenotype caused by either *ryr2* or *casq2* is almost identical; thus, a similar causal mechanism has been suggested. So far, in vitro testing shows that all the mutations on *casq2* that cause CPVT either disrupt protein folding or diminish high capacity Ca^{2+} binding and polymerization (Kim et al. 2007; MacLennan and Chen 2009). Therefore, those mutations reduce the total Ca^{2+}-binding and Ca^{2+}-buffering capacity of the SR lumen by the amount that can be ascribed to calsequestrin. In the absence of calsequestrin or in the presence of calsequestrin with impaired polymerization, especially in a state where SERCA is fully activated by adrenergic stimulation, a reduced Ca^{2+}-buffering capacity in the SR will permit luminal Ca^{2+} concentrations to overshoot the normal threshold of RyR for a store overload-induced Ca2+ release (SOICR), causing arrhythmia (MacLennan and Chen 2009). The same pathophysiologic consequence can be ascribed to a malignant hyperthermia (MH) episode in the case of mutated skeletal calsequestrin, *casq1*. Calsequestrin was also identified as one of the major antigens in the thyroid-associated ophthalmopathy (TAO), a progressive orbital disorder associated with Grave's hyperthyroidism and, less often, with Hashimoto's thyroiditis.

Affinity to Small Molecules

Both Casq1 and Casq2 have shown significant affinity toward various types of pharmaceutical compounds such as tricyclic antidepressants and phenothiazine- and anthracycline-derivatives, and such binding results in a significant disruption of Ca^{2+}-binding capacity, polymerization, and its communication with other critical components of the channel complex (Kim et al. 2005; Park et al. 2005; Kang et al. 2010). Considering the concentration of calsequestrin in muscle tissue ($\sim$100 mg/ml) and the affinity between calsequestrin and these classes of drugs (1–100 μM), long-term or high-dose administration could lead to their accumulation in the SR, which substantially could reduce the calcium content of the SR (probably due to decreased buffering capacity and increased free Ca^{2+}) (Kang et al. 2010). Long-term exposure to such drugs could produce a chronic toxicity to both cardiac and skeletal muscles despite their moderate affinity.

All CPVT-related calsequestrin mutations result in disrupted behavior in both its Ca^{2+}-binding capacity and Ca^{2+}-dependent polymerization, which is similar to the interference caused by small molecule association. Therefore, those pharmaceutical compounds could seriously affect people who already have

impaired calsequestrin, such as in the case of CPVT patients. The effects of some mutations or drug-association by themselves on the function of calsequestrin might be benign enough not to cause arrhythmias; however, there might exist an additive or synergetic interference effect on the normal function of calsequestrin by drug binding and hereditary mutation together. Therefore, specific caution has been posted for those people at high risk of serious cardiac complications (Kang et al. 2010).

Definition

Most aerobic organisms are exposed to oxidative stress, which results in the generation of free reactive oxygen species (superoxide, hydrogen peroxide, hydroxyl radical) that interfere with the cell's metabolism, cause oxidative damage of cellular macromolecules, and may eventually also cause cell death. Thus, eliminating these free oxygen radicals is absolutely mandatory for cell survival.

In this context, catalases are antioxidant enzymes that accelerate the rate of hydrogen peroxide decomposition to molecular oxygen and water with near

kinetic perfection. Exhibiting one of the highest known turnover numbers, a catalase molecule can convert approximately 4×10^7 substrate molecules to the referred products each second. The catalytic efficiency (kcat/Km) of catalase ($4.0 \times 10^8\ M^{-1}\ s^{-1}$) is very high indeed. Because the efficiency is at the diffusion limit, catalase is said to have achieved "catalytic perfection." This activity is dependent on a heme cofactor with a bound iron atom, which is cycled between oxidation states. Many catalases also have been shown to be peroxidases, that is, they can oxidize short-chain alcohols including ethanol and other substrates in a two-step hydrogen peroxide-dependent reaction. In addition to their active-site heme groups, it has been described that many heme-containing catalases bind a second prosthetic group, NAD(P)H, which is not required for the peroxide dismutase activity. Bound NADPH can protect the enzyme against oxidative damage by the peroxide substrate by tunneling electrons toward the active-site heme group to regenerate its active oxidation state.

On the other hand, it has been found that some heavy metal/metalloid derivatives like the tellurium (Te) oxyanion tellurite (TeO_3^{2-}) act as natural substrates (electron acceptors) for the NAD(P)H-dependent oxidoreductase activity of bacterial and mammalian catalases. Particularly, tellurite is a strong oxidizing agent with high toxicity to both, prokaryotic and eukaryotic organisms.

Toxicant Reduction as a Mechanism of Resistance

Deciphering the origin of bacterial tellurite resistance has been the goal of many microbiologists for years. Several groups have reported the isolation and characterization of some genetic resistance determinants, and the biochemical mechanism underlying TeO_3^{2-} resistance suggests a multifactorial response that includes the reduction of tellurite to elemental tellurium.

The oxidant character of the tellurium oxyanions tellurite (TeO_3^{2-}) and tellurate (TeO_4^{2-}) makes them toxic to most microorganisms. Gram-negative bacteria are particularly sensitive to tellurite while some Gram-positive species including *Corynebacterium diphtheriae*, *Staphylococcus aureus*, *Streptococcus faecalis* and *Geobacillus stearothermophilus* V are naturally resistant to this salt.

Tellurite-resistant cells turn black when grown in liquid or solid media amended with this compound; the higher the tellurite concentration in the culture medium, the blacker the resulting cells (Fig. 1). However, this phenotype is also observed in sensitive bacteria growing at permissive tellurite concentrations. Electron microscopy studies have allowed the identification of the subcellular location of these black deposits both in Gram-positive and in Gram-negative bacteria. In turn, X-ray diffraction studies demonstrated that this insoluble, nondiffusible material corresponds to the less toxic Te form, elemental tellurium (Te^0).

The presence of tellurite-reducing activities that depend on an electron donor coenzyme such as NAD(P)H or $FADH_2$ has been observed in *Escherichia coli* (Cooper and Few 1952), *Mycobacterium avium* (Terai and Kamamura 1958), *Thermus spp.* (Chiong et al. 1988), *Rhodobacter sphaeroides* (Moore and Kaplan 1992), and *G. stearothermophilus* (Moscoso et al. 1998), among other bacteria.

Bacterial Tellurite Reductases

It has been proposed that several oxidoreductases, including the terminal oxidases of the bacterial respiratory chain contribute to tellurite reduction. An example of them is nitrate reductase, present in membrane fractions of *E. coli* that can mediate the reduction of tellurite (Avazéri et al. 1997). Tellurite-reducing activity was also identified in the E3 component of the pyruvate dehydrogenase complex from *E. coli*, *Zymomonas mobilis*, *Streptococcus pneumoniae*, and *G. stearothermophilus* (Castro et al. 2008). All these activities showed a NAD(P)H dependence, suggesting a wide distribution among microorganisms.

Catalases Exhibit Tellurite Reductase (TR) Activity

TR activity in catalases was first identified in a bacterial strain isolated from the effluent of a Chilean mining company, *Staphylococcus epidermidis* CH. This bacterium exhibits natural resistance to a series of quaternary ammonium compounds and also shows an important tellurite resistance phenotype. *S. epidermidis* CH is 5- and 100-fold more

Catalases as NAD(P)H-Dependent Tellurite Reductases, Fig. 1 Bacterial reduction of K_2TeO_3. Bacteria growing on LB-agar plates containing (*right*) or not (*left*) sublethal tellurite concentrations

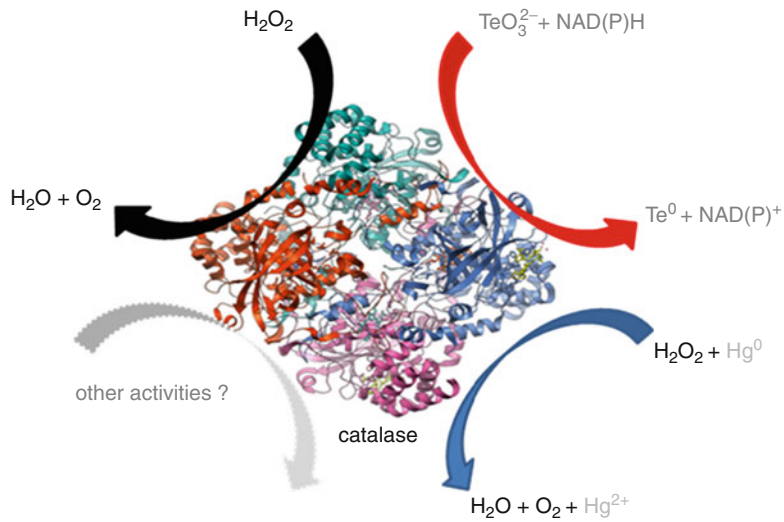
resistant to K_2TeO_3 than *G. stearothermophilus* V and *E. coli*, respectively. In order to gain some insight on the naturally occurring tellurite resistance in these Gram-positive bacteria, studies were focused on the nature of toxicant's bioreduction.

Crude extracts of *S. epidermidis* catalyze the in vitro, NADH-dependent reduction of K_2TeO_3, as shown by a standard spectrophotometric assay. An absorbance increase correlates directly with the blackening of the sample due to Te^0 production. Apart from being dialyzable, the enzymatic nature of the entity responsible for tellurite reduction was inferred by its sensitivity to heat, protein-denaturing agents, detergents, and proteases. The product of tellurite reduction by the *S. epidermidis* CH extract was identified as metallic tellurium by Induced Coupled Plasma-Optical Emission (ICP-OE) spectroscopy. The spectrum of NADH-dependent tellurite reduction obtained with the cell-free extract of *S. epidermidis* CH evidenced a major peak that matched with the Te^0 signal obtained by chemical reduction of potassium tellurite with 2-mercaptoethanol (Calderón et al. 2006).

A search for the enzyme responsible for TR activity was initiated. An enriched preparation coming from a series of chromatographic separations of the proteins present in cell-free extracts of *S. epidermidis* CH contained two major proteins with apparent *Mr* of ~60 and 75 kDa. Amino-terminal sequence analysis predicted that one of them was identical to catalase (predicted *Mr* ~58.2 kDa). Since in a previous work catalase was shown to be an NAD(P)H oxidase (Singh et al. 2004), the above evidence indicated that the NADH-dependent TR activity observed in this fraction would come likely from catalase (Fig. 2).

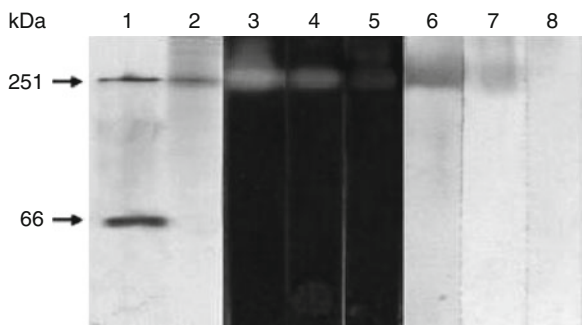
Heme-dependent monofunctional catalases differ in the strength with which they bind NAD(P)H and in substrate specificity of their accessory peroxidase activities. For example, bovine catalase binds both NADPH and NADH very tightly, whereas monofunctional bacterial catalases bind them more weakly. Bovine catalase and KatG, the bifunctional catalase/peroxidase from *E. coli*, display secondary peroxidase activities for a variety of substrates (Keilin and Hartree 1945; Oshino et al. 1973; Singh et al. 2004). Although somewhat diverse in their biochemical properties, monofunctional heme-containing catalases have core primary sequences conserved among prokaryotes and eukaryotes. Therefore, if the *S. epidermidis* CH monofunctional heme-containing catalase mediates tellurite reduction, the immediate assumption was that catalase from bovine liver was also able to reduce tellurite to Te^0 in vitro. In fact, purified bovine liver catalase showed a branch tellurite-reducing activity.

The in situ dismutation of hydrogen peroxide by purified bovine catalase in native polyacrylamide gels co-migrates with the TR activity. In a similar way, the *S. epidermidis* CH 60 kDa catalase also reduce tellurite in situ. On the other hand, the heterologous expression of *S. epidermidis* CH *katA* gene (encoding catalase) in *E. coli* (*E. coli*/pCAT), evidenced in situ activities for hydrogen peroxide dismutase and tellurite reduction. Experiments were carried out with extracts from exponentially growing *S. epidermidis* CH. A pBAD



Catalases as NAD(P)H-Dependent Tellurite Reductases, Fig. 2 Catalase activities. A catalase molecule showing its various identified activities: peroxidase (*black arrow*), TR (*red*), mercury oxidase (*blue*), among others (*gray*)

vector-harboring *E. coli* (pBAD), which does not produce *S. epidermidis* catalase, was used as negative control. Also, the standard assay for tellurite-reducing activity was challenged with a known catalase inhibitor. The assay performed with cell-free extracts from *S. epidermidis* CH or *E. coli*/pCAT was inhibited by 50% in presence of increasing concentrations of sodium azide (Fig. 3). The same result was obtained when pure bovine liver catalase was used instead of the bacterial extract.



Catalases as NAD(P)H-Dependent Tellurite Reductases, Fig. 3 In situ determination of catalase and tellurite reductase activities of bovine liver catalase (BLC). The enzyme (255 kDa) was assayed to show catalase (lanes 3–5) and tellurite reductase (lanes 6–8) activities in a polyacrylamide gel under native conditions. Lane 1, MW standards [phosphoenol pyruvate carboxyquinase (PEPCK) from *Saccharomyces cerevissiae* (8 µg, 251 kDa) and bovine serum albumin (BSA, 12 µg, 66 kDa)]; lane 2, BLC with Coomasie blue staining; lane 3, BLC revealed for catalase activity; lane 4, as in 3, but previously incubated with 2 mM sodium azide for 3 min; lane 5, as in 3, but previously incubated with 10 mM sodium azide for 3 min; lane 6, BLC revealed for tellurite reductase activity; lane 7, as in 6, but previously incubated with 2 mM sodium azide for 3 min; lane 8, as in 6, but previously incubated with 10 mM sodium azide for 3 min

Catalases and Bacterial Resistance to Tellurite

E. coli defective in catalase is sensitive to tellurite. Expression of the *S. epidermidis* catalase gene confers increased resistance to tellurite and to hydrogen peroxide in this bacterium, arguing that catalase seems to provide a physiological defense line against these two strong oxidants. This recombinant strain also displays a higher level of resistance to hydrogen peroxide than its otherwise isogenic parent. Therefore, the expression of the *S. epidermidis* catalase gene complements the *E. coli* deficiency. Furthermore, these data indicate that the *S. epidermidis* CH *katA* gene is a tellurite resistance determinant that, at least in part, is responsible for the high resistance of this Gram-positive bacterium to tellurite in vivo.

The information collected to date strongly suggests that the phenomenon of bacterial tellurite resistance has its origin in the combined or synergic- action/cooperation of various different enzymatic activities that play defined roles in bacterial metabolism, such as catalases. Certainly that their participation in the reduction, and thus probably in tellurite resistance, could be merely an accident, but anyway beneficial to the microorganism.

Kinetics Studies with Bovine Catalase

The reaction proposed for the catalase-mediated tellurite reduction is

$$TeO_3^{2-} + 3NAD(P)H + 3H^+ + 2O_2 \rightarrow Te^0 + 3NAD(P)^+ + 2O_2^- + 3H_2O$$

Thus, the reduction of tellurite by catalase requires molecular oxygen and produces superoxide as one of its products. This scheme is predicted to be favorable thermodynamically, involving as half-reactions the reduction of tellurite, the oxidation of NADH, and the formation of superoxide from oxygen.

The K_m of bovine liver catalase for tellurite was determined by assaying the rate of evolution of superoxide resulting from the reduction of tellurite by this enzyme (Calderón et al. 2006). Superoxide production rate is dependent on tellurite concentration and follows simple Michaelis-Menten kinetics. Under these experimental conditions, catalase has an apparent K_m for tellurite of 0.9 mM, a value that is comparable to that for peroxide (Nicholls and Schonbaum 1963), maybe indicating that tellurite could represent a natural substrate for the enzyme.

Catalase appears to be quite broad in its substrate range than originally thought, including two active sites that can participate in a variety of redox and condensation reactions. Tellurite is not the only metalloid derivative that behaves as catalase substrate. In fact, both eukaryotic and prokaryotic catalases carry out the heme-dependent oxidation of metallic mercury, a reaction that is stimulated by hydrogen peroxide (Magos et al. 1978; Du and Fang 1983; Ogata and Aikoh 1983; Smith et al. 1998). Thus, it is currently suspected that catalases would display a wider range of substrates than those of which we are currently aware, which could play multiple roles in the cell's defense against strong oxidizing agents encountered in nature, as a variety heavy metal ions.

Catechol Oxidase and Tyrosinase

Catherine Belle
Département de Chimie Moléculaire, UMR-CNRS 5250, Université Joseph Fourier, ICMG FR-2607, Grenoble, France

Names and (Some) Synonyms

Catechol oxidase (CO), EC 1.10.3.1, 1,2-Benzenediol: oxygen oxidoreductase, Diphenoloxidase, *o*-Diphenolase, Catecholase

Tyrosinase (Ty), EC 1.14.18.1, Monophenol, L-dopa:dioxygen oxidoreductase, Monophenol monooxygenase, Monophenol oxidase, Cresolase

General Description and Properties

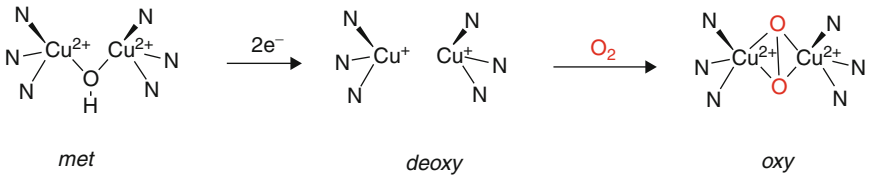
Catechol oxidase (CO) and tyrosinase (Ty) are oxidoreductases (EC1) that possess active sites with two copper atoms (type 3 copper centers). Reports on these enzymes' molecular weights are diverse and variable. Tertiary and quaternary structures of CO and Ty also display considerable variability in amino acid sequences. However, significant sequence homology between the active site regions is observed. The copper ions are surrounded by three nitrogen donor atoms from histidine residues. Ty and CO have been identified in three distinct forms in various stages of the catalytic cycle: a native *met* state (Cu^{II}-Cu^{II}), a reduced *deoxy* state (Cu^{I} Cu^{I}), and an *oxy* state with a dioxygen bound to the dicopper center (Cu^{II}-O_2^{2-}-Cu^{II}) (Fig. 1).

The copper(II) ions in the *met* state are bridged by aquo (hydroxo) ligands, which provide antiferromagnetic coupling between the copper ions, leading to EPR (electron paramagnetic resonance)-silent behavior.

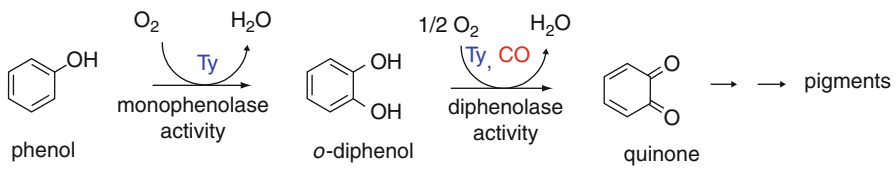
This type of active site is analogous to hemocyanin active sites, which serve as oxygen carriers and are the third group of proteins discovered to have a type 3 copper active site. Ty enzymes mediate the hydroxylation of monophenols to *o*-diphenols (monophenolase or cresolase activity) and the subsequent oxidation to quinones. Catechol oxidases exhibit only diphenolase (or catecholase) activity (i.e., two-electron oxidation of *o*-diphenols to quinones) (Fig. 2). Ty catalyzes the oxygenation of a variety of phenols, while CO catalyzes oxidation of a variety of *o*-diphenol; both reduce molecular dioxygen to water during catalysis. A lag phase is present (in vitro) for monophenolase activity, but not for diphenolase activity.

CO and Ty activities are pH-dependent. The optimal pH values reported for each enzyme differ because of differences in the sources and substrates used for the activity measurements. These optima range from pH 5 to 7.5, but neither enzyme displays significant activity in basic conditions.

The *oxy* forms of the active sites can be obtained by treatment of the *met* forms with excess of dihydrogen



Catechol Oxidase and Tyrosinase, Fig. 1 Schematic representation of the three identified and structurally characterized forms for Ty and CO



Catechol Oxidase and Tyrosinase, Fig. 2 Reaction pathway of the monophenolase and diphenolase activity catalyzed by Ty and CO, leading to the production of protective pigments

peroxide. The CO *oxy* form is less stable than that of Ty; CO cannot be fully converted to this form, and the *oxy* form spontaneously decays, with partial enzyme inactivation because the enzyme exhibits catalase activity (Gerdemann et al. 2002). The instability of the *oxy* form may contribute to CO's lack of monooxygenase reactivity toward monophenols, although this difference in activity may also be due to structural factors (see below).

Occurrence

CO is mainly found in and isolated from a large group of plants copper in plants, including potatoes and apples, and it is found in many different tissues of these plants such as leaves, fruit, and flowers. Ty is more widely distributed, and forms with slight variations are found in many organisms, including plants, fungi, bacteria, and mammals. These enzymes exist in complexes ranging from monomers to hexamers and are found freely dissolved (bacteria, plants) or bound within organelles or membrane (mammals) (Rolff et al. 2011).

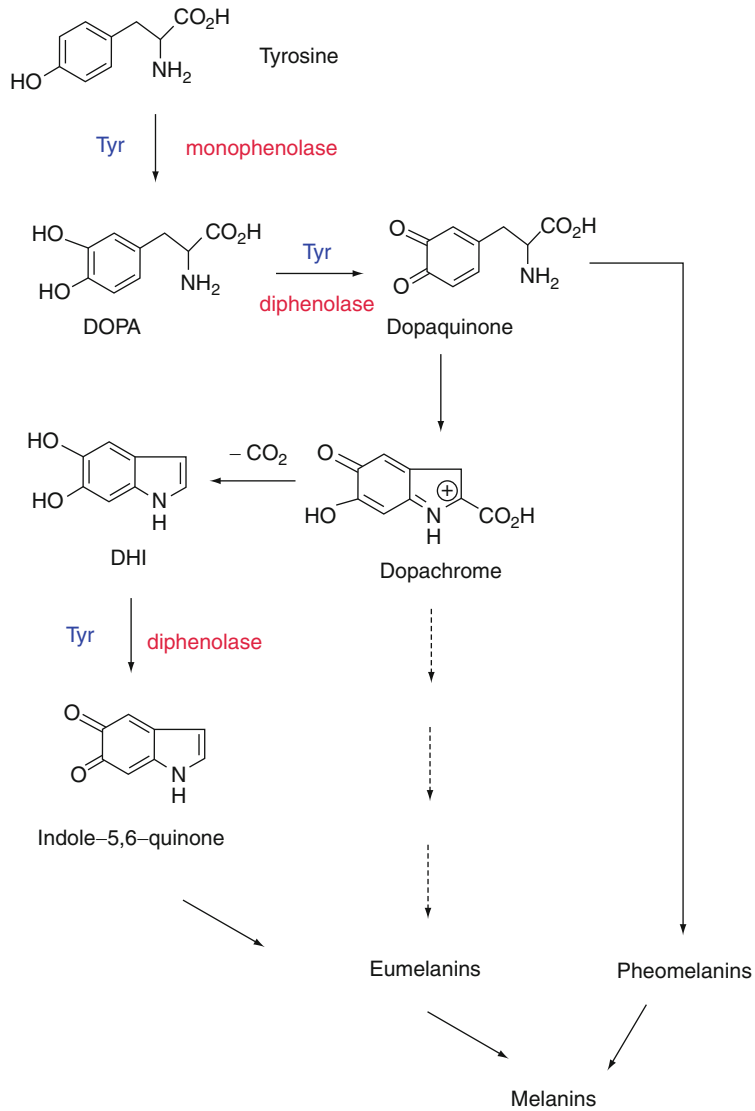
Functions

The most evident proposed function of Ty and CO is in the biosynthesis of pigments of polyphenolic origin. Such pigments are widely distributed in plants (tannins), arthropods (cuticles), and mammals (melanins). These pigments are heterogeneous polyphenol-like biopolymers with complex structures. The colors of these pigments, which range from yellow to black, are a result of the autopolymerization of highly reactive quinones formed by the oxidization of phenol and catechol precursors. The browning of fruits, vegetables, and mushrooms after tissue damage induced by stress, pathogens or wounding is one of the most common outcomes of catechol oxydase- or tyrosinase-mediated melanization (Mayer 2006).

In mammals, the final products of Ty activity are melanin pigments responsible for skin, eye, and hair colors (Nordlund et al. 2006). The absence or inactivation of Ty leads to albinism. Melanin is produced in melanocytes, cells located in the basal layer of the dermis. Ty catalyzes the initial conversions of tyrosine leading to the formation of dihydroxyphenylalanine (DOPA) and dopaquinone (Fig. 3). It is also associated with the oxidation of 5,6-dihydroxyindole (DHI) in indole-5,6-quinone. This multistep process leads to the formation of eumelanin (the most protective melanin against photoinduced damage). Skin color depends principally on relative amounts of eumelanin (brown/black) and pheomelanin (red/yellow). In the human brain, tyrosinase is expressed at low levels, but Ty can perform the function of tyrosine hydroxylase (catalyzing the formation of tyrosine in DOPA in the brain) in its absence and may be linked to catecholamine neurotoxicity.

Inhibitors

Special attention has been devoted to CO inhibition to suppress the browning of plants and fruits during storage (Mayer 2006). Several inhibitors acting as chelating agents for copper or substrate analogues have been



Catechol Oxidase and Tyrosinase,
Fig. 3 Biosynthetic pathway of melanins and the involvement of tyrosinase enzyme. *Dotted line* is related to an additional pathway found in mammals

reported. In the food industry, sulfite is commonly used to inhibit enzymatic browning. In humans, high levels of melanin cause a variety of disorders (Nordlund et al. 2006), such as cutaneous hyperpigmentation (solar lentigo, melasma, naevi, freckles, age spots) and ocular retinitis pigmentosa. Moreover, Ty inhibitors are highly sought after as skin-lightening agents for cosmetic products. Human Ty is an important target in both cosmetics and medicine for the modulation of melanogenesis in different organs.

Spectroscopic Studies

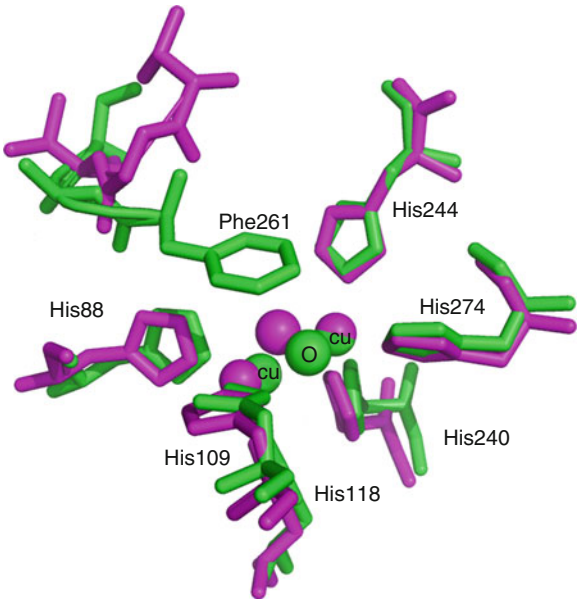
Before the crystal structures of CO and Ty were reported, spectroscopic studies were the only tools for the investigation of the structures and mechanisms of these enzymes. A useful review describing the variety of spectroscopic techniques employed has been published (Tepper et al. 2010). Both type 3 copper centers have similar spectroscopic features. In the *met* state, they are characterized by an EPR-silent Cu(II) pair with an $S = 0$ ground state resulting from antiferromagnetic coupling between the two $S = 1/2$ electronic spins of each copper(II). UV/Vis spectra display a weak d-d transition from 600 to 700 nm, and an intensive UV/Vis absorption maximum around 345 nm is observed after binding of dioxygen because of a peroxo $O_2^{2-} \rightarrow$ Cu(II) charge transfer transition (Solomon et al. 1996; Gerdemann et al. 2002).

The Raman spectrum of the *oxy* form is characterized by an O-O stretching vibration around 750 cm^{-1}. Other spectroscopic techniques, such as EPR, X-ray absorption spectroscopy (XAS), and proton paramagnetic nucleus magnetic resonance (NMR), have yielded data supporting coordination by histidines for Ty or inhibitor binding (Tepper et al. 2010).

Structural Features

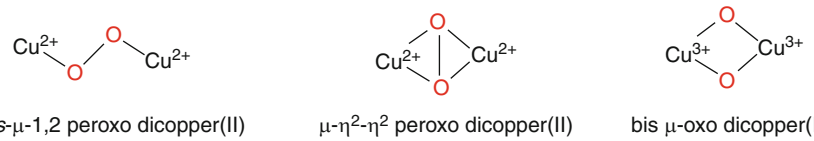
The nature of the related copper center has been discussed for over a century. X-ray crystal structures have recently been resolved for Ty and CO in various forms and from different sources. In 1998, Krebs and collaborators succeeded in the first structural determination of CO from *Ipomoea batatas* (*met*, *deoxy*, and an inhibited form with the bound inhibitor phenylthiourea) (Gerdemann et al. 2002). For Ty despite the large number of Ty sources, Ty have been recently solved from bacterial sources: (1) from recombinant *Streptomyces castanaeoglobisporus* (*met*, *deoxy*, and *oxy* forms) (Matoba et al. 2006), which contained an associated Cu "caddie" protein covering the entrance of the active site; (2) from *Bacillus megaterium* Ty (*met* form and a form with kojic acid) (Sendovski et al. 2011). The Cu. . .Cu pairs in the *met* forms are separated by distances in the range from 2.9 to 3.9 Å and are bridged by one or two water molecules. The observed Cu. . .Cu distances in the *deoxy* forms, generated by anaerobic reduction, increase to more than 4 Å, and bridging solvent molecules were not observed. The only structurally characterized *oxy* form was prepared by H_2O_2 addition to a *Streptomyces castanaeoglobisporus met* form. The Cu. . .Cu distance in this structure was 3.4 Å, similar to the *met* form, but the bridging density was modeled as a μ-η^2:η^2-peroxo peroxide ion. All of the reported structural data suggest that the dicopper active site is highly flexible along catalytic cycles. Although all the dicopper active sites structurally characterized can be well superimposed, interesting differences are observed and reveal structural reasons for the divergences in function and mechanisms as illustrated on Fig. 4 with superposition of *met* forms of *Streptomyces castanaeoglobisporus* Ty and *Ipomoea batatas* CO structures.

While the structure of one copper site (CuB) is very conserved in the analyzed enzymes, the other CuA site exhibits more pronounced differences. In CO, the



Catechol Oxidase and Tyrosinase, Fig. 4 Superposition of the copper active site in *met* forms for *Ipomoea batatas* CO (*green*, (PDB) Protein Data Bank code: 1BT3) and *Streptomyces castanaeoglobisporus* Ty (*pink*, PDB code: ZMX). The numbering is shown for CO (Graphic done by Dr. H. Jamet using PyMOL software (http://www.pymol.org))

partial obstruction of access to the dicopper center by a phenylalanine residue (Phe261) presumably creates substrate-binding specificity (Gerdemann et al. 2002). In the active sites of *Streptomyces castanaeoglobisporus* and *Bacillus megaterium* tyrosinases, the same location is occupied by a glycine (Gly204) or valine (Val218), respectively, both of which are less bulky than phenylalanine. The involvement of amino acid residues near the active site as proton acceptors has also been discussed (coordinated histidine or other noncoordinating residues located near the active site). Another interesting feature in the structure of *Ipomoea batatas* catechol oxidase (Gedermann et al.) is a covalent thioether bond between a carbon atom of a histidine ligand (His109) (one of the ligands of the CuA ion) and the cysteine sulfur atom of Cys 92. A similar type of bond is seen in *Vitis vinifera* PPO and tyrosinase from *Neurospora crassa*. The absence of such a Cys-His bridge, in human tyrosinase for instance, means that thioether modification does not play a direct role in the functional activity of the enzymes but instead imposes structural constraints around the copper center (CuA). In particular, such restraints may help to impose the trigonal pyramidal



Catechol Oxidase and Tyrosinase, Fig. 5 Schematic representation of relevant dicopper-dioxygen cores

geometry (which can also be regarded as a distorted trigonal bipyramid with a vacant apical position) on the CuA ion in the +2 oxidation state of CO. This thioether bond may also prevent the displacement of His109 and a didentate binding mode of the substrate to a single Cu(II) ion. This feature may, in turn, optimize the redox potential of the metal for the oxidation of the catechol substrate and allow for rapid electron transfer in redox processes. Despite a clarification of the active site structures of different forms of CO and Ty by X-ray crystallography, the corresponding catalytic mechanisms are not yet fully characterized.

Synthetic Analogs

Because of the historical lack of structural data for catechol oxidase or tyrosinase, functional and structural analogs of the dicopper active site have been studied. Diverse models of Ty (Rolff et al. 2011 and Itoh and Fukuzumi 2007 for recent reviews) and CO (Koval et al. 2006) have been prepared and discussed. Model complexes have been especially useful in understanding the binding mode of molecular oxygen that in all cases, upon reaction with the Cu(I) Cu(I) *deoxy* form, results in a peroxide bound to a dicopper site. Various possible coordination modes of O_2 to dinuclear copper have been observed. Three of these motifs – bis(μ-oxo), μ-η^2:η^2-peroxo, and trans μ-1,2-peroxo (Fig. 5) – have proven to be dominant and can mediate monophenolase or diphenolase activity, although other examples have been identified or inferred. In the bis(μ-oxo) isomer, the O–O bond is broken, and the copper ions occupy a formal +3 oxidation state coordinated by two O_2^- ligands. The μ-η^2:η^2-peroxo and *trans* μ-1,2-peroxo isomers, in contrast, each features a peroxide dianion bound to two Cu(II) ions.

The different isomers exist in equilibrium with one another, with small activation energies for interconversion, and are alternative intermediates for substrate attack during catalysis although it has not yet been observed in the enzymes. Synthetic CO models have only achieved turnover numbers about 10,000-fold lower than those of the native enzymes (Gerdemann et al. 2002). Very few catalytic models of Ty have been synthesized (Rolff et al. 2011), despite the need in synthetic chemistry for friendly catalytic systems capable of performing *o*-hydroxylation of phenolic substrates using O_2.

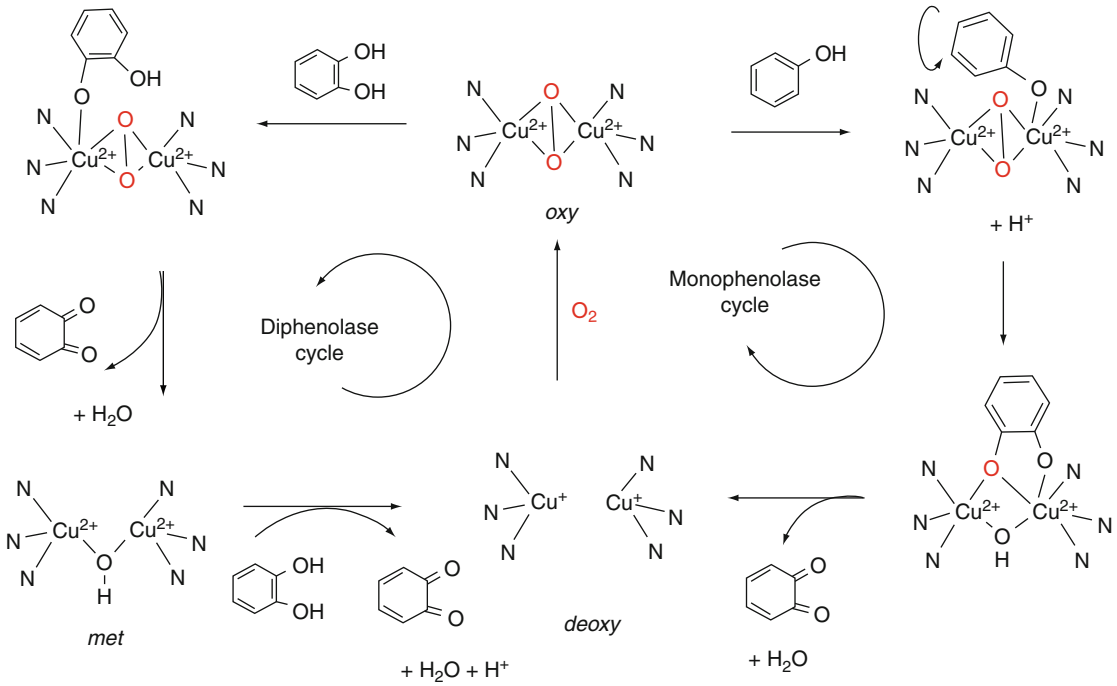
Molecular Mechanism

The extensive structural, spectroscopic, and kinetic data available, in conjunction with synthetic analogs of the active site, have inspired proposals for the rational mechanisms of these enzymes (Solomon et al. 1996; Tepper et al. 2010; Rolff et al. 2011). A schematic scenario is described on Fig. 6, which includes the following steps:

- Peroxide is formed from the *deoxy* form in a μ-η^2:η^2 peroxo dicopper complex.
- The hydroxyl group of the phenol substrate binds to a copper.
- The peroxo electrophilically attacks the *ortho* position of the phenolic substrate (after rotation of the peroxo or substrate reorientation).
- The hydroxo group is protonated, the formed quinone is released, and the *deoxy* form is restored.

To explain the differences between catechol oxydase and tyrosinase, several factors are not yet known, including (1) substrate binding modes; (2) proton transfer, with the possibility that second-sphere hydrogen-bonding partners are involved in the mechanism; and (3) the exact step at which the copper-bound dioxygen is released.

Kinetic and spectroscopic studies of model systems have suggested other mechanistic possibilities, including (1) a one electron reduction of the dicopper(II)



Catechol Oxidase and Tyrosinase, Fig. 6 Schematic illustration of the proposed mechanistic pathways for monophenolase and diphenolase activity

core, leading to the formation of a radical Cu(I)-semiquinone intermediate; (2) the involvement of other Cu_2O_2 adducts as intermediate species; and (3) the formation of hydrogen peroxide as a side product of the catalytic reaction. Although to the best of our knowledge, these species have been observed only under particular conditions during the substrate oxidation by Ty, CO, or model systems, the possibility of different oxidation pathways, either in the natural enzymes or associated with a malfunction, requires further study (Koval et al. 2006).

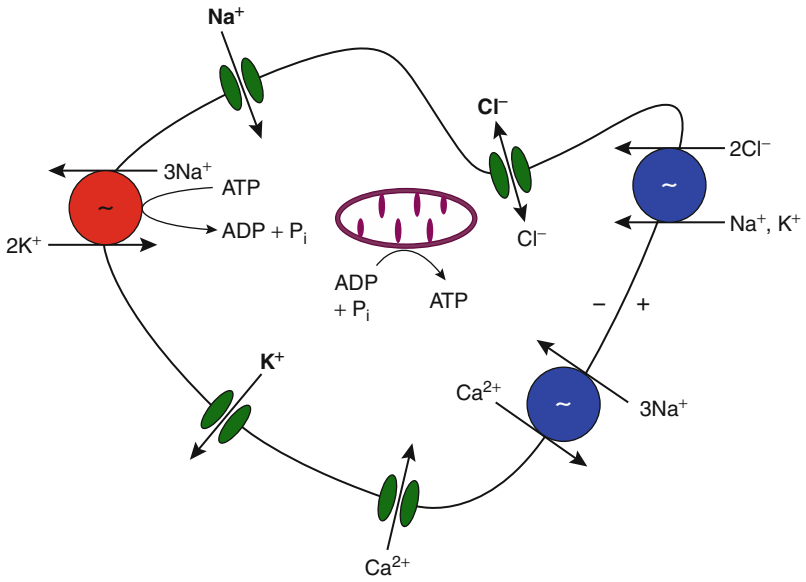
Cellular Electrolyte Metabolism

Olaf S. Andersen
Department of Physiology and Biophysics, Weill Cornell Medical College, New York, NY, USA

Definition

Electrolyte metabolism refers to the processes that regulate the electrolyte composition of the body fluid compartments, which in turn regulates the distribution of water among the different compartments – and thus the cell volume. The movement of ions and other polar solutes through cellular membranes is catalyzed by membrane proteins. Transmembrane differences in the concentrations of K^+, Na^+, and Cl^- are important for the generation of transmembrane potential



Cellular Electrolyte Metabolism, Fig. 1 Schematic representation of a cell, with channels (green) that are selective for K^+, Na^+, Ca^{2+} and Cl^- plus a primary active transporter, the Na^+,K^+-ATPase (red), which maintains the ion distribution between the extracellular and intracellular compartments, and two secondary active transporters (blue), which use the energy stored in the Na^+ concentration difference and the membrane potential difference to move Cl^- into the cell, by the Na^+,K^+, Cl^--cotransporter, and Ca^{2+} out of the cell, by the Na^+,Ca^{2+}-exchanger. The ATP is generated in the mitochondria by oxidative phosphorylation from ADP and inorganic phosphate (P_i). in resting cells, when there is no net charge movement across the plasma membrane, the intracellular fluid is electrically negative relative to the fluid compartment

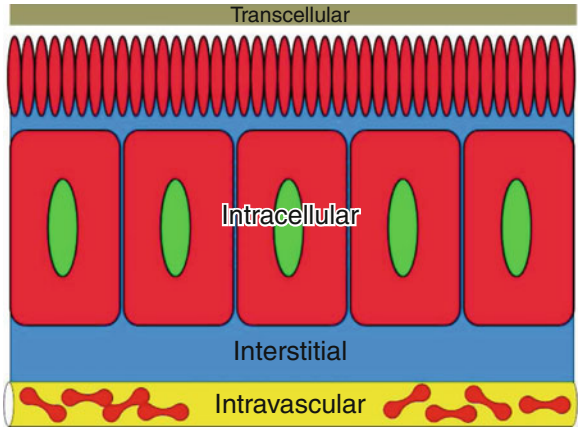
differences. Transmembrane differences in the concentration of Na^+ are important for the maintenance of cell volume.

In addition to being structural elements in proteins (Yamashita et al. 1990), the alkali metal cations, together with the halide anions, are important for the generation of transmembrane potential differences (Sten-Knudsen 2002) and the regulation of cell volume (Hoffmann et al. 2009). Transmembrane potential differences (or membrane potentials) are generated when the ion concentrations in the extracellular and intracellular fluids differ. The cell volume changes when water moves across the membrane in response to a difference in the total solute concentrations (difference in water activity) in the two compartments. The major solutes in both compartments are the inorganic ions, which means that movement of water between the two compartments will cause the electrolyte concentrations (and thus the membrane potential) to change, and maintained changes in membrane potential will cause changes in the ion concentrations and the distribution of water.

The transmembrane movement of ions and water are catalyzed by integral membrane proteins that are embedded in the lipid bilayer that forms the barrier for nonselective solute movement. (Water also can move through the bilayer by dissolving into the bilayer hydrophobic core and diffuse across it, by the so-called solubility-diffusion mechanism (Finkelstein 1987)). Figure 1 shows a schematic cell with the four major ions (K^+, Na^+, Ca^{2+}, and Cl^-), which can cross the cell membrane by passive electrodiffusion through ion-selective channels, as well as by active (energy-dependent) transporters. The membrane proteins catalyze the transmembrane movement of ions and other polar solutes by providing a polar path by which the solutes can cross the membrane, thus avoiding the large desolvation penalty that would be incurred if the solutes were moving through bilayer hydrophobic core.

Fluid Compartments in Multicellular Organisms

In mammals and other multicellular animals, about 60% of the body mass is water, which is distributed



Cellular Electrolyte Metabolism, Fig. 2 The body fluid compartments (see text for details)

between two major fluid compartments (Fig. 2): the extracellular compartment (~20% of the body mass), the environment in which the body cells live, which is divided into the intravascular fluid compartment or plasma (~5% of the body mass) and interstitital fluid compartment (~15% of the body mass); and the intracellular compartment (~40% of the body mass).

The interstitial and intravascular fluid compartments have similar electrolyte compositions: high concentrations of Na^+, Cl^-, and HCO_3^-; low concentrations of K^+, Ca^{2+}, and Mg^{2+}; and a very low concentration of H^+ (Table 1). The two compartments are separated by the capillary wall, which is freely permeable to small electrolytes but imposes a barrier for the movement of proteins; the key difference thus is that the intravascular fluid contains the plasma proteins, some of which serve as carriers for trace metals, for example, serum albumin (Co^{2+}), ceruloplasmin (Cu^{2+}), and transferrin (Fe^{3+}). Though the intracellular fluid compartment is discontinuous, being distributed in all the body's cells, each of which being enveloped by a cell membrane, the intracellular fluid in all cells share common features that justify combining all the intracellular fluid into of a single compartment, namely, high concentrations of K^+, organic phosphates, and protein; low concentrations of Na^+, Mg^{2+}, Cl^-, and HCO_3^-; and very low concentrations of Ca^{2+} and H^+ (Table 1). The major variation among different cells is the intracellular $[Cl^-]$, which varies between ~5 mmoles/L in muscle cells and ~80 mmoles/L in red blood cells (intracellular water is ~2/3 of the cell mass, and the concentrations are per liter water). In addition to these two major compartments, the fluid in the gastrointestinal tract, the urine, and the cerebrospinal and intraocular fluids are lumped into the chemically transcellular fluid compartment, which have the common feature that they are lined by epithelia that regulate their composition.

The ion concentrations of the extracellular (intravascular) and intracellular fluids are listed in Table 1, together with the equilibrium potentials for the different ions (see Ion Permeation and Membrane Potentials, below). As noted above, the intracellular $[Cl^-]$ varies among cell types; the listed values pertain to a "typical" cell.

In Table 1, the values refer to the concentrations of the "free" ions, which may differ from the total concentration of the ion in plasma or cytoplasm. The total Ca^{2+} concentration in plasma, for example, is ~2.5 mM, but ~50% is bound to proteins, phosphate, and organic anions; the free $[Ca^{2+}]$ is only ~1.3 mM. Similarly, the free $[Mg^{2+}]$ is ~50% of the total Mg^{2+} concentration. This binding/buffering is even more pronounced in the intracellular compartment. For H^+, the buffer capacity β is defined as (Roos and Boron 1981)

$$\beta = \frac{\Delta B}{\Delta \mathrm{pH}}, \tag{1}$$

where B is the amount of strong base that is needed to produce a given change in pH; β ≈ 50 mmole/(L·pH). The intracellular fluid is well buffered.

In the case of Ca^{2+} (and Mg^{2+}), the buffering is described using the ion-binding ratio, κ_S, defined as (Zhou and Neher 1993)

$$\kappa_S = \frac{\Delta(\text{total Ion}^{2+})}{\Delta(\text{free [Ion}^{2+}])}; \tag{2}$$

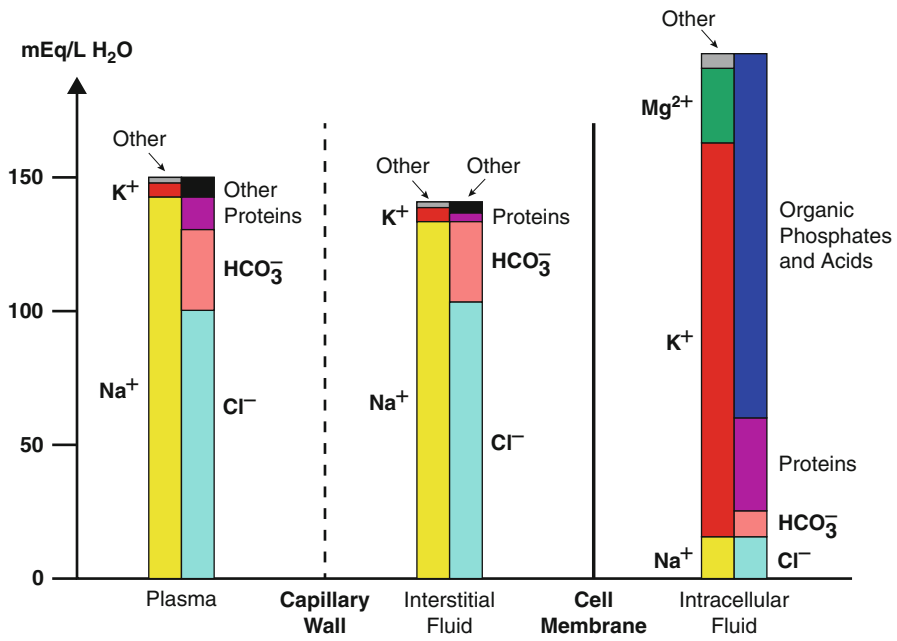
for Ca^{+2}, $\kappa_S \approx 100$; for Mg^{2+}, $\kappa_S \approx 20$. The low intracellular $[Ca^{2+}]$, $[Ca^{2+}]_i$, in particular means that Ca^{2+} becomes an important intracellular messenger because the transmembrane Ca^{2+} fluxes are large enough to cause measurable changes in $[Ca^{2+}]_i$.

It is sometimes helpful to express the electrolyte concentrations in units of milliequivalents per liter (Eq/L or mEq/L). One converts from molar concentrations to Eq/L by multiplying the molar ion concentration by the absolute value of the ion's valence, such that the concentration in mEq/L denotes the total charge contributed by the ion in question. The ionic compositions (in mEq/L) of the major body fluid compartments are shown in Fig. 3.

Cellular Electrolyte Metabolism, Table 1 Extracellular and intracellular ion concentrations and equilibrium potentials

Ion	Extracellular concentration (mM)	Intracellular concentration (mM)	Equilibrium potential (mV)
Na^+	145	~12	+67
K^+	4.5	~150	−94
H^+	0.00004	~0.0001	−24
Ca^{2+}	~1.5	~0.0001	+129
Mg^{2+}	~0.5	~0.5	0
Cl^-	115	~10	−65
HCO_3^-	25	~10	−24

Ion concentrations in millimoles per liter water. Values for mammals, modified from (Andersen et al. 2009) Table 17–3
The [Ca^{2+}] are the free ion concentrations; intracellular [Cl^-] varies considerably among cell types, ranging from ~5 mM in skeletal muscle to ~80 mM in red blood cells
The equilibrium potentials (see Eq. 4) were calculated for $T = 37$ °C using the listed concentrations



Cellular Electrolyte Metabolism, Fig. 3 Composition of plasma, interstitial fluid, and intracellular fluid. Note that the amount of positive and negative charge is the same in each compartment

In each fluid compartment, the total concentration of positive charge (the sum of the mEq/L for all cations) is equal to the total concentration of negative charge (the sum of the mEq/L for all anions). That is, there is electroneutrality in each compartment; this is important because even a very small charge imbalance, a difference between the amount of positive and negative charge present, would be associated with very large electrical potential differences between different fluid compartments (see Ion Permeation and Membrane Potentials, below).

Ion concentrations in the interstitial fluid differ slightly from those in plasma because the capillary wall allows ions, but not plasma proteins, to pass through. Plasma proteins carry a net negative charge, and the cation concentrations in plasma water will be higher than in interstitial water, whereas the inorganic anion concentrations will be less (the so-called Gibbs-Donnan effect).

The composition of the intracellular fluid differs from that of the extracellular fluid (Table 1). The different distributions of Na^+ and K^+ between the extracellular and intracellular solutions result from the action of ion transport systems in the plasma membrane (Fig. 1), which control the passive and active ion movement across the membrane. For the anions, the different distributions are due to both the ion transport systems and the large amounts of membrane impermeable multivalent protein anions and organic phosphates in the intracellular fluid.

Though not clear from the figure, the total free solute concentrations are the same in the intracellular and interstitial fluid compartment, the two compartments are in osmotic balance.

Considering the distribution of the body water between the intracellular and extracellular compartments and the chemical composition of the compartments, one can deduce that most of the body's Na^+ is in the extracellular fluid, whereas most of the K^+ is in the intracellular fluid. There are ~60 mmoles of Na^+ per kg body mass: ~10% in the intracellular fluid; 50–60% in the extracellular fluid; and the rest in bone. There are also ~60 mmoles of K^+ per kg body mass: ~95% in the intracellular fluid; ~2% in the extracellular fluid; and the rest in bone. Even small shifts of K^+ from the intracellular to the extracellular compartment thus may lead to large changes in the extracellular $[K^+]$ concentration, $[K^+]_e$, and vice versa for Na^+.

Ion Permeation and Membrane Potentials

Most cell membranes are endowed with different types of ion channels (Fig. 1) that differ in their ability to discriminate among different ions, their ion selectivity. Because the extracellular and intracellular ion concentrations differ (Table 1), the membrane potential ($V_m = V_i - V_e$, where V_i and V_e denote the electrical potential of the intracellular and extracellular compartment, respectively) will vary as a function of the number and type of conducting channels in the membrane.

The rate of ion movement through a channel, the single-channel current (i), varies as a function of V_m and the channel's reversal potential, V_{rev}, defined as the membrane potential where $i = 0$:

$$i = g \cdot (V_m - V_{rev}), \tag{3a}$$

where g is the single-channel conductance. g varies depending on the channel type, the permeant ion concentration(s) and V_m; most channels have conductances that range between 5 and 50 pS ((Hille 2001) Figure 12.8). The total membrane current (I) that is carried across by all channels of a given type will be:

$$I = N \cdot i = N \cdot g \cdot (V_m - V_{rev}) = G \cdot (V_m - V_{rev}), \tag{3b}$$

where N denotes the number of *conducting* channels in the membrane and G the total membrane conductance contributed by the channels in question.

In the case of highly selective channels that catalyze the transmembrane movement of only a single ion type, V_{rev} is equal to the ion's equilibrium (or Nernst) potential E:

$$E = \frac{-k_B T}{z \cdot e} \cdot \ln\left\{\frac{C_i}{C_e}\right\}, \tag{4}$$

k_B is Boltzmann's constant, T the temperature in Kelvin, z the ion valence, e the elementary charge, and C_i and C_e the intracellular and extracellular ion concentrations, respectively. (Membrane potentials, and equilibrium potentials are measured relative to the extracellular solution; membrane currents are defined to be positive when the current flow is from the intracellular to the extracellular solution).

Membrane potentials arise because ions diffuse from high to low concentrations; the diffusive flux, J_D, is given by Fick's first law

$$J_D = -A \cdot D \cdot \frac{dC}{dx}, \tag{5}$$

where A is the membrane area, D the diffusion coefficient, C the concentration and x distance (from the intracellular toward the extracellular solution). This diffusive ion movement will establish a *small* charge imbalance between the intracellular and extracellular fluids, which will give rise to a membrane potential difference, ΔV, given by

$$\Delta V = -\frac{\Delta Q}{C_m}, \tag{6}$$

where ΔQ is the net charge transfer across the membrane ($= \Delta n \cdot z \cdot e$, where Δn denotes the net transfer of ions across the membrane) and C_m the membrane capacitance ($= A \cdot C_{sp}$, where C_{sp} is the specific membrane capacitance, ~1 μF/cm^2). In response to the generation of ΔV, an electrical force will act on the ions causing them to migrate (in the opposite direction to the diffusive flux); the electromigrative flux, J_E, is given by

$$J_E = -A \cdot u \cdot C \cdot z \cdot e \cdot \frac{dV}{dx}, \tag{7}$$

where u is the ion mobility ($= D/k_B T$). The resting membrane potential then is the potential difference

where diffusive and electromigrative fluxes exactly balance each other:

$$J_E + J_D = 0 \quad \text{or}$$
$$A \cdot D\left(\frac{dC}{dx} + C \cdot \frac{ze}{k_B T} \cdot \frac{dV}{dx}\right) = 0. \tag{8}$$

Equation 8 can then be integrated to yield the Nernst or equilibrium potential, E, cf. (4). (Strictly, E should be expressed in terms of the ion activities, but activity coefficients are neglected in (4) because the ionic strengths of the extracellular and intracellular solutions are similar).

If a cell membrane were endowed with only one type of highly selective channels that were closed (nonconductive) at time $t < 0$, for them to open at $t = 0$, V_m would move from 0 mV to E as

$$V_m(t) = E \cdot (1 - \exp\{-t/\tau\}), \tag{9}$$

where $\tau = C_m/G_m$; the net charge transfer would be, cf. (6), $E{\cdot}C_m$. G_m varies between 0.1 S/cm^2 (in nerve and muscle, where rapid potential changes are critical) and 10^{-8} S/cm^2 (red blood cells), meaning that τ varies between 10 μs and 100 s.

Membrane potential changes require charge transfer across the membrane, which means that electroneutrality cannot be exact – but the error is small, as illustrated by considering the net charge transfer required to move the membrane potential from 0 mV to the equilibrium potential for K^+, E_K. For a spherical cell of radius, r, equal to 10 μm and containing 150 mM K^+(and an equal concentration of negative charge), there is $4{\cdot}\pi{\cdot}r^3/3{\cdot}[K^+]$ or $6.28{\cdot}10^{-13}$ moles of K^+ in the cell. The net charge transfer (in moles of charge) is $4{\cdot}\pi{\cdot}r^3{\cdot}C_m{\cdot}E_K/F$, where F is Faraday's constant, or $1.23{\cdot}10^{-17}$ moles. The net K^+ movement needed to establish the membrane potential is ~0.002% of the total amount of K^+ in the cell! Membrane potential changes results from very small net charge movements across the membrane; it is reasonable to invoke electroneutrality.

If there is only a single type of highly selective ion channels in the membrane, the resting membrane potential – the time-invariant potential of a cell "at rest" when the net current (charge transfer) across the membrane is 0 – will be equal to the equilibrium potential for the ion in question. If the membrane is endowed with several different types of highly selective ion channels – the major current-carrying ions are Na^+, K^+, Cl^-, and Ca^{2+} – then V_m becomes a weighted average of the equilibrium potentials for the different ions:

$$V_m = \frac{G_{Na} \cdot E_{Na} + G_K \cdot E_K + G_{Ca} \cdot E_{Ca} + G_{Cl} \cdot E_{Cl} - I_{active}}{G_{Na} + G_K + G_{Ca} + G_{Cl}}, \tag{10}$$

where the subscripts denote the values for the different ions and I_{active} is the current generated by the active (energy-dependent) transporters. In the resting cell, G_K usually is much larger than the membrane conductances for other ions and V_m will be close to E_K.

Cell Volume and Osmotic Balance

Cell membranes are, with few exceptions, very permeable to water (Finkelstein 1987). Water occupies volume, and a net water movement between the intracellular and extracellular compartments will be associated with changes in cell volume. Cell volume regulation thus requires osmotic balance across cell membranes – the chemical potential of water, μ_W, must be the same on both sides of the membrane such that there is no net water flow (Finkelstein 1987):

$$\mu_{W,i} = \mu_{W,e}, \tag{11}$$

where the subscripts "i" and "e" denotes the intracellular and extracellular compartments, respectively. For dilute solutions,

$$\mu_W = \mu_W^0 + RT \cdot \ln x_W + P \cdot \overline{V}_W, \tag{12}$$

where μ_W^0 denotes the standard chemical potential of water, x_W and $\overline{V}_W$ its mole-fraction and partial molar volume, and P the hydrostatic pressure. Combining (11 and 12),

$$\mu_W^0 + RT \cdot \ln x_{W,i} + P_i \cdot \overline{V}_W = \mu_W^0 + RT \cdot \ln x_{W,e} + P_e \cdot \overline{V}_W \tag{13}$$

or,

$$\Delta\Pi = P_i - P_e = -\frac{RT}{\overline{V}_W} \cdot \ln\left\{\frac{x_{W,i}}{x_{W,e}}\right\}, \tag{14}$$

where $\Delta\Pi$ is the osmotic pressure difference between the two solutions, and

$$\Pi_i = -\frac{RT}{\overline{V}_W} \cdot \ln\{x_{W,i}\} \quad \text{and} \quad \Pi_e = -\frac{RT}{\overline{V}_W} \cdot \ln\{x_{W,e}\} \tag{15}$$

are denoted the osmotic pressures of the intracellular and extracellular solution, respectively. x_W is, by definition, given by

$$x_W = \frac{n_W}{n_W + n_s} = 1 - \frac{n_s}{n_W + n_s} = 1 - x_s, \text{ where } n_s = \sum n_i, \tag{16}$$

where n_W and n_i denote the number of moles of water and the different solute species, n_s is the total number of moles of solute, in the solution, and x_s the mole fraction of total solute. For dilute solutions, when $n_s << n_W$ (and $x_W \approx 1$), it becomes useful to express (15) in terms of the (total) solute mole fractions (concentrations), rather than x_W: and

$$\Pi_i = -\frac{RT}{\overline{V}_W} \cdot \ln\{1 - x_{s,i}\} \approx \frac{RT}{\overline{V}_W} \cdot x_{s,i} \approx RT \cdot \frac{n_{s,i}}{\overline{V}_W \cdot x_{W,i}} \approx RT \cdot C_{s,i}$$

and

$$\Pi_e = -\frac{RT}{\overline{V}_W} \cdot \ln\{1 - x_{s,e}\} \approx \frac{RT}{\overline{V}_W} \cdot x_{s,e} \approx RT \cdot \frac{n_{s,e}}{\overline{V}_W \cdot x_{W,e}} \approx RT \cdot C_{s,e} \tag{17}$$

where $C_{s,i}$ and $C_{s,e}$ denote the total solute concentrations in the two compartments. In the dilute solution limit, (14) thus can be rewritten as

$$\Delta\Pi = \Pi_i - \Pi_e = RT \cdot (C_{s,i} - C_{s,e}) = -RT \cdot (C_{W,i} - C_{W,e}) \tag{18}$$

Thus, if $x_{W,i}$ were different from $x_{W,e}$ (if $C_{s,i} \neq C_{s,e}$), there would be a hydrostatic pressure difference across the cell membrane. A difference in total solute concentration of 1 mM, would produce an osmotic pressure difference of 0.0246 atm or $2.49 \cdot 10^3$ Pa. Any transmembrane pressure would be associated with a membrane tension, T_{mem}, given by Laplace's law (for a spherical cell of radius r):

$$T_{mem} = \frac{\Delta\Pi \cdot r}{2} \tag{19}$$

For $r = 10$ μm, a pressure difference of $2.5 \cdot 10^3$ Pa would produce a tension of 12.5 mN/m, which is sufficient to tear the membrane apart (Dai et al. 1998). Experimental determinations of T_{mem} in living cells show that $T_{mem} \approx 0.1$ mN/m (Dai et al. 1998), meaning that the total solute concentrations in the two compartments differ by only ~4 μM, or ~0.001%. It is reasonable to invoke osmotic balance.

The major intracellular solutes (the inorganic ions) are able to cross the membrane, and cell viability depends on exquisite control of the intracellular solute concentration, which is controlled by the combined action of the different membrane proteins that catalyze transmembrane solute movement (Fig. 1). One ion, Na^+, is effectively impermeant due to its relative low permeability and active extrusion by the Na^+,K^+-ATPase (the sodium pump), and cell volume is maintained by the Na^+,K^+-ATPase, which keeps $[Na^+]_i$ low. But it is not enough to keep $[Na^+]_i$ low; it is equally important to maintain $[Na^+]_e$ high, as Na^+ de facto becomes the major impermeant solute in the extracellular fluid. Extracellular Na^+ homeostasis is maintained by the combined actions of the gastrointestinal tract and the kidneys, where the Na^+,K^+-ATPase again plays a key role in the transepithelial ion movement, cf. (Palmer and Andersen 2008).

Cerium

Takashiro Akitsu
Department of Chemistry, Tokyo University of Science, Shinjuku-ku, Tokyo, Japan

Definition

A lanthanoid element, the first element of the f-elements block, with the symbol Ce, atomic number 58, and atomic weight 140.115. Electron configuration $[Xe]4f^{1}5d^{1}6s^{2}$. Cerium is composed of three stable (^{140}Ce, 88.450%; ^{136}Ce, 0.185%; ^{138}Ce, 0.251%) isotopes and one radioactive (^{142}Ce, 11.114%) isotope, discovered (*Berzelius and Hisinge; Klaproth*) in 1803 and isolated by Mosander. Cerium exhibits oxidation states III and IV; atomic radii: 182 pm, covalent radii: 205 pm, redox potential (acidic solution) Ce^{3+}/Ce −2.34 V, Ce^{3+}/Ce^{2+} −3.2 V; electronegativity (Pauling) 1.12. Ground electronic state of Ce^{3+} is $^{2}F_{5/2}$ with S = 1/2, L = 3, J = 5/2 with $\lambda = 640\ cm^{-1}$. Most stable technogenic radionuclide ^{144}Ce (half-life 284.9 days, $E_{max}(\beta) = 2.98$ MeV.) The most common compounds: CeO_2 (soluble in acids in the presence of reduction agent), $Ce(NO_3)_3{\cdot}6H_2O$, $CeCl_3{\cdot}6H_2O$, $CeSO_4{\cdot}4H_2O$. Biologically, cerium is of low to moderate toxicity, can cause itching, skin lesions, and death (at animals injected with large doses) due to cardiovascular collapse (Atkins et al. 2006; Cotton et al. 1999; Huheey et al. 1997; Oki et al. 1998; Rayner-Canham and Overton 2006).

Cerium, Physical and Chemical Properties

Fathi Habashi
Department of Mining, Metallurgical, and Materials Engineering, Laval University, Quebec City, Canada

Cerium is the most abundant rare-earth element and exceeds in abundance tin, cobalt, and lead. It is separated from other rare-earth elements by oxidation of solutions resulting from attack of bastnaesite or monazite. The most important uses of misch metal or cerium are their ability to react with oxygen, hydrogen, nitrogen, sulfur, arsenic, bismuth, and antimony, thus reducing the effects of these elements on the properties of the metals.

Misch metal or cerium-containing master alloys are added to cast iron to improve ductility, toughness, and the microstructure. Cerium allows graphite to form nodules, causing nucleation in spheroidal and vermicular cast iron, and neutralizes the harmful effect of the tramp elements. Addition of misch metal to copper alloys improves tensile strength and deep-drawing properties. The heat resistance and ductility of aluminum conductor cables are improved without any significant decrease in electrical conductivity. Lighter flint alloy consists basically of misch metal and iron. Some other metals are added in small amounts to modify the pyrophoric properties and to improve processing. The frictional pyrophoric properties of cerium-iron are based on a combination of microstructure and mechanical and chemical properties of the alloy. The typical crystal structure of commercial alloy consists of tough, brittle primary crystals of Ce_2Fe_{17} enclosed by a layer of $CeFe_2$ embedded in a soft matrix of $CeFe_2$ and Ce. The principal uses for cerium compounds are as polishing agents and as a component in glass.

Physical Properties

Atomic number	58
Atomic weight	140.12
Relative abundance in Earth's crust,%	2.5×10^{-3}
Density, g/cm^3	6.770
Crystal structure at room temperature, $a_0 = 0.51612$ nm	Face-centered cubic
Melting point, °C	798
Boiling point, °C	3,433
Heat of fusion ΔH kJ/mol	5.5
Specific heat at 25°C, J mol^{-1} K^{-1}	27.0
Coefficient of linear thermal expansion at 25°C, K^{-1}	27.0×10^{-6}

Chemical Properties

Cerium has not only the normal rare-earth +3 oxidation state but also the exceptional +4 state which simplifies its separation from the other rare-earth elements. Misch metal is a mixture of cerium, lanthanum, neodymium, and praseodymium with cerium as the major constituent. It is the lowest-priced rare-earth metal, because no expensive chemical separation is needed to produce it being produced by fused-salt electrolysis of rare-earth chlorides.

Misch metal is ductile. The freshly cut surface has a metallic gray appearance. In air, the surface oxidizes to form yellow to greenish-gray rare-earth hydroxide carbonates or oxide hydrates. Massive metal burns above 150°C in pure oxygen; however, chips, turnings, and powder burn at this temperature even in air. Misch metal dissolves in dilute mineral acids with evolution of hydrogen.

Cesium, Physical and Chemical Properties

Fathi Habashi
Department of Mining, Metallurgical, and Materials Engineering, Laval University, Quebec City, Canada

Cesium is a very soft, ductile, silvery white metal. It is the last member of the alkali metals (if Francium, the metal following it in the group, is ignored since it is radioactive with very short half-life). Since it has the largest atomic size of the group then the outermost electron will be far away from the nucleus and therefore easily lost because of the weak electrostatic force of attraction. Consequently, cesium is the most reactive, not only the alkali metals but also of all metals. It also has the lowest hardness among all metals. Applications of nonradioactive cesium include photoelectric cells, optical character recognition devices, photomultiplier tubes, video camera tubes, optical components of infrared spectrophotometers, catalysts for several organic reactions, crystals for scintillation counters, and in magnetohydrodynamic power generators.

Physical Properties

Symbol	Cs
Atomic number	55
Atomic weight	132.91

Chemical Properties

Cesium is a monovalent typical metal, with electronic structure 2, 8, 18, 18, 8, 1. When it loses its outer most electron, it will have the electronic structure of inert gases. Because of its extremely low ionization potential, cesium is usually more reactive than lithium, sodium, or potassium and pronouncedly more reactive than rubidium. When cesium is exposed to air, an explosion-like oxidation to form cesium superoxide, CsO_2, occurs; contact with water results in a vigorous reaction to form cesium hydroxide and hydrogen gas, which may ignite spontaneously.

Radioactive cesium isotope, ^{137}Cs (half-life 30.1 years), is a product of atomic bomb explosions and nuclear reactors disasters, together with ^{90}Sr, and both are widely present in the biosphere.

Definition

The aim of this entry is to resume and discuss the material currently available on therapeutic effects of cesium salts, their applications in medicine, and their toxicity.

Introduction

Cesium is naturally present as the stable ^{133}Cs in various ores and to a lesser extent in soil. The most important radioactive nuclides are ^{131}Cs and ^{137}Cs, with half-lives of 10 days and 30 years, respectively. Cesium enters easily into the plant and animal systems and is deposited in soft tissues. The total content of this intracellular form is very low, no more than 0.00131 g. Cesium salts are used as catalysts and for the production of special glasses and ceramics. In molecular biology, they are applied for decades for density gradient ultracentrifugation in order to isolate viral particles, subcellular organelles and fractions, and nucleic acids from biological samples.

An extensive literature including vast reviews arose concerning the distribution and residence times of cesium in the body and means of enhancing its excretion. The knowledge about cesium metabolism and toxicity is sparse, since acute and chronic toxicity is not sufficiently studied. However, cesium is by no means a novel topic in medicine. More than 120 years ago, Sidney Ringer, the scientist who is well known for his isotonic solution resembling blood serum in its salt constituents, engaged in a study of this rare alkaline element. For the first time, he postulated that cesium (as well as rubidium, another heavy element) was supposed to behave as physiological analog for potassium, and therefore employed for replacement therapy. Lately, this prognostic turned out to be confirmed only partially.

Once cesium enters the body, it is distributed through the system, with higher concentrations in the kidneys, skeletal muscle, liver, red blood cells, myocardium, placenta, and breast milk. Its biological half-life in humans is between 1 and 4 months. Naturally, it binds preferably to anionic intracellular components of erythrocytes and decreases their ability to give up oxygen in tissues. Absorption of cesium from the stomach to blood is assumed to be negligible, the same as for potassium. The absorption and distribution of cesium radioactive isotopes are identical to those of the stable ^{133}Cs.

Physiological Effects of Cesium

So far, no data has been located regarding gastrointestinal, hematological, musculoskeletal, hepatic, renal, endocrine, dermal, ocular, body weight, immunological, neurological, or development effects. No reports were located in which cancer in humans or animals could be associated with intermediate or chronic-duration oral exposure to stable cesium. Nevertheless, this element is known to produce remarkable and even dangerous metabolic effects regarding cardiovascular system.

It is worth reminding that cardiac K^+ channels are membrane-spanning proteins that allow the passive movement of K^+ ions across the cell membrane along its electrochemical gradient. Meanwhile, the pathophysiological mechanisms of the immediate Cs^+ effects on cardiac tissues consist in replacing K^+, leading to the blockade of inwardly rectifying K^+ current at ventricular level, and nodal hyperpolarization-activated cation current, both of which primarily affect the resting membrane potential. Furthermore, Cs^+ block of I_{k1} (inward rectifier current) involves interactions between cations at binding sites within the channel pore, and the inhibition of inward I_{k1} is likely to be explained by Cs^+ entry into I_{k1} channels, favored by hyperpolarization. In an animal model, the marked

prolongation of the action potential duration (i.e., acquired long QTc syndrome) observed in man was also reproduced, but alterations were observed, such as ventricular tachycardia and torsade de pointes (Gmelin's 1973). These arrhythmogenic effects of Cs^+ ions have been linked to the inhibition of hyperpolarization-activated current and a reduction in cardiac K^+ currents, which may be blocked by Cs^+ ions from the intracellular or extracellular side. The investigation of such channelopathies continues to yield remarkable insights into the molecular basis of cardiac excitability.

Experimentally, results have been obtained in previous investigations in dogs and rabbits, when intravenous CsCl provoked an instant ventricular tachycardia associated with monophasic early afterdepolarizations. At tissue level, it was also shown that Cs^+ causes a voltage-dependent block of inward K^+ currents in resting skeletal muscle fibers. It is to suggest that the mechanisms involved are basically the same. However, it must be stressed that reaction rates are determined by molarity; so, in order to produce the same kinetic effect, cesium chloride might be taken in approximately double the amount in comparison to potassium chloride, and it is rarely achieved in practice.

The K^+channels regulate the resting membrane potential, the frequency of pacemaker cells, and the shape and duration of the cardiac action potential. In mammalian cardiac cells, K^+ channels include, among others, rapid (I_{Kr}) and slow (I_{Ks}) components of the delayed rectifier current, as well as the inward rectifier current (I_{K1}). Changes in the expression of K^+ channels explain the regional variations in the morphology and duration of the cardiac action potential among different cardiac regions and are influenced by heart rate, intracellular signaling pathways, drugs, and cardiovascular disorders. A number of cardiac and noncardiac drugs are capable of blocking cardiac K^+ channels, and can cause an acquired long QTc syndrome as well as torsade de pointes. In cases of extreme gravity, the arrhythmias can deteriorate to ventricular fibrillation and cardiac arrest. It was concluded that cesium is a potent potassium blocker, and therefore it has been widely used to study the characteristics of these channels.

Recently, in animal studies, cesium salts have shown epileptogenic properties in respect to neocortical and hippocampal areas. This effect has been suggested to be related to an alteration in extracellular potassium regulation by glia. However, so far, no clinical equivalent is known with regard to human neurophysiology.

Clinical Effects of Cesium Intake

Oral intake of cesium chloride has been widely promoted on the basis of the hypothesis referred to as "high pH cancer therapy" advanced in 1984 by K.A. Brewer who did his Ph.D. in physics. Cesium chloride therapy named as "complementary alternative method" has never been approved, neither by the US Food and Drug Administration (FDA) nor by the European Agency for the Evaluation of Medicinal products. It is no surprise as this proposal plainly assumes that the usage of alkaline ions and, in particular, cesium might (or should) provoke substantial increase in pH within malignant cells. It assumes also that only tumor cells tend to incorporate cesium ions. This alone is enough to establish that the therapy is not based on good information. Nevertheless, the alkalinity is not a key point, since CsCl is not different from KCl, as dissociation degrees of their respective hydroxides are very close. Hence, the presence of cesium ions in the cell can, by no means, guarantee increased intracellular pH in human body, although, in principle, fluorescent pH probes could be useful at least for comparative studies of cesium action. So, there are neither theoretical nor experimental grounds for the idea of CsCl (or any other stable cesium salt) application in cancer treatment.

Meanwhile, desperate patients looking for an immediate miraculous relief from cancer would not go into these subtleties. So, the fact that this method is not currently officially endorsed led to adverse reaction, that is, blaming the "medical establishment" for their conservative and unsupportive standpoint. All this ever more stimulated widespread self-treatment without bearing in mind that it could lead to serious problems. Ordinary people with no medical knowledge and individuals with discovery delusions started to take and recommend large amounts of cesium chloride with no clinical evaluation of its possible hazardous consequences. Cesium chloride is sold as a routine dietary supplement in the USA. Unlike companies that produce drugs, the providers do not have to show evidence of safety or health benefits to the FDA before selling their products.

Finally, a paper has recently been published, bluntly stating that two patients suffering from terminal malignancies "were administered intravenous doses of an unapproved therapy," consisting of a solution containing cesium chloride. Both patients died. As the cases are unrelated, it seems that the procedures were carried out with experimental purposes. No "informed consent" has been issued. No data as to the dosage applied, clinical circumstances, or results of postmortem examination of these ethically inappropriate events were supplied.

Clinical Examples of Cesium Ingest

Herein, only representative clinical examples are discussed. In a report released in April 2004, US Agency for Toxic Substances and Disease Registry stated that no communications had been located in literature regarding death in humans following acute, intermediate, or chronic duration exposure to stable cesium. However, in 2003, a paper was published describing two deaths following acute exposure to this element. Case 1 was a 41-year-old male with kidney cancer, and case 2 was an 82-year-old male with lung cancer. As mentioned before, both patients were administrated a solution containing cesium chloride. Forensic records collected on these two cases indicated that on one patient (case 1), two cesium therapies were administrated on two consecutive days. Initially, the patient developed uncontrolled chills and seizures, and went into cardiac arrest while in the doctor's office. Case 2 apparently collapsed while he was receiving the intravenous injection containing the cesium chloride.

According to comparison of cesium levels in exposed and nonexposed tissues, in case 1, cesium content in liver tissue was 100,000 times higher than in control samples, and it was 10,000 times higher in brain than in controls. In case 2, cesium levels were substantially lower – 10,000 and 1,000 times, respectively. In both instances, cesium in whole blood was relatively lower, indicating its immediate migration into tissues, in accordance to the model of cesium distribution in the body. So, these cases should be qualified as acute poisoning with cesium chloride. It is worth reminding that even more innocuous potassium chloride is lethal, when injected intravenously in the form of concentrated solution.

In order to illustrate the safety of high pH therapy, another case report has described the effects of oral intake of cesium chloride. The author volunteered to experience on himself the effect of long-term oral administration of 6 g per day of cesium chloride. The drug was dissolved in water and consumed immediately after the morning and evening meals, which were diet-restricted to attain approximately 1% potassium intake. There was an initial general feeling of well-being and heightened sensory perception. A gradual decrease in appetite was noted initially before it was stabilized at a later date. Discontinuation of rich bread meals resulted in pre-nausea sensation which was followed by diarrhea. Almost immediately, a tingling sensation in the lip and cheek regions was experienced, but no harmful effects were noted in intellectual capacities or in driving skill.

Another self-treatment by alternate therapy is related to a woman presented to the emergency department following an episode of hypotension syncope. The patient was thirsty, disoriented, and hypotensive. An electrocardiogram indicated a sinus rhythm with a long QTc interval, with episodes of polymorphic ventricular tachycardia. The patient had a 2-year history of colon cancer with liver metastases and had received chemotherapy. At the same time, she had been self-treating with an alternative therapy of oral cesium salts for several weeks and a vegetarian diet. As in the previous case, the patient experienced numbness or tingling of the lips. She developed hypokalemia, but magnesium and calcium levels were unchanged. She was treated with saline solution supplemented with potassium, discharged herself 3 h late, but returned the next day following a second episode of syncope or possible seizure and still was hypokalemic. Electrocardiogram depicted sinus bradycardia, premature ventricular, and a more prolonged QTc interval. During the next 3 days, following discontinuance of cesium, the QTc interval gradually shortened to 390 ms, and potassium remained in the reference levels. This observation confirmed the history of cesium consumption but could not be directly related to the dose of cesium in the kinetic studies because those models involved intravenous administration and acute response rather than chronic exposure to oral cesium salts.

Another case of cesium chloride therapy was reported describing a man with recurrent syncope, who underwent a naturopathic treatment consisting of

2 g of cesium chloride four times a day intravenously for 2 weeks for prostate cancer. During treatment, he had his first episode of syncope. He continued to take cesium chloride three times a day. Two months later, he was hospitalized because of recurrent syncopes. The electrocardiogram showed a prolonged QTc interval and ventricular ectopic beats. Runs of torsade de pointes tachycardia were recorded on telemetry. The serum potassium level was 2.8 mEq/L. Analysis of a blood sample revealed a plasma cesium level of 830 μmol/L that is approximately 276,000 times higher than reference data and comparable to the values found in the case of acute poisoning discussed early but without a lethal outcome. The patient was treated with intravenous potassium and magnesium. The QTc interval remained prolonged and ventricular premature beats persisted after normalization of the serum potassium level. The patient agreed to stop taking cesium chloride. After 6 months of follow-up, he had not had any further episode of syncope and the corrected QTc interval had returned to normal.

Another case presentation, in this case with no cancer involvement, concerns a woman presented to a local hospital after experiencing three episodes of syncope during the past week. Prior to this, she had never had syncope or near-syncope. Her latest syncopal episode required cardiopulmonary resuscitation. She had no prior history of cardiovascular or neurological disease and was taking no prescription medications. However, she was taking an array of dietary supplements and natural products including cesium salt. She described this as part of a "detoxification program" for menorrhagia that entailed drinking 1–2 gal of water a day along with cesium salt. She had been doing this for the last 2 weeks. An electrocardiogram revealed normal rhythm and profound QTc prolongation. She had only mild hypokalemia and mild hypomagnesemia.

These were corrected with no significant change in the QTc. Although there was never electrocardiographic documentation of torsade de points, her physician recognized that cesium might have prolonged the QTc interval and induced arrhythmia. Hence, she was treated by prompt cessation of her "detoxification regimen" and correction of electrolyte abnormalities. A urine assay for cesium revealed a level of 750 mg/L, which is 65,000 times higher than the data for general population. Daily electrocardiograms showed gradual normalization of her resting QTc. The patient did well and returned to her previously asymptomatic syncope-free state.

Recently, a life-threatening torsade de pointes resulting from "nature" cancer treatment was described in a case report of a woman with recurrent syncope attacks. One of her naturopathic drugs was subsequently confirmed containing 89% CsCl by weight. Besides conventional treatment of QTc prolongation and torsade de pointes, the patient was given a 4-week course of oral Prussian blue to enhance gastrointestinal elimination of cesium. This is the first published case of a nonradioactive cesium poisoning treated with Prussian blue.

Practically no data are available for children, but recently a case was described in an adolescent 16-year-old girl with metastatic hepatocellular carcinoma. She had received courses of chemotherapy that resulted in minimal tumor regression. Against the advice of her oncologist, an alternative regimen was started that included cesium chloride supplements. Two weeks later, two brief syncopal episodes were observed. An electrocardiogram revealed occasional premature ventricular contractions, and QTc interval prolongation. After admitting to the hospital, she experienced monomorphic ventricular tachycardia. Her plasma cesium level was 2,400 mg/L. Two days later, the QTc interval on electrocardiogram had normalized.

Therapeutic Usage of Cesium

After the Chernobyl and recent Fukushima nuclear accidents, cesium was recommended as preventive therapy for radiation poisoning by the isotope ^{137}Cs. The principle of this treatment is quite clear: to saturate the body with the stable cesium (preferably in the form of cesium iodide) enhancing the clearance of radionuclide and effectively replacing it with a safer isotope. Actually, the data suggest that there is a threshold of maximum cesium saturation in the red blood cells and any additional exposure will not stimulate ^{137}Cs excretion. It is important that cesium salts are water soluble, which means that it is excreted from the body via urine and it happens very quickly. So, the most effective way of protection is to stay well hydrated.

As to the cancer treatment, ^{131}Cs and ^{137}Cs have been promoted to deal with various types of malignancies. The so-called cesium brachytherapy is a method of radiation usage in which sealed sources are

employed to deliver a radiation doses at a distance of up to a few centimeters by surface, intracavitary, or intestinal applications. Radiation kills or arrests the growth of the cancer with minimal damage to healthy tissue. The isotope is usually incorporated into ^{137}Cs-Na borosilicate glass. The leach rates of the radioactive source are within permissible limits. Radioactive isotope 137 brachytherapy is used for carcinomas of cervix uteri, intestinal cancers, carcinoma of the tongue and floor of the mouth. Excellent results (with recurrence $< 3\%$) have been achieved in the treatment of the skin of nose epitheliomas. The radioactive isotope ^{131}Cs, which was approved in 2003 by the FDA for use in brachytherapy for prostate cancer and other malignancies, has the advantage of a shorter half-life. That means faster dose delivery, that cancer cells have less opportunity to repopulate, and less protracted radiation to normal healthy tissues, so side effects are minimal.

Summary

The knowledge about cesium metabolism and toxicity is sparse. Oral intake of cesium chloride has been widely promoted on the basis of the hypothesis referred to as "high pH cancer therapy," a complimentary alternative medicine method for cancer treatment. However, no properly confirmed tumor regression was reported so far in all probability because of neither theoretical nor experimental grounds for this proposal. The aim of this entry is to resume and discuss the material currently available on cesium salts and their applications in medicine. The presence of cesium in the cell does not guarantee high pH of its content, and there is no clinical evidence to support the claims that cancer cells are vulnerable to cesium. Cesium is relatively safe; signs of its mild toxicity are gastrointestinal distress, hypotension, syncope, numbness, or tingling of the lips. Nevertheless, total cesium intakes of 6 g/day have been found to produce severe hypokalemia, hypomagnesemia, prolonged QTc interval, episodes of polymorphic ventricular tachycardia, with or without torsade de pointes, and even acute heart arrest. However, full information on its acute and chronic toxicity is not sufficiently known. Health care providers should be aware of the cardiac complications, as a result of careless cesium usage as alternative medicine. Radioactive cesium is successfully used for cancer treatment in the form of brachytherapy that is a sealed-source radiotherapy which is effective alternative for the standard external beam therapy.

Definitions

Contact dermatitis: A skin reaction (dermatitis, i.e., eczema) resulting from exposure to allergens (allergic contact dermatitis) or irritants (irritant contact dermatitis).

Introduction

Chromium (Cr) (Greek chroma, meaning color) is one of the most widely distributed metals and was discovered in 1797 by the French chemist Louis Nicolas Vauqelin who named it after its color characteristics. Cr is found in nature as Cr ironstone ($FeCr_2O_4$) and as red lead ore ($PbCrO_4$, chrocoite). Cr ironstone is used commercially and is mined in southern parts of Africa, the Philippines, and Kazakhstan. The majority is used for metallurgical purposes such as stainless steel and other alloys. It is also used for leather tanning, preservation of woods, color pigments in paints, and laboratory chemicals. In addition, Cr compounds are present in raw materials used for the production of cement. Skin exposure to Cr may cause contact allergy and allergic contact dermatitis (Lidén et al. 2010).

Allergic and Irritant Contact Dermatitis

Contact dermatitis is an eczematous skin reaction that results from exposure to either irritant substances (*irritant contact dermatitis*) or allergenic substances which are capable of eliciting an allergic reaction (*allergic contact dermatitis*). In both cases, an inflammatory reaction is elicited by immune cells present in the skin which culminates in an eczematous reaction (dermatitis) on exposed skin areas characterized in its acute phase by redness, swelling, scaling, itching, and vesicles containing a clear fluid (Fig. 1). Irritant contact dermatitis is often provoked by prolonged and frequent skin contact with water, chemical detergents, and solvents, often in combination and worsened by humid or dry environments. In other words, the inflammatory reaction and the resulting irritant contact dermatitis are provoked not by one specific substance but by a combination of several unspecific factors. Therein lies the key difference between irritant contact dermatitis and allergic contact dermatitis – the fact that allergic contact dermatitis is elicited by skin contact with a specific molecule from the environment which triggers specific memory immune T cells to initiate an allergic reaction which results in eczema (Rustemeyer et al. 2010).

Chromium and Allergic Reponses, Fig. 1 Dermatitis (eczema) on the palms

Allergic contact dermatitis (i.e., allergic contact eczema) is the final stage of a series of events starting with contact sensitization. This first *sensitizing* stage is caused by a group of reactive chemicals referred to as allergens which are able to permanently change a subgroup of memory immune cells so that they will proliferate and target the skin component upon allergen reexposure. Mostly, these allergens are man-made, but naturally occurring contact-sensitizing chemicals are also known; however, they represent a very limited clinical problem. Contact sensitizers, also known as haptens, are small molecules with a weight below 500 Da. The hapten is able to penetrate the skin but is too small to trigger an immune response by itself. The sensitizing capacity is obtained by the hapten binding to proteins to form an antigenic hapten–protein complex in the upper layers of the skin. The next step involves the transport of the antigenic hapten–protein complex to the draining lymph nodes by Langerhans cells. Here, subsets of specific immune T cells recognize the antigenic complex, proliferate vigorously, and are then released in large numbers into the bloodstream. Upon renewed contact with the same allergen, a phase known as the *elicitation* or *effector* phase is initiated during which a range of chemical mediators are released culminating in an eczematous reaction which peaks within 18–72 h (Rustemeyer et al. 2010). Allergic contact dermatitis resulting from work-related exposure is known as *occupational allergic contact dermatitis*. Contact allergy is considered to be a chronic and potentially lifelong condition. Risk factors of contact allergy and allergic contact dermatitis include the sensitizing potential of the allergen, high allergen concentrations (dose per unit area), frequent exposure, occlusion, long duration of exposure, presence of penetration enhancing factors, and an altered skin barrier function.

Although occupational contact dermatitis is not life-threatening, it can have a considerable physical and psychosocial impact (Kadyk et al. 2003). Patients frequently complain of symptoms relating to their skin condition that also affect their mental state, and others describe interference with work and daily activities. Dermatitis on the hands is especially associated with significant impairment. An intact skin barrier on the hands is pivotal to protect the hands during everyday tasks. In the work setting, the hands are vital for both functionality and presentation, for instance, in occupations with direct interaction with other people – food service, child care, and sales. Even lesions that are noncontagious are often regarded as disgusting by others. Apart from the detrimental effect on quality of life of the dermatitis itself, it may also cause sick leave and occupational changes. The exact economical impact is unknown but may amount to several billion dollars annually in the USA alone (Kadyk et al. 2003).

Allergic Contact Dermatitis: Diagnosis and Treatment

Patients with a history and clinical picture of allergic contact dermatitis can be accurately diagnosed by a procedure known as *patch testing*. Basically, the patient is reexposed to the suspected allergen(s) under controlled conditions. This is done by applying appropriate amounts of allergen on to the skin, typically on the upper back. Here, it remains for 2 days, after which the patches containing the allergens in question are removed. In the case of contact allergy, the patient will develop an eczematous reaction at the skin site exposed to the allergen. The response can be graded according to severity of the reaction. Readings are typically done on days 2, 3, and 7, which ensures that even delayed reactions are recorded (Lindberg and Matura 2010). If a diagnosis of contact allergy is made, it is highly recommended that the patient avoids future contact with that particular allergen. Occupational changes can sometimes be necessary if avoidance of an allergen is impossible. Often, preventive measures, i.e., the use of protective gloves, aprons, or masks, are adequate to control the problem.

Most mildly-to-moderately affected patients can be treated effectively with topicals consisting of skin moisturizers combined with anti-inflammatory ointments while severely affected patients may require periodic phototherapy or systemic anti-inflammatory treatment. Interestingly, allergic Cr contact dermatitis is a particular challenge since it is associated with an often severe form of eczema which is difficult to treat. Cr may also elicit a systemic allergic dermatitis response (widespread eczema) when ingested, and this has been reported after oral intake of vitamin tablets containing only 150-μg Cr-chloride (Ozkaya et al. 2010).

Chromium as an Allergen

Cr is a transitional metal and exists in several oxidation states from 0 to +6, of which the ground states 0, +2, +3, and +6 are common. Only the trivalent Cr(III) and the hexavalent Cr(VI) oxidation states are stable enough to act as haptens. Metallic Cr, oxidation state 0, does not possess sensitizing potential since it tends to form an insoluble layer of oxide on the surface. Cr may fluctuate between the hexavalent and trivalent states depending on factors such as temperature and pH. Human as well as animal studies have shown that Cr(IV) may consistently be considered a stronger sensitizer and elicitor of allergic contact dermatitis when compared to Cr(III). This is explained by higher bioavailability of Cr(VI) since it is more water soluble than Cr(III), penetrates the skin more easily, and accumulates in the skin to a higher degree than Cr(III). Once inside the skin, Cr(VI) is converted to Cr(III), and the trivalent form binds more easily to proteins than Cr(VI), potentiating antigen presentation and elicitation of allergic dermatitis. Patch testing is routinely performed with 0.5% potassium dichromate, the hexavalent form of Cr.

Several studies have investigated how much Cr is required to elicit an allergic skin reaction. One such study showed that 1 of 14 Cr-allergic individuals reacted to 1 ppm occluded Cr(VI) (Allenby and Goodwin 1983). The patch test threshold was established at 10 ppm in 17 Cr-allergic patients who were patch tested on normal skin (Basketter et al. 2001), and furthermore, and in that same study, the presence of an irritant lowered the threshold from 2 to 1 ppm in 2 of 17 patients. A review on nine patch test studies on the elicitation threshold levels for Cr(VI) at different levels of pH found that the level was 15 ppm for 10% and 7.6 ppm for 5% of the sensitized population (Stern et al. 1993). A recent review on Cr allergy showed that exposure to occluded patch test concentrations of 7–45 ppm Cr(VI) resulted in allergic contact dermatitis in 10% of Cr-allergic patients (Hansen et al. 2002). Further data are needed to determine the exact eliciting capacity of Cr(III), but it is generally accepted that much higher concentrations of Cr(III) than Cr(VI) are needed to elicit dermatitis. This is supported by three studies; one included 54 patients and showed that one individual reacted to Cr(III) at a threshold concentration of 1,099 ppm (Nethercott et al. 1994); the second study estimated the minimal elicitation threshold $(MET)_{10\%}$ for Cr(VI) at a much lower 6 ppm (Hansen et al. 2003); the third study showed that 50 ppm Cr(III) was insufficient to elicit allergic Cr dermatitis in 18 Cr-sensitized patients (Iyer et al. 2002). All in all, Cr(VI) is a much more potent allergen than Cr(III).

Occupational Sources of Cr Exposure

Table 1 provides an overview of Cr-containing items and chemicals as well as work procedures that may be associated with occupational Cr exposure. As a metal, Cr can be found in various alloys such as stainless steel and on Cr-plated surfaces. Also, Cr is found in raw materials used for the production of cement. Paints, usually yellow, red, and orange often contain hexavalent Cr which can also be released by cutting or tooling of metals treated with anticorrosion agents. When zinc-galvanized sheet metal is cut or tooled, Cr may leak out and come into contact with the skin. Stainless and nonstainless steel may release Cr on welding, and the Cr-containing fumes may be distributed to the facial skin. Cr may also be released from metal products which are chromated in order to prevent rust or surface oxidation. Such products may include common household items such as screws, fittings, and other materials which are used both in an occupational and nonoccupational setting. Indeed, a recent study confirmed that the release of Cr(VI) from chromated metal products can be high enough to provoke allergic reactions in individuals already sensitized to Cr (Geier et al. 2009).

Chromium and Allergic Reponses, Table 1 Work procedures, chemicals, and metallic items which may release or cause occupational exposure to chromium

Stainless steel welding
Chromate production
Chrome plating
Ferrochrome industry
Chrome pigments
Leather tanning
Painters
Workers involved in the maintenance and servicing of copying machines and the disposal of some toner powders from copying machines
Battery makers
Candle makers
Dye makers
Printers
Rubber makers
Cement workers
Landfill sites with chromium-containing wastes
Cement-producing plants
Reagents used for analytic standards
Anticorrosion agents
Catalysts
Engraving
Metallic tools
Magnetic tapes
Wood preservatives

Chromium and Allergic Reponses, Table 2 The EU chromium directive (Directive 2003)

I	Cement and cement-containing preparations may not be used or placed on the market if they contain, when hydrated, more than 0.0002% soluble Cr(VI) of the total dry weight of the cement
II	If reducing agents are used, then without prejudice to the application of other Community provisions on the classification, packaging, and labeling of dangerous substances and preparations, the packaging of cement or cement-containing preparations shall be legibly and indelibly marked with information on the packing date, as well as on the storage conditions and the storage period appropriate to maintaining the activity of the reducing agent and to keeping the content of soluble Cr(VI) below the limit indicated in paragraph 1
III	By way of derogation, paragraphs 1 and 2 shall not apply to the placing on the market for, and use in, controlled closed and totally automated processes in which cement and cement-containing preparations are handled solely by machines and in which there is no possibility of contact with the skin

Chromium and Allergic Reponses, Table 3 Chemicals and metallic items which may cause nonoccupational exposure to chromium

Leather products, shoes, gloves, handbags, furniture

Chromated metal products, i.e., screws, metal rings, tools, and fittings
Mobile phones
Eye shadows

As much as 90% of the global leather production is tanned using trivalent Cr(III) sulfate. This is performed to obtain softness, durability, and flexibility of the leather and make it usable for furniture, footwear, and clothing. During the tanning process, Cr(III) reacts with the leather, stabilizing certain proteins which make the finished product more resistant to degradation. Most of the Cr(III) is tightly bound in the leather, but some can still be released and come into contact with the skin (Lidén et al. 2010). One study showed that tannery workers who were exposed to Cr(III) developed allergic Cr dermatitis, emphasizing that the trivalent form of Cr may also sensitize (Estlander et al. 2000).

Historically, exposure to Cr and associated Cr-allergic contact dermatitis has mainly been caused by occupational contact with cement but also following exposure to leather, metal, paint, and plywood. In 1983, Danish legislation made the addition of ferrous sulfate mandatory in cement to reduce the water-soluble Cr content to not more than 2 ppm. Since then, the prevalence of Cr allergy in construction workers decreased, an observation that was confirmed in Germany. A similar decrease in countries without regulation could not be observed. As a direct result of the decreasing prevalence of Cr allergy observed in construction workers after the Danish legislation, the European Union (EU) passed a similar directive in 2005 (Directive 2003), Table 2.

Nonoccupational Sources of Cr Exposure

Table 3 provides an overview of Cr-containing items and chemicals that may be associated with nonoccupational Cr exposure. Leather is currently the most common cause of allergic Cr contact dermatitis and has lead to a significant increase in Cr allergy in Denmark between 1995 and 2007 (Thyssen et al. 2009).

Therefore, Cr-allergic contact dermatitis is now mainly a consumer problem which was underscored by a recent study (Thyssen et al. 2009) showing that 55% of 197 Cr-allergic patients with dermatitis had relevant leather exposure in their medical history. Women (39%) were more exposed to leather footwear compared to men (27.9%) and almost half the patients had dermatitis on the feet. A study measured Cr(VI) migration in a sample of leather goods and showed that Cr(VI) release from two shoes was 6 and 10 ppm, respectively (Hansen et al. 2002). An investigation by the German Risk Assessment Institute including more than 850 leather consumer items demonstrated that about 50% of these released more than 3 ppm Cr(VI) and that one tenth released amount in excess of 10 ppm Cr(VI) (http://www.bfr.bund.de/cd/9575). The Swedish Society for Nature and Conservation tested 21 pairs of leather shoes (http://www.naturskyddsforeningen.se/upload/press.badshoes.pdf) and found that levels of Cr(III) were very high ranging from 42 to 29,000 ppm, while no detectable levels of Cr(VI) were found. These values were well above the thresholds established by dose–response studies as described earlier. Other less frequent sources of Cr exposure in consumers include mobile phones, tattoo pigments, and eye shadows.

Acknowledgment Peter Jensen was supported by a grant from the Michaelsen Foundation.

Definition

Trivalent chromium plays an important role in potentiating the insulin response in cells sensitive to insulin. A deficiency in chromium could lead to an impaired response and thereby diabetes. Supplementing chromium in patients with diabetes with this deficiency could potentially improve glycemic control.

Introduction

The prevalence of diabetes mellitus worldwide was estimated to be 171,000,000 in the year 2000 and is expected to rise to 366,000,000 in the year 2030 (Wild et al. 2004). This rise is predominantly caused by the increase in patients having type 2 diabetes. Type 1 diabetes is characterized by an absolute shortage of endogenous insulin caused by an autoimmune reaction, which requires treatment with exogenous insulin to compensate for the absence of a patient's own insulin. Type 2 diabetes is to a large extent caused by an increase in insulin resistance, in other words a relative shortage of insulin. Patients are mainly treated by means of decreasing insulin resistance (by improving lifestyle or medication like metformine) and/or by decreasing the relative shortage of insulin (by medication like sulfonylurea compounds or exogenous insulin). In recent years, many additional modes of therapy have been introduced to treat patients, like bariatric surgery, incretines, and sodium-dependent glucose cotransporter 2 inhibitors, but are beyond the scope of this entry. In addition to the proportional rise in the aging population, overweight, in particular, plays an important role in this worrisome rise of patients with diabetes mellitus. The most important causes of being overweight are a decrease of physical activity and an increase of (unhealthy) food intake. Weight loss and an increase in physical exercise (even without weight loss) are effective self-care interventions and cost-effective, not only for the prevention of type 2 diabetes mellitus (T2DM), but also for tackling the cause for the majority of T2DM patients. Unfortunately, quite often these (general) self-care interventions are ineffective in daily practice. The majority of recently diagnosed T2DM patients, usually after a fruitless period of trying to improve their glycemic control by non-pharmacological means, will have to be treated with glucose-lowering drugs.

Various current guidelines for the treatment of T2DM advise the following non-pharmacological interventions (if applicable):

1. Stop smoking.
2. Maximize alcohol consumption to 2 units of alcohol a day.
3. Increase physical exercise to at least 30 min a day.
4. Reduce weight with 5–10%.
5. Restrict sodium to 50–100 mmol/day.
6. Improve food composition, with less fat and a normalized caloric intake.

In addition to these well-established interventions in regular medicine, patients are informed about other possibilities to improve their condition in many other ways. Patients are exposed to a multitude of suggested solutions outside the field of regular medicine, for example, in pharmacies, in supermarkets, on the Internet, in complementary medicine, etc. There is a very important difference between the six interventions mentioned above and the interventions like chromium supplementation that will be discussed below. The above-mentioned interventions require patients to actively change their habits, such as quitting their smoking habit (addiction) and/or reducing their alcohol consumption and/or increasing physical activity, etc. This means that patients really have to invest time and effort in changing their habits, and they may even suffer from withdrawal symptoms. Using supplements, like chromium, have a more passive character. The amount of effort and "pain" the patient has to invest influences a patients' motivation, and these factors

could have positive and negative influences on the success of the intervention.

During the last decades, chromium has become the second most popular dietary supplement after calcium in the United States, with sales amounting to approximately 100 million dollars annually. Chromium supplements are mainly used for weight loss. However, patients with diabetes also use these supplements to improve their glycemic control by increasing insulin sensitivity.

Physiology (in Short)

Vincent and colleagues have done extensive research investigating chromium's mechanism of action at the cellular level (Sun et al. 2000) (Chromium and "Glucose tolerance Factor"; Chromium and Insulin Signaling). They discovered that the intracellular oligopeptide, Apo-low-molecular-weight chromium-binding substance (also known as Apo-chromodulin), plays an important role in potentiating the insulin response in cells sensitive to insulin. The degree of activation of the insulin receptor depends on the number of chromium ions bound to this peptide (with a minimum of 0 and a maximum of 4 ions), and this may lead to an eightfold difference in insulin receptor activation (when 4 ions are bound compared to 0). This could be one of the possible explanations for the insulin resistance seen with chromium deficiency.

Case Report

Several animal studies and a case report on humans have shown that absence of chromium in the diet leads to diabetes, and that the chromium deficit is associated with insulin resistance. In these animals, supplementation of chromium led to normoglycemia without the need of any glucose-lowering therapy. The case report, published in 1977, discussed a woman, aged 40, who had to undergo a total enterectomy as the result of a mesenterial thrombosis (Jeejeebhoy et al. 1977). Following the procedure, she received total parenteral nutrition through a subclavian catheter nightly. A little more than 3 years later, she lost more than 5 kg in a period of less than 3 months, and her plasma glucose concentration rose to values of manifest diabetes mellitus. To achieve a normoglycemic state, 45 units of zinc insulin were administered daily. Causes for the hyperglycemia were sought, because insulin resistance in a young woman who is not overweight is very rare. Chromium deficiency was considered as a possible cause after an article by Mertz from 1969 was discovered, in which the biological functions of chromium are discussed. The chromium concentration in her serum and hair was measured and found to be low (chromium in hair 154 ng/g (N > 500 ng/g), chromium in serum 0.55 ng/g (N 4.9–9.5 ng/g)). She was treated intravenously with 250 micrograms of chromium chloride daily for 2 weeks. This treatment resulted in a clear decrease in the amount of insulin required to treat her diabetes mellitus. After 4 months of chromium supplements, she no longer required insulin. She continued to receive 20 μg of chromium intravenously daily and remained normoglycemic after a period of 1 year.

Clinical Trials

Anderson et al. have performed a trial that can be considered as the Landmark trial of chromium-intervention studies in patients with T2DM (Anderson et al. 1997). In a randomized controlled trial performed in Chinese patients (a trial published in 1997), a first tentative conclusion about the effects of chromium on glycemic control was given. Chromium picolinate supplements were given over a period of 4 months to a group of 180 Chinese patients with T2DM. The patients were randomized into three groups: a group that received placebo, a group that received 200 μg chromium, and a group that received 1,000 μg of chromium daily as chromium picolinate. After 4 months, the HbA1c in the placebo group was unchanged (8.5%), while the HbA1c in the 200 μg group showed a significant decrease from 8.5% to 7.5%. In the group treated with 1,000 μg chromium a decrease in the HbA1c from 8.5% to 6.6% was seen (HbA1c is a measure of glycosylated hemoglobin that represents the level of glycemic control of predominantly the preceding 6–8 weeks.)

In 2007, Balk et al. performed a systematic review of randomized controlled trials concerning chromium supplementation in T2DM (Balk et al. 2007). They found 11 studies with 14 different chromium-based interventions measuring HbA1c as an endpoint: 11 out of 14 found no effect or non-significant effects of chromium supplementation. However, when performing a meta-analysis of these trials (including the study of Anderson et al.), the overall effect of chromium supplementation in people with diabetes was statistically significant in favor of chromium supplementation (−0.6% [95% confidence interval (CI): –0.9 to −0.2]). This mean −0.6% benefit,

however, is largely due to the results of the study of Anderson et al. When excluding this study the effect of chromium on HbA1c is −0.3% (95% CI: –0.5 to −0.1). When stratifying the pooled results regarding methodological quality, sponsor involvement and western versus non-western studies, the effects of chromium supplementation turned out to be absent or non-relevant when studies were either of good methodological quality, or were without involvement of industry or were performed in western patients.

Since the review of Balk, two other double-blind, placebo-controlled randomized trials have been published. The first is a 6-month, double-blind study, performed in The Netherlands (Kleefstra et al. 2007). After 6 months the effect of chromium supplementation compared to placebo on HbA1c was +0.24 (95% CI: –0.06 to 0.54). The second study was a trial in which 30 Taiwanese patients with T2DM were enrolled (Albarracin et al. 2007). The patients were divided into three groups: a group which received placebo, a group that received 1,000 μg of chromium (chromium yeast), and a group that received 1,000 μg of chromium together with vitamin C and vitamin E. HbA1c levels dropped from 10.2% (standard deviation (SD) 0.5) to 9.5% (SD 0.2), which was a significant reduction. Unfortunately no between-group analyses (compared to placebo) were performed.

Discussion

There is, as discussed, a well-established role for trivalent chromium in glucose metabolism. However, especially in western patient with T2DM, this does not mean that supplementation of chromium in de forms and dosages as commonly used in studies leads to (relevant) effects on HbA1c. Questions that arise are among many others:

1. Are there patients, who are chromium deficient?
2. Can they somehow be selected, if chromium deficient patients do exist?
3. Is chromium supplementation beneficial in these patients?
4. Which forms of chromium in which dosages should be used?

It is of course of interest, that there are a few studies in non-western patients, which did find significant and clinically relevant effects of chromium supplementation on HbA1c. And of course it would be interesting to see these results replicated in methodologically sound trails. But, except for methodological issues, one could speculate about reasons for the differences in results between western and non-western patients, like genetic differences, but also the possible differences in intake of chromium with a low intake possibly leading to chromium deficiency, or the differences in dosages needed to be able to reach clinically meaningful effects in different patient populations.

Unfortunately, a reliable method for assessment of the chromium status is lacking as is sufficient information regarding the bioavailability of different forms of chromium. Future chromium research should focus on establishing a method for assessment of the chromium status. In addition, the bioavailability of different forms of chromium in Western patients (compared to non-western patients) should be investigated to be able to properly define a potentially effective dose.

Efficacy of chromium to improve glycemic control has not been established. Furthermore, there were some safety concerns with one form of chromium: chromium picolinate (Chromium Toxicity – Trivalent Chromium), and long-term safety has never been established. Last but not least, we should remember that patients with T2DM are not treated in order to lower HbA1c, but to improve the risk these patients have on microvascular and macrovascular complications (and to improve quality of life). At this moment, there are many non-pharmacological and pharmacological interventions possible in T2DM patients known, that reduce these risks. So, in the meantime, chromium should not be a treatment option in patients with T2DM, and non-pharmacological focus by diabetes health care providers together with patients should be on the items like quitting smoking, maximizing alcohol intake, increasing physical exercise, reducing weight, restricting sodium intake, and on improving food composition.

Chromium and Glucose Tolerance Factor

John B. Vincent
Department of Chemistry, The University of Alabama, Tuscaloosa, AL, USA

Synonyms

Glucose tolerance factor; GTF

Definition

As originally defined, glucose tolerance factor (GTF) is a material absent from *Torula* yeast that when fed to rats on a *Torula* yeast diet reverses apparent glucose intolerance in the rats. Early study on glucose tolerance factor equated the term with chromic ion. However, the term "glucose tolerance factor" was later used to refer to a material extracted and partially purified from brewer's yeast. The original studies have been shown to be methodologically flawed, and material from brewer's yeast has been shown to be an artifact. Given the considerable confusion over the name GTF and the history of GTF studies, the terms "glucose tolerance factor" and "GTF" should no longer be used use in chromium nutritional and biochemical research.

Initial Reports of a Glucose Tolerance Factor

The fields of Cr nutrition and Cr biochemistry had their beginnings in 1955 when Walter Mertz and Klaus Schwarz fed rats a semipurified *Torula* yeast–based diet (Mertz and Schwarz 1955); on the diet with Torula yeast as the sole protein source, the rats were reported to develop impaired glucose tolerance in response to an intravenous glucose load (1.25 g/kg body mass). Rats on the *Torula* yeast diet after an intravenous glucose challenge had a clearance rate of excess glucose (glucose above baseline at time zero), significantly greater than that of rats on a basal diet. The clearance rate was defined as the slope of a plot of ln (% excess glucose) versus time. The authors believed they had identified a new dietary requirement absent from the *Torula* yeast–based diet and whose absence was responsible for the glucose intolerance; they named this requirement "glucose tolerance factor" or GTF. Subsequently in 1959, these researchers claimed to identify the active ingredient of GTF as Cr^{3+} (Schwarz and Mertz 1959). Individually adding inorganic compounds of over 40 different elements to the Torula yeast diet could not restore glucose tolerance, while several inorganic Cr(III) complexes (200–500 μg Cr/kg body mass) did. Brewer's yeast and acid-hydrolyzed porcine kidney powder were identified as natural sources of "GTF," as extracts made from them could also restore proper glucose clearance in rats on the Torula yeast–based diet.

Unfortunately, while these studies are repeatedly cited and used as crucial evidence that Cr is an essential trace element for mammals, the methodology of these studies is flawed (Vincent 2001; Vincent and Stallings 2007). The Cr content of the diet was not determined, and the rats were maintained in wire mesh cages, allowing the rats to potentially obtain Cr

by chewing on the metal. Thus, the actual Cr intake of the rats in these studies is impossible to gauge. The use of the large amounts of the metal ions is also of concern. Large doses of chromium may have pharmacological effect on subjects with impaired carbohydrate and lipid metabolism. The methods used to prepare the extracts were not described. Questions about the statistical significance of the effect in terms of the use of excess glucose rather than total glucose have also been raised.

Research prior to the 1970s was consistent with these early results of Schwarz and Mertz. Studies utilizing rats fed a variety of diets found that rats on some diets in addition to the *Torula* yeast–based diet apparently possessed low glucose removal rates; the glucose removal rates could be improved by addition of GTF concentrates. The concentrates were prepared from dried brewer's yeast, an enzymatic digest of brewer's yeast, or dried defatted porcine kidney powder. However, the methods of preparation of these materials were never described; while the amounts of the concentrates added to the diet where given, the amounts of Cr that these concentrates contained generally were not given. (The history of the early studies on the potential essentiality of chromium has been reviewed numerous times (Vincent 2001; Vincent and Stallings 2007)).

Attempts to Isolate Glucose Tolerance Factor

Nearly all of the attempts to isolate and characterize GTF have involved brewer's yeast, identified as a source of GTF in the 1959 study. Mertz and coworkers finally reported the details of the extraction and isolation of brewer's yeast GTF in 1977 (Toepfer et al. 1977), 20 years after the initial report. Brewer's yeast was extracted with boiling 50% ethanol; the ethanol was removed under vacuum, and the aqueous residual was applied to activated charcoal. Material active in bioassays was eluted from the charcoal with a 1:1 mixture of concentrated ammonia and diethyl ether. After removal of the ammonia and ether under vacuum, the resulting solution was hydrolyzed by refluxing for 18 h in 5 M HCl. Finally, the HCl was removed under vacuum, the solution was extracted with ether, and the pH of the solution was adjusted to 3. The cationic orange-red material was further purified by ion exchange chromatography; the material was passed through three (although no detail is provided about the chromatography including the identity of the three columns). Unfortunately, these incredibly harsh conditions would have destroyed any proteins, peptides, complex carbohydrates, or nucleic acids that initially could have been associated with the chromium. Thus, the possibility that the form of chromium recovered after the treatment resembles the form in the yeast is remote at best. The isolated GTF possessed a distinct feature at 262 nm in its ultraviolet spectrum, while mass spectral studies (no experimental details provided) suggested the presence of a pyridine moiety. Hence, nicotinic acid was proposed as a component of GTF as it apparently sublimed from the material and was identified by extraction with organic solvents (no experimental details provided). Amino acid analyses indicated the presence of glycine, glutamic acid, and cysteine as well as other amino acids, although the relative amounts were not reported. The isolated material was cationic and orange in color. The results were interpreted to indicate that GTF was a complex of Cr, nicotinate, glycine, cysteine, and glutamate (Toepfer et al. 1977). However, the orange color could suggest the formation of a chromium(III) ammonia complex (Vincent 2001). In paper chromatography experiments, the GTF gave several bands, only one of which from each material was active in the biological activity assays and migrated with the same R_f value; thus, the GTF characterized from the previous steps was impure. (Biological activity of a chromium-containing species referred to the ability of the species to potentiate the action of insulin to stimulate in vitro the metabolism of epididymal fat tissue from "chromium-deficient" rats, i.e., on the Torula yeast diet or another diet giving rise to similar effects when rats are given glucose tolerance tests.) The Cr in these active bands represented 6% of the total chromium from "purified" material (Toepfer et al. 1977). No chemical or physical characterization studies were performed on the most purified, active component.

Meaningful interpretation of these studies is not possible. Characterization of bulk materials of which only a tiny minority is active does not allow for deciphering the composition of the active component(s). Thus, one cannot assume that the amino acid analysis of the bulk product reflects the "active" component. Similarly, nicotinate detected in the bulk is not necessarily in the "active" component. Thus, nothing is known about the active component's composition except the apparent

presence of some chromium. Because of the destructive isolation procedure used to obtain the Cr-containing material from brewer's yeast, the nature of the form of chromium in brewer's yeast cannot be deciphered from these studies. Based on this work, GTF has been proposed to be a Cr(III)-glutathione-nicotinate complex as glutathione is a tripeptide of glutamate, glycine, and cysteine, the three most abundant amino acids in the impure GTF extract. A three-dimensional structure has also been proposed for brewer's yeast GTF with two *trans* N-bound nicotinic acid ligands and amino acids occupying the remaining four sites of an octahedral around the chromic center (Mertz et al. 1974). This proposal, which actually appeared before the experimental report and has been reiterated numerous times in reviews and textbooks as the structure of the biologically active form of chromium, GTF, is without foundation. Yet the 1977 study dominated the understanding of the apparent nature of the biologically active form of chromium for the next two decades (Vincent 2001; Vincent and Stallings 2007).

Subsequent Studies

The results of the 1977 study have not been reproduced in several laboratories. Brewer's yeast has been found to contain amphoteric, anionic, and cationic complexes of Cr. However, many, if not all in one case, have been found to be artifacts formed between components of the growth media and chromium. The isolated species appear to have little if any similarity between research groups; thus, the isolated species may be very sensitivite to the conditions of the isolation, suggesting that artifacts are readily generated. Studies attempting to isolate and purify the active species from the yeast have repeatedly found that the active species could be separated from chromium-containing fractions. However, the identity of the active species is also controversial and may reflect that multiple species in the yeast (that no do contain Cr) may be able to give rise to effects in the bioassay. Gamma-aminobutyric acid was isolated and identified as the active species in one study. Similarly, studies using porcine kidney powder have not supported the original studies. A Cr-binding oligopeptide has been isolated porcine kidney powder; hydrolysis of this material produces species similar in properties to GTF from brewer's yeast and kidney powder. The studies since 1977 have been thoroughly reviewed (Vincent 2001; Vincent and Stallings 2007).

Recently, rats have been maintained on a purified diet (AIN-93G) without the added chromium in the mineral mix (16 μg Cr/kg food) in metal-free cages for 6 months. Other groups of rats received the diet with recommended 1,000-μg Cr/kg food in the mineral mix or the full diet with an additional 200-μg Cr/kg or 1,000-μg Cr/kg (Di Bona et al. 2011). No differences were noted in body mass or food intake between the groups. More significantly, the blood glucose of the rats on the diet with as low a Cr content as practically possible responded to an intravenous glucose challenge in a statistically identical fashion to that of the rats on the supplemented diets. The rates of glucose clearance and the areas under the glucose response curve were identical. When an intravenous glucose challenge (5 units insulin/kg body mass) was administered to the various groups of rats, the blood glucose levels of all the rats responded in an identical fashion. One notable difference was observed between the two groups of rats receiving the Cr supplementation beyond the Cr in the mineral mix and the rats on the diet without added chromium: The plasma insulin concentrations in response to the glucose challenge were lower for the supplemented rats that those concentrations for the rats on the diet without Cr supplementation (Di Bona et al. 2011). Thus, this study observed a pharmacological effect on high doses of Cr on insulin sensitivity (Vincent 2010). This study demonstrates that in the absence of other dietary stress (as could occur in the Torula yeast diet), no signs of Cr deficiency can be generated in rats provided a diet with as low a Cr concentration as practically possible, while high doses of Cr can have pharmacological effects. The authors proposed that since low-Cr diets do not generate any known deleterious effects and that effects previously attributed to low doses of Cr should be classified as pharmacological rather than nutritionally relevant effects, Cr should be removed from the list of essential trace elements for mammals (Di Bona et al. 2011).

Biological Activity Assays

The reproducibility and sensitivity of the assay for biological activity of chromium was improved when adipocytes isolated from epididymal fat tissue

of "Cr-deficient" rats were utilized. Replicate assays at a series of insulin concentrations could now be readily performed, allowing for detailed kinetics experiments. These assays showed that Brewer's yeast extracts and the synthetic Cr-nicotinate complexes described above potentiated the ability of insulin to stimulate glucose oxidation at a variety of insulin concentrations. The degree of stimulation also depended on the chromium concentrations of either the extract or synthetic complexes, leading to the conclusion that these compounds contain biologically active forms of chromium. However, further analysis of these results has shown that the original interpretation is incorrect. Addition of the chromium sources without adding insulin stimulated the metabolism of glucose; the stimulation due to insulin above this increased background was actually decreased. The chromium sources in fact made insulin less effective, consistent with components of the extracts binding to insulin and not allowing the complexed insulin to bind to its receptor (Vincent 1994).

The use of a microbiological assay (yeast fermentation assay) has been proposed to determine biological activity of chromium-containing materials, but it is also problematic. The yeast fermentation assay reportedly yields results that parallel rat fat pad assays when using brewer's yeast "GTF" as a Cr source. However, as the active component of yeast extracts can be separated from chromium, what exactly this assay measures in regard to chromium is questionable (Vincent 2001).

Synthetic Models

The proposed identification of nicotinate (3-carboxypyridine) in "GTF" stimulated an interest in the synthesis of chromic-nicotinate or chromic-nicotinic acid ester complexes and chromic complexes of 2-carboxypyridine (picolinate acid) and 4-carboxypyridine (isonicotinic acid). However, the inability of the identity of GTF to be elucidated and the demonstration that the isolated species could be separated from Cr-containing species led to a rapid decline in inorganic chemistry studies after 1985 (Vincent 2001). "Chromium nicotinate" is the product of the reaction of two or three equivalents of nicotinic acid with chromic ions in aqueous solution at elevated temperatures. The structure and composition of chromium nicotinate have been poorly described. As a solid, chromium nicotinate is intractable, being insoluble or unstable in common solvents. Hence, studies on the solid have been limited even though it has gained substantial use as a nutritional supplement (under the trade name ChromeMate marketed by InterHealth Nutraceuticals), and studies of the solution from which the "compound" precipitates have additionally provided little additional data. The addition of a Cr(III) salt, CrX_3, to an aqueous solution of sodium nicotinate generates purple solutions from which gray-purple polymers of the general formula $[Cr(nic)_2(H_2O)_x(OH)]_n$ precipitate along with some [nicH]X, which can be removed by subsequent extraction. The addition of a Cr(III) salt to a hot aqueous solution of nicotinic acid yields blue solutions, which contain a mixture of species with 1:1 and 1:2 Cr-to-nicotinate ratios; increasing the pH results in the formation of a blue-gray polymer with a 1:1 Cr-to-nicotinate ratio. Dissolution of the polymers in mineral acid results in the formation of soluble species with an overall purple color and a 1:1 Cr-to-nicotinate ratio. None of the species have been crystallized, and NMR studies suggest the species are more complex than the proposed formulas would indicate (Rhodes et al. 2009). Chromium picolinate, $[Cr(picolinate)_3]$, is the most popular form of chromium in nutritional supplements and has been marketed primarily by Nutrition21. The complex has been well characterized by a variety of techniques including X-ray crystallography; the complex has limited solubility in water, ~500 μM (Vincent 2001). Unfortunately, the choice of these compounds as nutritional supplements stems primarily from the flawed studies on glucose tolerance factor. Their low solubility limits absorption of the compounds to about 1% efficiency (similar to dietary chromium). While the use of chromium compounds as nutritional supplements appears currently to be unfounded, chromium nicotinate and/or chromium picolinate are currently being studied for their potential as therapeutic agents in subjects with altered carbohydrate and lipid metabolism and associated conditions such as type 2 diabetes (Vincent 2010).

Summary and Conclusions

The term "glucose tolerance factor" has developed different meanings, leading to confusion. Studies often fail to distinguish the difference among the

inorganic ion Cr^{3+}, Cr(III) complexes, and a purported biologically active form of chromium (i.e., the naturally occurring biomolecule(s) that has an inherent function when containing bound chromium(III)) when using the term "GTF." As originally proposed, GTF is a substance that is involved in maintaining normal glucose, prevents and cures impairment of glucose removal when given in the diet or by stomach tube, and results in impairment of intravenous glucose tolerance when it is deficient in the diet. As described above, this was soon thereafter equated with Cr^{3+}. As chromium must presumably interact with some organic biomolecule(s) to manifest any effect(s) in mammals, attempts were subsequently made to identify this (these) species. Unfortunately, the products of such attempts have also been termed GTF. The situation was not helped in the 1980s and early 1990s when nutritional supplements containing "glucose tolerance factor" were widely marketed; these products generally contained yeast extracts or synthetic complexes of Cr^{3+} and nicotinate, adding to the confusion (Vincent 2001; Vincent and Stallings 2007).

Over five decades ago, Schwarz and Mertz reported that Cr^{3+} (or GTF) was a nutrient for mammals; inorganic chromium(III) complexes apparently could restore the glucose tolerance of rats fed a *Torula* yeast–based (supposedly Cr-deficient) diet. Major portions of these studies, which were considered the pioneering work in the field of chromium biochemistry and nutrition, have been effectively refuted. The diet used by these workers has not been demonstrated to be chromium deficient; thus, any effects from supplementing the diet with quantities of Cr several fold larger than the normal dietary intake does not establish an essential requirement (Vincent 2010).

The biologically active form of chromium is not GTF, reportedly a Cr(III)-nicotinate-amino acid (or glutathione) complex. In fact, the composition of the artifact from yeast isolated by Mertz and coworkers was actually not established, and proposals for the three-dimensional structure of "GTF" are unfounded. The effects of materials isolated from brewer's yeast observed by Mertz and coworkers were probably serendipitous, as Cr^{3+} has been demonstrated repeatedly to be separable from agents in yeast responsible for in vitro stimulation of glucose metabolism in adipocytes. Yet even the detailed results by different laboratories of the most recent studies of yeast GTF still cannot be reconciled completely (Vincent 2001; Vincent and Stallings 2007). Given the considerable confusion over the name GTF and the history of GTF studies, the use of the term "glucose tolerance factor" or "GTF" should be terminated (Vincent 2001).

Definitions

Adequate intake (AI) – daily mean intake of a nutrient for apparently healthy people.

Introduction

Chromium can exist in multiple valence states but chromium (III) and chromium (VI) are of most practical importance (Gauglhofer and Bianchi 1991). Trivalent chromium is the most stable oxidation state and is likely to be the form in the diet because of the reducing substances in foods (Panel on Micronutrients 2001). Hexavalent chromium, a strong oxidizing agent which is rapidly reduced to trivalent chromium, is recognized as a pulmonary carcinogen (Gauglhofer and Bianchi 1991).

Determination of chromium in biological samples is very difficult because of the low concentrations of chromium in typical tissue samples. Urine, serum, and plasma are usually in the 0.1–0.2 ng/mL range which is close to the detection limit for most instruments. Contamination control and appropriate background correction systems are essential, and many chromium values reported before the 1980s were incorrect (Veillon 1989). An additional constraint is that chromium in serum or plasma may not be a satisfactory biomarker for chromium status (Offenbacher et al. 1997; Stoecker 2006). Consequently, many studies in the literature have tested effects of chromium supplementation without knowing initial chromium status of the participants. For chromium to have a nutritional effect, supplementation of chromium-deficient persons should be tested; a nutritional effect of chromium supplementation would not be expected in a clinical trial if participants already had adequate chromium status.

Food Sources

Chromium concentration in foods varies widely but is relatively low. Dairy products contained less than 1 μg chromium per serving and many meats contained less than 2 μg chromium per serving although some meats were higher perhaps reflecting chromium acquired during processing. Fruits and vegetables were variable, but consistently higher chromium concentrations were found in whole grain products, with some breakfast cereals being particularly rich in chromium (Anderson et al. 1992). Refined sugars and flour are generally lower in chromium than less refined products (Anderson et al. 1992). Acidic foods can take up chromium from storage and heating in stainless steel (Offenbacher et al. 1997). Chromium concentration of some beers was more than 10 ng/mL (Anderson 1987).

Chromium intake from self-selected diets has been investigated. Ten males and twenty-two females collected duplicate food and beverage samples for seven consecutive days. For men, the mean intake was 33 ± 3 μg/day with a 7 day mean range of 22–48 μg/day. For females, mean intake over 7 days was 25 ± 1 with a range of 13–36 μg/day. Mean chromium intake was approximately 15 μg /1,000 kcal (Anderson and Kozlovsky 1985). Other studies showing similar chromium intakes have been reviewed (Panel on Micronutrients 2001).

Absorption

Intestinal absorption of chromium from $^{51}CrCl_3$ is very low, demonstrating that most chromium from an oral dose remains unabsorbed in the intestine. Various studies which have reported the absorption of chromium to be between 0.5% and 2% have been reviewed (Anderson 1987; Offenbacher et al. 1997; Stoecker 2006).

A 12 day balance study was conducted on two men consuming 36.9 and 36.7 μg chromium/day. Their chromium balances were positive on these intakes and their average net absorption of chromium was 1.8% (Offenbacher et al. 1986). The chromium intake of 22 healthy elderly persons was 24.5 μg/day (Offenbacher et al. 1997). Using urinary chromium excretion as a proxy for absorption, Anderson and Kozlovsky reported that when dietary chromium intake was 10 μg, approximately 2% of the chromium was absorbed and when it was 40 μg, only 0.4–0.5% was absorbed (Anderson and Kozlovsky 1985). Adults receiving 200 μg of supplemental chromium daily as chromium chloride had urinary excretion of approximately 0.4% (Anderson 1987).

Absorption of chromium is primarily from the jejunum and is enhanced by the presence of amino acids, (Anderson 1987; Offenbacher et al. 1997;

Stoecker 2006). Simultaneous consumption of 1 mg chromium chloride with 100 mg ascorbic acid enhanced chromium absorption measured by area under an 8 h curve in three women to 1.4-, 2.7-, and 4.4-fold the levels obtained when chromium was consumed with water (Offenbacher et al. 1997). Several over-the-counter and prescription medications that reduce stomach acidity impeded chromium absorption in rats, but these studies have not been followed up in humans (Kamath et al. 1997).

Transport and Storage

Chromium competes with iron for a binding site on transferrin (Anderson 1987). Studies based on scans after dosing with $^{51}CrCl_3$ in control subjects and in patients with hemochromatosis showed that chromium disappeared rapidly from the blood, and organ deposition was highest in liver and spleen. Accumulation of ^{51}Cr was also seen in bone. Patients with hemochromatosis had only about half the retention of ^{51}Cr, and Lim and colleagues hypothesized that competition for binding sites on transferrin contributed to reduced uptake and whole body retention of ^{51}Cr (Lim et al. 1983; Sargent et al. 1979).

Functions

Chromium potentiates the action of insulin (Mertz 1969). Davis and Vincent demonstrated that a low molecular weight oligopeptide that binds four chromium ions markedly enhanced insulin receptor tyrosine kinase activity, thereby increasing the response of the receptor to insulin (Davis and Vincent 1997; Vincent 2000). However, there is not yet a biomarker that allows determination of baseline chromium status contributing to the equivocal results observed in the literature. Some studies show beneficial effects of chromium supplementation with various types of subjects while others show no significant effects of chromium (Offenbacher et al. 1997; Stoecker 2006).

In a randomized placebo-controlled trial with diabetic individuals in China, participants received, twice a day, placebo, 100 μg chromium or 500 μg chromium as chromium picolinate. Fasting blood glucose and glucose 2 h after a 75 g oral glucose load were both significantly reduced in the group receiving 1,000 μg chromium per day but not in the group receiving 200 μg chromium per day after both 2 and 4 months of supplementation. Fasting and 2 h insulin were significantly reduced in both groups at 2 and 4 months. Hemoglobin A_{1c} was significantly reduced by the higher chromium dose (7.4 ± 0.2% vs. 8.6 ± 0.2 for placebo). After 4 months of chromium supplementation, both supplemented groups had significantly reduced HbA_{1c} with the higher dose group being lower than the group dosed with 200 μg chromium per day. Unfortunately, data on dietary chromium intake was not available from this study (Anderson et al. 1997).

Seventeen nondiabetic subjects participated in a study in which they consumed diets containing 5 μg Cr/1,000 kcal for a total of 14 weeks. On the basis of an oral glucose tolerance test (1 g/kg body weight), they were divided into a control group (nine subjects with 90 min glucose values <5.56 mmol/L) and a hyperglycemic group (eight subjects with 90 min glucose values >5.56 mmol/L but <11.1 mmol glucose/L). The first 4 weeks of the study were for equilibration. At week 5, half of the subjects received 200 μg chromium as chromium chloride while the other half received a placebo. At week 10, supplement and placebo were reversed in a crossover design. There were no significant effects of chromium supplementation in the control subjects. However, in the hyperglycemic subjects, sums of glucose, insulin, and glucagon after a glucose tolerance were significantly lower with chromium supplementation than with placebo. Thus, it appeared that chromium intakes of only 5 μg/1,000 kcal were detrimental to persons with marginally elevated blood glucose (Anderson et al. 1991).

A carefully conducted study of chromium supplementation and resistance training in men (aged 56–69 years) showed significant effects of resistance training on skeletal muscle size, strength, and power. However, the double-blind daily supplementation of 924 μg chromium as chromium picolinate showed no significant effect on these parameters (Campbell et al. 1999).

Excretion

Urinary chromium losses have been related to the insulinogenic properties of carbohydrates

(Anderson 1987). Chromium excretion increases with exercise, but a study with a stable isotope of chromium also indicated that chromium absorption may be increased in response to acute exercise and strength training. Further study is required to determine if an increase in chromium absorption could be related to improvement in insulin response seen with exercise (Rubin et al. 1998).

Dietary Recommendations

An AI (adequate intake) for chromium was estimated as part of the process of developing the Recommended Dietary Intakes published by the Institute of Medicine (Panel on Micronutrients 2001). An AI is established when data are insufficient to identify dietary intakes at which half of healthy individuals would be expected to display a specified deficiency sign (Estimated Average Requirement (EAR)). Establishing an EAR is critical to the process of developing a recommended dietary allowance (RDA); when it is not possible to set an RDA for a nutrient, an AI is presented representing the mean intake of apparently healthy people. The AI for chromium for adults was based on an energy estimate for age multiplied by 13.4 μg chromium/1,000 kcal. The AI for women 19–50 years of age is 25 μg/day and for men of the same age is 35 μg/day. In older adults, average consumption of energy nutrients decreases, and the AI accordingly is set at 20 μg/day for women above the age of 50 and at 30 μg/day for men above the age of 50.

The AI for infants was derived from data showing that chromium concentration of breast milk is approximately 0.25 μg/L (Anderson, 1993). Based on the assumption of 0.78 L/day consumption of human breast milk in exclusively breast-fed infants, the AI for infants 0–6 months of age is set at 0.2 μg/day. The AI for infants 7–12 months of age is estimated to be 5.5 μg/day. This increase represents the increased intake of approximately 400 kcal per day of complementary food by infants of this age. The AI for chromium increases gradually throughout childhood based on metabolic weight (kg ¾) extrapolated from the adult AI.

Manifestations of Deficiency

Several reports have been reviewed that indicate a role for chromium in carbohydrate metabolism (Anderson 1987; Mertz 1993; Offenbacher et al. 1997). In 1977, a patient was reported who upon receiving total parenteral nutrition for 3.5 years developed unintentional weight loss, peripheral neuropathy, and impaired glucose tolerance (Jeejeebhoy et al. 1977). The high circulating levels of free fatty acids and the respiratory quotient of 0.66 indicated use of lipid as fuel. Increased infusion of glucose and 45 units of insulin daily did not control weight loss and other symptoms. Chromium concentrations in blood and hair were severalfold below normal values for that laboratory. A large infusion of intravenous chromium (250 μg daily for 2 weeks) normalized the glucose tolerance test, the respiratory quotient, and the peripheral neuropathy. Insulin infusion was stopped and glucose intake had to be reduced to avoid overweight. At the time of publication of this case report, infusion of 20 μg chromium as $CrCl_3$/day had maintained the patient for 18 months (Jeejeebhoy et al. 1977).

Insulin signal transduction; Insulin signaling; Insulin-signaling pathway

Definition

Insulin signaling refers to the cascade of processes triggered by insulin binding with its receptor, and as a result, cellular glucose uptake and utilization can take place. It has been extensively documented that trivalent chromium (Cr^{3+}) can improve insulin sensitivity by enhancing insulin signal transduction; however, the mechanisms of its action have not been fully understood. The contemporary theories explaining the possible mechanisms of Cr^{3+} action in insulin signaling are based on certain phenomena that include its role in the LMWCr, involvement in phosphorylation reactions, assisting insulin binding to its receptor, increasing number of insulin receptors, activation of Akt proteins, and interaction with cytokines and oxidation processes, as well as increasing cell membrane fluidity.

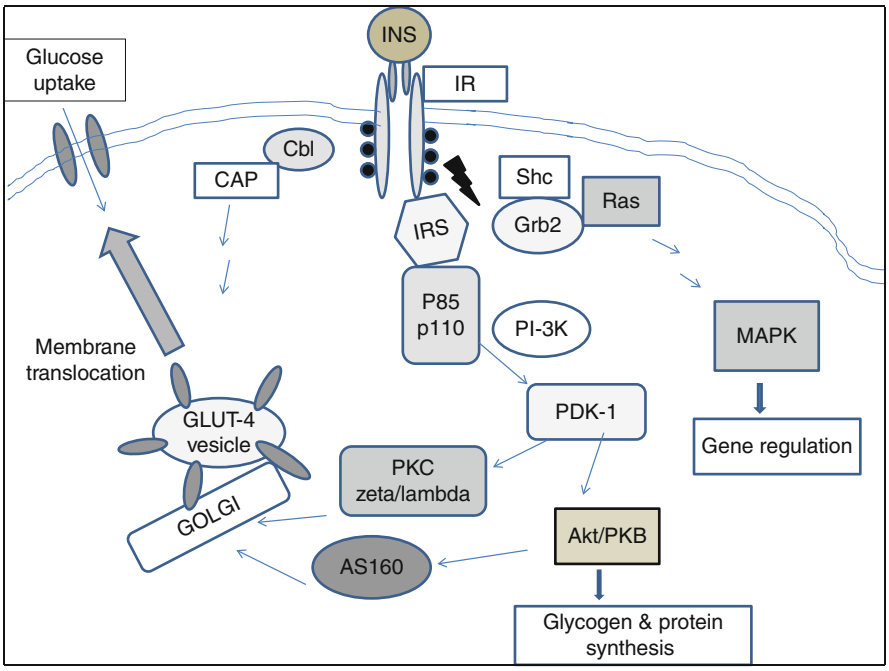
Insulin Signaling

Insulin (INS) is a hormone with pleiotropic functions that influences gene expressions and mitogenesis and regulate metabolism of glucose, lipids, and proteins. The insulin molecule contains 51 amino acids and is composed of two peptide chains (A and B) linked by disulfide bonds. In most species, the A chain consists of 21 amino acids, and the B chain, of 30 amino acids. These chains initially are contained within a single

polypeptide chain (preproinsulin) that is converted to proinsulin and finally to insulin. Insulin is synthesized in the pancreas within the beta cells (β-cells) of the islets of Langerhans and can be released when stimulated by various factors. Increased blood glucose concentration is the primary stimulant to insulin secretion. After a meal, in response to elevated levels of the blood nutrients (glucose, lipids, acids), the β-cells of the pancreatic islets of Langerhans secrete insulin. Insulin regulates glucose homeostasis at many sites, reducing hepatic glucose output (via decreased gluconeogenesis and glycogenolysis) and increasing the rate of glucose uptake into striated muscle and adipose tissue. The insulin-signaling pathway therefore plays an essential role in glucose and energy homeostasis. Impairment of the insulin-signaling pathway (at various levels) leads to insulin resistance and development of type 2 diabetes mellitus (T2D) and the complications associated with this disease.

The first step of insulin action is its binding to insulin membrane receptor (IR) present in many cells (muscle, adipocytes, brain, liver). Insulin receptor belongs to the superfamily of receptor tyrosine kinases and is an integral membrane protein existing in dimeric form: α-subunit and β-subunit. These subunits are linked to each other by disulfide bonds present on the extracellular side of the plasma membrane. Each α-subunit contains a binding site for insulin.

Insulin binding to the α-subunit of IR induces a conformational change in the β-subunit, which triggers the cascade of signals inside target cells. This process is very complex, involving various interactions between intracellular biomolecules. The first step of this process, after binding of insulin with IR, is autophosphorylation of the IR β-subunit, which activates the tyrosine kinase domains. The insulin receptor tyrosine kinase (IRTK) is activated by two separate events, where three residues (Tyr_{1158}, Tyr_{1162}, and Tyr_{1163}), located in the regulatory loop, play a central role in this process. In the first phase, insulin binding increases the activity of IRTK and stimulates its β-subunit autophosphorylation. In the second phase, autophosphorylation of the insulin receptor fully activates the enzyme toward specific intracellular insulin receptor substrate proteins (IRS). IRS are related by functional properties and not sequence similarity. Four substrates belong to the IRS family (IRS1, IRS2, IRS3, IRS4). Other substrates include growth factor receptor–bound protein 2 (Grb-2), receptor-associated binder-1 (Gab1), $p60^{dok}$, the c-Cbl proto-oncogene (Cbl), adaptor protein with pleckstrin homology (PH) and Src homology 2 (SH2) domains (APS), and three isoforms of SH2 domain-containing alpha-2 collagen-related protein (Shc). IRS contain an NH_2-terminal PH domain and/or a phosphotyrosine-binding domain, COOH-terminal tyrosine residues that create SH2 protein-binding sites, proline-rich regions that engage Src homology 3 (SH3) domains, or WW domains (protein modules that bind proline-rich ligands) and serine-threonine-rich regions that bind other proteins. All substrates, except Shc, contain an SH2 domain that targets the substrate to the insulin receptor. Three main pathways propagate the signal generated through the insulin receptor: the IRS/phosphatidylinositol kinase (PI-3K) pathway, the retrovirus-associated DNA sequences (RAS)/mitogen-activated protein kinase (MAPK) pathway, and the Cbl-associated protein (CAP)/Cbl pathway. The RAS/MAPK cascade does not play a role in regulation of glucose transport but is largely involved in gene regulatory responses in insulin-sensitive tissues. The CAP/Cbl pathway is a PI-3K independent pathway participating in the insulin-mediated glucose transport through activation of TC10, a member of the Rho family of small guanosine triphosphate (GTP)–binding proteins. The most important role in insulin-dependent glucose transport is played by PI-3K. It consists of p10 catalytic subunits (three isoforms) and a p85 regulatory subunit (two isoforms) that have two SH2 domains that bind to phosphotyrosine motif on receptor tyrosine kinases or substrates. IRS-1 and IRS-2 dock with the p85 regulatory subunit, which in turn activates the p110 catalytic subunits. The PI-3K substrate phosphatidylinositol-4,5-bisphosphate (PIP_2) is phosphorylated on the 3-OH position of the inositol ring to produce phosphatidylinositol triphosphate (PIP_3), and formation of this lipid recruits PH domain-containing proteins, such as the serine-threonine kinases 3-phosphoinositide-dependent protein kinase-1 (PDK-1), protein kinase B (PKB)/Akt, and atypical kinases C zeta and lambda isoforms (aPKCs). PDK-1 phosphorylates PKB and aPKCs on a threonine residue located in the activation loop of the catalytic domain, causing their activation. Akt promotes the phosphorylation of p70S6



Chromium and Insulin Signaling, Fig. 1 Simplified model of insulin signaling pathways following insulin receptor activation in skeletal muscle cell

kinase and also plays a role in insulin signaling to glycogen synthesis by mediating the insulin-induced phosphorylation and inhibition of glycogen synthase kinase 3 (GSK-3) (Glund and Zierath 2005). Phosphorylation of Akt substrate (AS160) signals the Golgi to mobilize a family of glucose transporters (GLUT 1–4 proteins) for trafficking to the plasma membrane. Finally, activation of Akt results in the translocation of GLUT-4 vesicles (in muscle and adipose tissue) to the plasma membrane. These transporters then bind and fuse with the plasma membrane facilitating glucose transport via carrier-mediated-facilitated diffusion, initially enhanced by insulin binding to IR. The simplified schematic model of insulin-signaling events is presented in Fig. 1. Once the IR is inactivated, the transporter GLUT-4 returns to the Golgi. Generally, the efficacy of insulin signaling is determined by insulin binding to its receptor and activation of the kinases along the cascade.

In summary, insulin signaling can be enhanced by enhancing the binding of insulin to its receptor, the activation of kinases along the cascade, or inhibition of the dephosphorylation of insulin receptor.

Alterations in insulin signal transduction have serious consequences for glucose and lipid metabolism, leading to metabolic disorders such as insulin resistance and diabetes mellitus. Glucose homeostasis is impaired in patients with non-insulin-dependent diabetes mellitus (type 2 diabetes) as a result of defects in glucose transport in skeletal muscle. Although the primary causes of insulin resistance and type 2 diabetes have not been fully elucidated, genetic and environmental factors are thought to contribute to the development of the disease. A number of different altered metabolic states, such as persistent elevation of circulating glucose, insulin, fatty acids, and cytokines, can lead to peripheral insulin resistance. Insulin resistance may result, for example, from alterations in insulin receptor expression, binding, phosphorylation state, kinase activity, and/or the GLUT-4 vesicle budding, trafficking, docking, and fusion events. Reduction in the amounts of insulin receptor kinase itself, as well as a reduction in the extent of IRS protein tyrosine phosphorylation and PI-3K association/activation were found in patients with type 2 diabetes. However, whether these changes in insulin receptor function represent primary lesions that cause insulin resistance or whether they occur secondary to hyperinsulinemia or hyperglycemia is uncertain. There are also opinions that there may be no single or common defect that

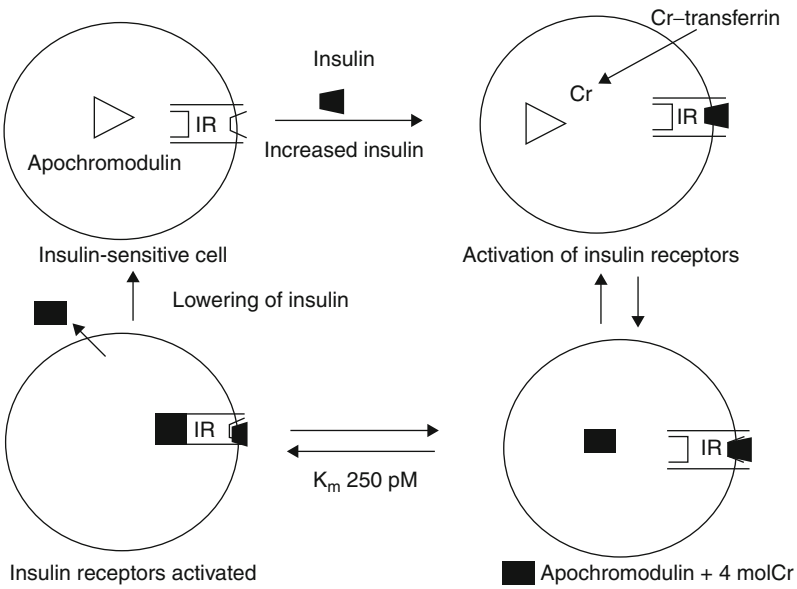
underlies peripheral insulin resistance. Most likely, insulin resistance is a complex phenomenon in which several genetic defects combine with environmental stresses to generate the phenotype (Pessin and Saltiel 2000).

The Role of Cr in Insulin Signaling

According to some researchers (Anderson 2003), some of the signs and symptoms of insulin resistance include glucose intolerance, hyperinsulinemia, increased LDL cholesterol, increased triacylglycerols, elevated total cholesterol, and decreased HDL cholesterol have been associated with decreased dietary intakes of chromium (Cr). For over 50 years, trivalent chromium (Cr) has been considered as an essential element for mammals, and for over 30 years for humans, plays an important role in carbohydrate and lipid metabolism and provides significant beneficial effects in the insulin-signaling system. In the presence of Cr, in its biologically active form, much lower amounts of insulin are required. However, the scientific base of this very concept was not fully explored and remains under question. Cr is believed to be required for optimal insulin activity and normal carbohydrate and lipid metabolism. A number of studies have considered the impact of Cr supplementation on blood glucose and insulin levels in animal models and humans. Several (but not all) randomized, placebo-controlled clinical trials have demonstrated statistically significant improvements in blood glucose and insulin levels following dietary supplementation of 200–1,000 μg Cr/day, mostly in the form of chromium tris(picolinate), $Cr(pic)_3$, by type 2 diabetic subjects for periods of 4 weeks to 4 months. Thus, $Cr(pic)_3$ has been considered as an insulin sensitizer. The bioavailability of Cr from Cr compounds depends on the type of ligand; however, it is generally low (0.1–2%). The mode of action of Cr on glucose metabolism involves several biochemical changes leading to increased insulin sensitivity. The mechanism of Cr action remains obscure despite multiple pathways of action being proposed, including a decrease in hepatic glucose production and an increase in peripheral glucose disposal. Early reports suggested that Cr enhances insulin binding, insulin receptor number expression, insulin internalization, and increases beta-cell sensitivity, but the exact mechanism whereby Cr participates in the functions of insulin has not been fully elucidated. Major theories explaining the mechanism of Cr action in insulin signaling are presented below.

The Role of LMWCr in Insulin Signaling

An interesting theory explaining the role of Cr^{3+} in the regulation of glucose metabolism is connected with a discovery of the oligopeptide LMWCr (low-molecular-weight-chromium-binding substance), also termed chromodulin. This peptide was isolated and purified from animal tissues (rabbit, bovine, dog, mouse, porcine liver or kidney) or fluids (bovine colostrum) exposed to potassium dichromate. Chromodulin has a molecular weight of approximately 1.5 kDa and is comprised of only four types of amino acid residues (glycine, cysteine, glutamate, and aspartate) and binds with high affinity to four chromic ions. The amino acid composition of the LMWCr isolated from bovine liver was identified to be approximately E:G:C:D::4:2:2:2 (Vincent 2007). In the absence of insulin, chromodulin does not affect the insulin receptor tyrosine kinase (IRTK) activity (and a membrane phosphotyrosine phosphatase in rat adipocyte) but stimulates its activity eightfold in the presence of insulin. Removal of Cr from the LMWCr results in the loss of kinase-potentiating activity (Davis and Vincent 1997). The proposed mechanism for the activation of IRTK activity by LMWCr has been described in detail by Vincent and Bennett (Vincent 2007) and is presented in Fig. 2. In short, this mechanism is explained on the assumption that the inactive form of LMWCr (as apoLMWCr without Cr) is stored in insulin-sensitive cells, while in response to insulin, Cr bound in transferrin is moved from the blood to these cells, loading of apoLMWCr with Cr to form the active form (holoLMWCr). The holoLMWCr then binds to the IR amplifying IRTK activity. A decrease of blood insulin level facilitates relaxation of the conformation of the IRS, excretion of the holoLMWCr from the cells into the blood, and finally brings about the termination of the insulin signaling. The site of activation appears to be located at or near the kinase activation site since addition of chromodulin to a fragment of the β-subunit that contains the active site and does not require insulin for activation resulted in a similar stimulation of kinase activity. Activation of insulin receptor kinase by the



Chromium and Insulin Signaling, Fig. 2 A proposed mechanism for the activation of insulin receptor (IR) kinase activity by chromodulin in response to insulin. The inactive form of the IR is converted to the active form by binding insulin. This triggers the movement of Cr from transferrin into the insulin-dependent cells and the binding of Cr to apochromodulin. The holochromodulin containing 4 mol Cr/mol chromodulin then binds to the IR further activating IR kinase activity. Apochromodulin is unable to bind to the IR. When the concentration of insulin decreases, holochromodulin is released from the insulin-sensitive cells (Permission from Vincent 2000)

LMWCr requires 4 mol Cr/mol oligopeptide and is specific for Cr.

Cr Affects a Cascade of Phosphorylation Reactions

Cr is believed to activate the insulin receptor kinase and inhibit phosphotyrosine phosphatase (PTP-1) that inactivates the IR phosphatase, leading to increased phosphorylation of the IR, which is associated with increased insulin sensitivity. Studies conducted on Chinese hamster ovary cells showed that Cr activates insulin kinase activity at low doses of insulin.

Cr Binds Directly to Insulin Receptor

Cr in the form of multinuclear Cr assembly (like that occurring in LMWCr) has been proposed to bind to the extracellular α-subunits of the IR concomitant with insulin binding that in turn activates the IRTK activity. However, this mechanism has not been proven and remains speculative.

Cr Increases the Number of Insulin Receptors

Cr^{3+} has been suggested to increase IR number, as observed in red blood cells of hypoglycemic subjects after 6 weeks treatment. However, the mechanism of Cr action on IR was not explained, and other studies did not confirm such effects in animal models.

Cr Activates Akt

Some studies reported that supplemental Cr ($Cr(pic)_3$) increases Akt phosphorylation in type 2 diabetic subjects. The same effect was observed in vitro in mouse 3T3-adipocytes treated with $Cr(phenylalanine)_3$; thus, this phosphorylation was suggested to be the mechanism of Cr action in insulin signaling (Yang et al. 2005).

Cr Interacts with Cytokines and Decreases Oxidation

Another possible mechanism of Cr action in the insulin-signaling pathway may involve interaction with cytokines (TNF-α, IL-6) and lipid peroxidation. In vitro studies showed that Cr (as $CrCl_3$) inhibits TNF-α secretion and oxidative stress induced by exposure of cultured U937 monocytes to high glucose medium. Cr has been proposed to enhance insulin sensitivity by lowering of TNF-α secretion,

a cytokine known to inhibit the sensitivity and action of insulin. Cr was also shown to prevent lipid peroxidation (in vitro H_2O_2-treated cells); thus, its antioxidative effect might be essential in insulin signaling (Jain and Kannan 2001).

Cr Increases Cell Membrane Fluidity

Another possible mechanism of Cr action in insulin signaling involves changes in membrane lipids depots. Insulin-stimulated glucose transport has been observed to be decreased when membrane fluidity diminishes. Studies in vitro showed that in the presence of insulin, Cr (as $CrCl_3$ or $Cr(pic)_3$) increases membrane fluidity by decreasing plasma cholesterol level in 3T3-L1 adipocytes. The regulation of glucose transporter (GLUT-4) translocation by Cr did not involve known insulin-signaling proteins such as the insulin receptor, IRS-1, PI-3K, and Akt. Interestingly, cholesterol add-back to the plasma membrane prevented the beneficial effect of Cr on both GLUT-4 mobilization and insulin-stimulated glucose transport (Chen et al. 2009).

In skeletal and heart muscle cells, insulin directs the intracellular trafficking of the fatty acid translocase/CD36 to induce the uptake of cellular long-chain fatty acids (LCFA). Both insulin and Cr (as $Cr(pic)_3$) have been demonstrated to induce CD36 translocation to the plasma membrane in 3T3-L1 adipocytes. These data indicate that Cr improves glucose transport by modification of lipid depots and represses lipid-induced insulin resistance.

Despite over 50 years of intense studies on the role of Cr in glucose and lipid metabolism, the mechanisms of its action, as well as essentiality of Cr for animals and humans, remain under question. A recent well-controlled study on rats fed with a diet of as little Cr as reasonably possible failed to demonstrate any deleterious effects on body composition or glucose metabolism and insulin sensitivity compared to Cr "sufficient" diet, suggesting that Cr can no longer be considered as an essential element (Di Bona et al. 2011). The beneficial role of supplementary Cr may result from a pharmacological effect, increasing insulin sensitivity.

Chromium and tanning

Definition

The process of conversion of hides/skins which putrefy within hours of death of an animal to a commodity meeting the lifestyle, aesthetic, and fashion requirements of the user is described by the term "tanning." Chromium(III) ions based tanning owing to the kind of

thermal stability and customer preferred properties that it confers is the most predominant methodology. It has been an intriguing factor to leather chemists as to why other metal ions or natural polyphenols are not able to match the properties conferred by chromium(III). Tanner, in the past, has been challenged by the poorer uptake and hence the release of chromium into the wastewaters. A reasonable understanding of the type of chromium(III) species found in tanning solutions, their interaction with collagen, the species present in the spent solutions, etc., has now been possible. Methodologies for overcoming the poorer uptake of chromium by the skin matrix, employing the principles of green chemistry have been developed and implemented at industrial levels. The challenge however is to enhance the rate of diffusion and fixation of chromium to the three-dimensional skin matrix.

Tanning: Moving Skin to a Fashionable Commodity

Viscoelasticity and a unique animal-dependent pore size distribution enables leather, a stabilized animal skin, to breathe and readjust to volume fluctuations such as that in foot. The process by which the skin protein, collagen, is stabilized against wet and dry heat, thermomechanical stress, and enzymatic attack is known as tanning. In this process, the tanning agent (inorganic metal ions like Cr^{3+}, Zr^{4+}, Ti^{4+}, Fe^{2+}/Fe^{3+}, etc.; organic products such as plant polyphenols, aldehydes, etc.) forms cross-links (H-bonds, covalent and coordinate covalent linkages) with active sites in the collagen (predominant skin protein). The consumption of leather and leather products is said to have increased by 55% over the past 30 years, with estimated trade value in USD being 120 billion per year. Leather, as a commodity, is traded based on lifestyle, aesthetic, and performance preferences of the consumer. Accordingly, the choice of the tanning agent is guided by the end properties achievable from each type. 1.6 billion square feet of leather (of the total 1.8 billion square feet processed annually) is tanned or retanned using chromium, thus signifying the role of this metal ion in conferring the consumer preferred properties. Chromium-tanned leathers tend to be softer and more pliable than their plant polyphenol counterparts. They also have the highest thermal stability, reported till date, and are very stable in water, and the production time is much shorter than other tanning agents.

Skin, after the operations prior to tanning, is predominantly composed of collagen. Collagen is distinctive, in that it is composed of a regular arrangement of amino acids in each of the three chains of collagen subunits (Ramachandran 1963). A Gly-Pro-X or Gly-X-Hyp, where X may be any of the various amino acids, is the sequence followed. Proline and hydroxyproline constitutes 1/4 of the total sequence and glycine accounts for 1/3 of the sequence. The tropocollagen or the collagen molecule, which is 300 nm long and 1.5 nm in diameter, is made of three left-handed polypeptide strands, twisted to form a right-handed coiled coil triple helix, a cooperative quaternary structure stabilized by numerous hydrogen bonds. Each triple helix associates into a right-handed microfibril, and they coil together to become the well-ordered crystalline fibril. Collagen fibers are bundles of fibrils, and these fibers are bundled up to provide fiber bundles, which are subsequently packed in a three-dimensional array, unique of the type of animal, to form the skin. Diffusion of the tanning material into the skin matrix, through the enormous number of pores, and then binding to the active sites is the key to tanning.

Chromium: The Most Preferred Tanning Agent

The aqueous chemistry of chromium is limited to di-, tri-, and hexavalent states. Chromium(III) forms $3d^2 4s 4p^3$ hybrid orbitals. This when coupled with the tripositive character of the metal ion enables the formation of thermodynamically stable coordinate covalent bonds with the side chain carboxyl sites of aspartic and glutamic acids in collagen. Historically, chromium-based tanning was performed using chrome alum applied in solution at pH of ~2, followed by a basification to pH 4 to fix the chromium to collagen. Subsequently, a two-bath tanning process where the skin was treated in a solution of chromic acid overnight, followed by its reduction to trivalent chromium at pH 4, in another bath had been employed. Cr(VI) being responsible for lung cancer, chrome ulcers, nasal septum perforation, and brain and kidney disorders, such two-bath processes have been replaced with one-bath processes employing chromium(III) salts,

even though in earlier times, this change was prompted by a possible reduction in duration of tanning.

There are several factors that influence the fixation of chromium onto collagen and thus provide hydrothermal and enzymatic stability to collagen. These factors can in general be grouped as those relating to (a) the type of chromium salt employed for tanning, (b) the reactivity of collagen toward chromium, and (c) environmental factors (Chandrasekaran et al. 1999).

Collagen tanned with basic chromium(III) chloride or perchlorate did not provide for shrinkage temperatures as effective as that with coordinated sulfate. When the counterion employed was a chloride or perchlorate, the stability of the resultant chromium–collagen bond was only moderate. It is expected that chromium(III) along with its counterion must create a matrix with the supramolecular water structure. In this, the counterion can act as a water structure breaker or maker. While sulfate is a structure maker, the chloride is a structure breaker, indicating as to why chromium with its sulfate counterion is able to provide more stability to collagen (Covington et al. 2001). As the presence of coordinated sulfate is necessary for the efficient reaction of chromium(III), basic chromium (III) sulfate salt, which is a synergistic combination of Cr(III) molecular ions and their counterions, is the preferred tanning agent. Basic chromium(III) sulfate is prepared by the reduction of Cr(VI) using molasses or sulfur dioxide. The process variables such as temperature, concentration of reactants, nature of reductants, etc. influences the composition of the chromium tanning salt produced. Accordingly, 15 different types (Fig. 1) of chromium(III) species have been identified in basic chromium(III) sulfate solution. This diversity in chemical structure results in variable kinetic lability and thermodynamic affinity to the sites of collagen. Extended X-ray absorption fine structure (EXAFS) studies of chromium(III) bound to collagen showed that the dominating bound species are linear tetrachromium compounds (Covington 2001).

There is little direct evidence for the size and shape of chromium(III) species influencing their binding to collagen. While several authors have intuitively assumed the species to be linear, the solution chemistry does favor the formation of three-dimensional species such as the cyclic tetramer as well. While monomeric species such as the hexaaquachromium(III) ion is kinetically inert and hence not useful as a tanning agent, the dimeric and trimeric species are thermodynamically favorable in stabilizing the collagen matrix through complexation. It has been reported that irreversible binding of chromium is achieved only if the binding constants are greater than 15 M^{-1} for the (1):

$$\left[(H_2O)_4Cr(OH)_2Cr(H_2O)_4\right]^{4+} + P-COO^- \overset{K}{\longleftrightarrow} \left[(H_2O)_3(P-COO)Cr(OH)_2Cr(H_2O)_4\right]^{3+} + H_2O \quad (1)$$

where P – COO^- represents the carboxylic acid side chains of aspartic and glutamic acids in collagen (Rao et al. 1999).

It has been reported that Cr^{3+} and collagen segments form clusters of 20–40 nm between the fibrils, with Cr (III) acting as a cross-linker. Such external cross-links do not destroy the triple-helix conformation of

collagen. Binding constants for collagen–chromium complexes are not available due to the heterogeneous character of collagen. One of the methods by which this has been circumvented is by studying the reaction of chromium(III) oligomers with thiocyanate. The trimeric species has been shown to react with thiocyanate with a bimolecular rate constant of $9.3 \times 10^{-4}\,M^{-1}\,s^{-1}$ at 30°C (Rao et al. 1999).

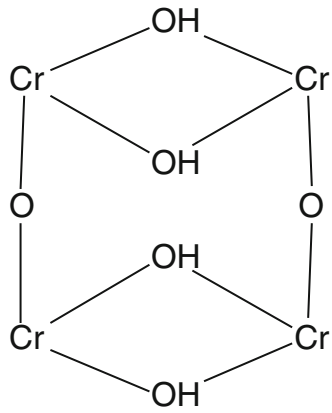
Another method by which the ability of chromium species to effectively cross-link with collagen is evaluated is the ease of collagen cleavage by CNBr. SDS-PAGE provides information on the number of collagen fragments formed on CNBr cleavage, and the trimeric chromium species was more effective toward collagen cross-linking than the dimeric species. Interaction studies carried out between rat tail tendon collagen and the chromium species followed by evaluation under an atomic force microscope provided evidence for organization of monomeric collagen into quarter staggered fibrils in the presence of Cr(III) dimer.

In the case of leather, the substrate, skin, is a three-dimensional matrix of finite thickness. This brings in an additional parameter of diffusion into the collagenous matrix. Diffusion into the skin matrix can be considered as those occurring through the macropores, micropores, or molecular pores. While diffusion through the macropores is limited only by the transport pathways, gel structures, swelling of collagenous matrix, and other mass transfer phenomena, that of micropores is predominantly governed by surface tension, solvent dielectrics, capillary phenomena, and electrolytes (Ramasami 2001). The molecular cavity size, polarity restrictions, charged sites, and range of distances for molecular interactions are expected to influence the diffusion through molecular process. In any event, the rate of diffusion can influence the rate of fixation as diffusion precedes fixation. In the case of chromium, the binding sites being the carboxyl groups of aspartic and amino acid residues, the pH and temperature play an important role in penetration and fixation. While penetration is achieved at a lower pH of 2.8–3.0, the fixation is achieved at pH 3.8–4.0. For this, the hide or skin is subjected to a process called as pickling, wherein the pH of the skin is reduced from near neutral conditions, employing slow but steady feeds of concentrated sulfuric acid. This process is carried out in the presence of neutral salts so as to avoid swelling of collagen in acidic condition. After the penetration of chromium into the skin matrix is achieved, the pH of skin is raised to 3.8–4.0. During this process, the basicity of chromium is increased, and the chromium(III) molecules are polymerized by olation. With increase in molecular weight of the chromium(III) complex, hydrophobicity and hence the reactivity toward collagen increases. Raising the pH to 3.8–4.0 is considered as a high-risk process as any sudden jump of pH would result in the precipitation of chromium. This has resulted in a search for basification free processes.

One of the old methods to avoid basification was to leave enough residual alkali in the pelt, which later gets employed for basification. In the 1990s, a "ThroBlue process," where chromium tanning salts devoid of associated sodium sulfate, is applied at pH 7 along with a polyamide, thus ensuring a basification free process with higher uptake of chromium had been reported. In recent years, a polymeric compound containing an aromatic sulfonic acid was employed in the place of "pickle" and was followed by the use of basic chromium sulfate. This process also eliminated the need for basification (Sreeram and Ramasami 2003).

In spite of reducing the pH of the skin matrix to 2.8–3.0 to facilitate penetration of chromium(III) salts, some binding to the surface proteins can be expected. Mono- and dibasic carboxylic acids, referred to as masking agents, are generally added either to the pickle or to the tanning bath to control the rate of reaction and penetration of chromium(III) species into the hide protein. Coordination of chromium(III) to the masking agents reduces the cationic charge and then enhances the diffusion of chromium into the skin matrix. Masking increases the reaction rate, owing to an increase in the reactivity of collagen. The masking ratio, defined as the ratio of number of moles of carboxylic masking agent to the number of gram atoms of chromium, lies typically in the range of 0.5–1.0. In practical terms, only formate and phthalate are conventionally important masking agents (Covington 2001).

The second objective of reaction of chromium species with collagen is to bring about (to collagen) stability against enzymatic hydrolysis. Dimeric and trimer chromium(III) species was reported to bring about secondary and quaternary structural changes to collagenase, the enzyme which breaks the peptide bonds in collagen. The mode by which these species



Chromium and Leather, Fig. 2 Structure of cyclic tetrameric chromium(III) species found in unspent solution of chromium (III) sulfate after tanning

inhibited the action of collagenase on collagen was reported to be competitive (Gayatri et al. 2000).

It has been estimated that only 10% of the bound chromium is involved in cross-linking, and therefore, only 1/40 of the carboxy groups are required for chromium–collagen cross-linking. Therefore, the earlier efforts of converting the amino groups into carboxyl terminated groups by way of pretreatment with glycine and formaldehyde or glyoxal and *n*-thioureidopyromellitamic acid and thus increase the uptake of chromium should be considered as one of providing more binding sites at the surface of the fiber bundles rather than improving the diffusion of chromium into the matrix (Wang and Zhou 2006).

Addressing Challenges in Chromium-Based Tanning

In spite of a greater level of understanding of how diffusion of chromium into the matrix as well as its fixation to the collagen can be improved, the uptake of chromium, in general, during the process of tanning has only reached levels of 70–80%, as against 40–60% achievable about two decades ago. Rao et al. reported that the spent chromium solution after the process of tanning predominantly contained a cyclic tetrameric species (Rao et al. 1998) (Fig. 2), which reacted with an anion like NCS^- with an equilibrium constant of $1.2 \pm 0.1\ M^{-1}$, as against 15.7 ± 0.1 and $14.6 \pm 0.1\ M^{-1}$ for dimeric and trimeric species (Rao et al. 1999). The equilibrium constant values reflect the low thermodynamic affinity of the tetrameric species for the nucleophile. The reaction of collagenase with the cyclic tetrameric species was reported to be uncompetitive in character, indicating that the tetrameric species could not bring about stability to collagen. The molecular size of the tetrameric species (9.2 Å) is considered to be one of the causes of poorer uptake of this species during tanning. By introducing phthalates and employing appropriate molasses to acid ratios and temperature during the process of conversion of Cr(VI) to Cr(III), a modified basic chromium sulfate has been prepared, which exhibited over 85% uptake of chromium. There are also reports that tumbling a wet pickled pelt and chromium salt in a highly hydrophobic medium, such as paraffin wax, can result in the solute effectively partitioned between an inert solvent and water within the pelt. Consequently, a very rapid uptake of chromium is achievable. However, the subsequent complexation of the chromium(III) and its fixation are dependent on the surrounding water molecules, and therefore, the fixation needs to be carried out in the conventional manner. An alternative to this method is to control the solute–solvent interaction. Hydration reactions, being controlled by the dielectric constants, the addition of even small quantities of ethylene glycol, ethanolamine, or ethylenediamine (dielectric constants of 38, 34, and 14, respectively), markedly change the properties of water, reduce its solvating effect, and thus increase the rate of diffusion and thus fixation of chromium. It has been reported that the ethanolamine-based pretreatment of collagen results in an uptake of chromium to the levels of 90%. The mineral analogue of this reaction is the use of aluminum(III) salts prior to offering of chromium, which provides for about 90–95% uptake of chromium (Covington 2009).

Chromium(III) has been included among the essential trace elements and has considerable beneficial effects on glucose metabolism. However, the ability of chromium(III) to cross-link DNA and proteins, and also participate in nonenzymatic phosphorylation and influence the calcium transport channels, calls for caution while discharging chromium(III) into soil or wastewaters. Further, conversion of Cr(III) to Cr(VI) in the presence of manganese oxides present in the soil has also been reported. Based on these considerations, the discharge norms for industrial wastewaters specify

the permissible levels of chromium to be below 2.0 ppm. This calls for recycling of chromium in the tanning process. Recycling of chromium can be either direct or indirect.

Direct recycling of spent chromium solution (from a conventional tanning) containing 0.15–0.5% chromium, 3.3–3.5% NaCl, and 2.8–3.3% Na_2SO_4 along with fresh chromium(III) salt for replenishing the concentration of chromium was found to have disadvantages of poorer uptake of chromium and quality of leather. This has been attributed to the structure and reactivity of the cyclic tetrameric species and adverse effect of accumulated neutral salts (Sreeram et al. 2005). Direct recycling of such chromium-bearing liquors into tanning requires membrane-based processes, which can reduce the neutral salts from 7% to 1%. In the absence of membrane-based processes, the recycling of spent chromium solutions into the pickle seems to be more advantageous. The direct recycling of spent chromium solutions from high exhaust tanning systems such as ethanolamine–chromium or aluminium–chromium directly without membrane separation processes into the pickle produces leathers devoid of grain harshness, possibly due to lower chromium content, or in turn lower higher-charged chromium(III) species. This is corroborated from the fact that the preacidification of spent chromium solution to a pH of 1 reduces the 3+ and above charged species to below 7% as against 73% in the case of pH 3.8.

Another way by which chromium(III) in the spent solutions can be completely recovered is the precipitative removal. Chromium(III) in solution can be easily precipitation as chromium(III) hydroxide by the addition of alkali. Though in principle, any alkali can be used, commercially adopted batch processes employ either magnesium oxide or magnesium oxide and lime as they afford lower-settled volumes, owing to higher bulk density of the chromium(III) hydroxide generated. However, the supernatant from such processes have a high total dissolved solids content (from the magnesium sulfate generated in the reaction). Discharge of such solutions to water bodies can adversely affect the salinity of the water. By suitable modifications to the conical reactors employed to precipitate chromium(III) hydroxide, hydrostatic pressure and turbulence within the reactor systems can be generated. Under such circumstances, a continuous mode of precipitation, employing sodium carbonate as precipitant, results in chromium(III) hydroxide precipitate volumes of around 20% as against 10% in the case of magnesium oxide (Sreeram and Ramasami 2003). Both batch and continuous methods are currently in commercial practice, and they result in discharge of supernatants having below 0.3% chromium. The precipitated chromium(III) hydroxide upon acidification results in basic chromium(III) sulfate solution, which is reemployed in tanning.

While direct or indirect recycling of spent solutions can overcome the discharge of chromium into wastewaters, the major challenge is the disposal of chromium(III) containing leather scraps as well as leather products as solid wastes. This waste amounts to 10% of the total raw hide/skin processed or approximately, at the current levels of production, 0.8 million tons, globally.

Leather wastes can be effectively used in the manufacture of boards for soling, heeling materials, general heavy components, light shoe inserts, and fancy goods, such as lamp shades, etc. Other alternate use for such protein rich waste is as a reducing agent in the manufacture of basic chromium sulfate. These chromium(III) salts thus generated have the added advantage of improved masking owing to the presence of oligopeptides. Other uses include that as adsorbents for dyes from wastewaters (Rao et al. 2004). The dye-bearing solid waste can subsequently be calcined under controlled conditions to generate chromium-based pigments.

Way Forward

The poorer uptake of chromium led to research initiatives toward replacing chromium. However, the higher thermal and enzymatic stability provided by chromium(III) remained unsurpassed. With increasing knowledge about the structure of collagen and newer analytical tools for the understanding of how chromium complexes react with collagen, the methodologies for improving the uptake and fixation of chromium are increasing. Some efforts toward speciation of chromium found in wastewaters led to the identification of species which are relatively unbound to collagen. This can lead to development of tanning salts devoid of such species. The chemistry of masking

needs to improve so as to provide improved penetration of chromium at lower process times. The rate of reaction of chromium with collagen and the stability of chromium–collagen bonds need to be enhanced not only for increasing the fixation of chromium but also for reducing the discharge of chromium during subsequent posttanning operations. In essence, the profitable and sustainable employment of chromium as a tanning agent seems to be a reality in the future.

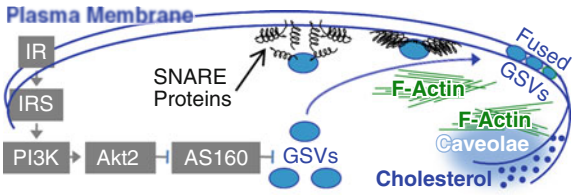
Definition

The surface of cells is defined by a membrane termed the plasma membrane. This membrane is composed of several classes of lipids including phospholipids, sphingomyelin, glycosphingolipids, and cholesterol. In this structure, the phospholipids are the primary component arranged into two parallel sheets or leaflets referred to as a bilayer. The other lipids, especially cholesterol, regulate the fluid consistency of the membrane. The rigid steroid ring of cholesterol, in particular, adds integrity to the membrane by partially immobilizing the fatty acid side chains of phospholipids. While this stiffening decreases plasma membrane fluidity, the high concentration of cholesterol in animal cell plasma membranes counters this firming effect by separating the phospholipid fatty acid chains and disrupting their crystallization. Cholesterol also plays an important role in membrane biology by forming specialized microdomains known as lipid rafts and caveolae, recognized to function in numerous cellular processes including regulation of glucose transport by insulin and chromium.

Basic Mechanisms of Insulin Action in Health and Disease

Glucose Transport Regulation by Insulin

Under normal insulin responsiveness, insulin promotes the removal of excess glucose from the circulation by stimulating the exocytic recruitment of intracellular



Chromium and Membrane Cholesterol, Fig. 1 Schematic illustration of insulin signals, cytoskeletal mechanisms, and plasma membrane parameters involved in insulin-stimulated GLUT4-storage vesicle (GSV) exocytosis. See text for abbreviations and details

glucose transporter GLUT4 storage vesicles (GSVs) to the plasma membrane of skeletal muscle and fat cells (Hoffman and Elmendorf 2011). This stimulated redistribution of intracellular GSVs results in plasma membrane GLUT4 accrual that facilitates cellular glucose uptake (Fig. 1). Activation of GSVs by insulin requires a phosphatidylinositol 3-kinase (PI3K) signal involving the upstream insulin receptor (IR) and insulin receptor substrate (IRS) activators and the downstream Akt2 and AS160 target enzymes (Fig. 1, shown in gray). Exocytosis of GSVs is mediated by interactions between specific GSV and plasma membrane protein complexes known as SNAREs (Fig. 1, shown in black). Vesicle SNAREs (v-SNARES, vesicle soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors) bind target membrane SNAREs (t-SNAREs) in company with numerous accessory proteins. Syntaxin4 and SNAP23 (23 kDa synaptosomal-associated protein) are the t-SNARES, and VAMP2 is the v-SNARE involved in GSV fusion. At the plasma membrane, the enzyme phospholipase D1, together with its product phosphatidic acid, appear to be necessary for GSV and plasma membrane fusion. Mechanistically, phosphatidic acid has been suggested to act as a fusogenic lipid in biophysical modeling studies by lowering the activation energy for membrane bending (i.e., negative membrane curvature) during generation and expansion of fusion pores (Hoffman and Elmendorf 2011).

In addition to engaging signaling cascades to the GSV and plasma membrane, insulin also elicits a rapid, dynamic remodeling of actin filaments into a cortical mesh, and this mesh is necessary for GLUT4 translocation (Fig. 1, shown in green). Fluorescence confocal labeling of cortical filamentous actin (F-actin) shows actin filaments emanate from cholesterol-enriched plasma membrane caveolae microdomains (Hoffman and Elmendorf 2011). Caveolae, which are a special type of lipid raft, are small (50–100 nm) invaginations of the plasma membrane (Parton and Simons 2007). These flask-shaped structures are rich in proteins as well as lipids such as cholesterol and sphingolipids (Fig. 1, shown in light blue). Through the years, many functions for caveolae have been postulated in insulin and GLUT4 action. Although caveolae function needs to be cautiously interpreted because problems are associated with each of the numerous strategic approaches used to study these structures; substantial evidence supports a role for caveolae in cortical F-actin regulation (Hoffman and Elmendorf 2011). For example, biochemical disruption of this caveolin-associated F-actin, termed Cav-actin, structure does not affect the organization of clustered caveolae; however, disruption of the clustered caveolae disperses the Cav-actin structure. Quantitative electron microscopy and freeze-fracture analyses revealed that cytoskeletal components, including actin, are highly enriched in the membrane area underlying the neck part of caveolae. Together, these findings apparently assign caveolae a critical functionality in cortical F-actin organization. Given the unequivocal importance of cortical F-actin in insulin-regulated GLUT4 translocation, these findings also emphasize the importance of caveolae in GLUT4 regulation.

GLUT4 Dysregulation in Type 2 Diabetes

Despite the increase in the mechanistic knowledge of insulin action, the global prevalence of diabetes in 2010 was 284 million people worldwide, constituting around 6.4% of the world population. Projections for 2030 estimate the prevalence reaching 439 million individuals, comprising ~7.7% of the world population (Farag and Gaballa 2011). This is attributed in large part to the rising incidence of obesity worldwide, which makes it essential to focus attention on molecular mechanisms underlying insulin resistance that are fueled by obesity. In this regard, a large number of endocrine, inflammatory, neural, and cell-intrinsic pathways have been shown to be dysregulated in obesity and impair insulin signaling by increasing inhibitory serine phosphorylation of IRS1, which can have a direct impact on GLUT4 regulation (Qatanani and Lazar 2007).

However, several studies showing GLUT4 dysregulation without apparent defects in proximal

insulin signaling point to the existence of other disabling factors of insulin-regulated GLUT4 exocytosis (Hoffman and Elmendorf 2011). Whether critical flaws in cytoskeletal F-actin organization, lipid bilayer composition, and/or GSV and plasma membrane fusion priming contribute to insulin resistance is not known, yet a clear association has been demonstrated between the diabetic milieu, cytoskeletal disorganization, and bilayer abnormalities (Hoffman and Elmendorf 2011). For example, isolated neutrophils from patients with type 2 diabetes display decreased actin polymerization compared to neutrophils from nondiabetic control subjects. This impairment is associated with persistent expression of the endothelial adhering beta 2-integrin CD11b/CD18, potentially exacerbating vascular dysfunction in diabetic patients. Also, diabetic rat retinal endothelial cells have a prominent reduction in F-actin integrity, a finding closely linked to vascular leakage. Loss of rat mesangial cell F-actin has also been reported after exposure to early diabetic-state-like conditions, possibly causing diabetic hyperfiltration. Further support has been derived from examination of erythrocytes from overweight, insulin-resistant individuals which show marked changes in the phospholipid composition of the plasma membrane.

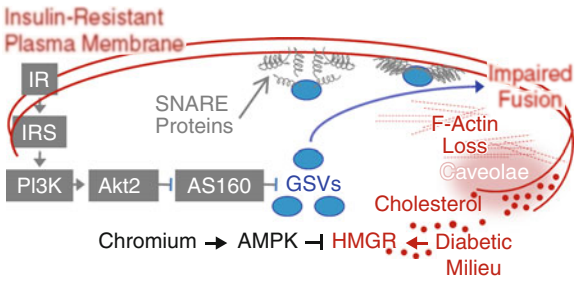
With regard to insulin action and glucose transport, cholesterol complexing drug experiments have demonstrated that removal of cholesterol from the plasma membrane augments basal glucose uptake and metabolism (Hoffman and Elmendorf 2011). Consistent with cholesterol causing highly ordered gel-like states, moderate increases in PM fluidity increase glucose transport in adipocytes, and insulin-stimulated glucose transport declined when fluidity was diminished (Czech 1980). Mechanistically, it is now appreciated that nonphysiological plasma membrane cholesterol depletion greater than 50% reduces the rate of internalization of plasma membrane GLUT4 by more than 85% (Hoffman and Elmendorf 2011). Although this certainly explains the gain in plasma membrane GLUT4, it is an artificial, experimentally induced gain. In contrast, reductions of plasma membrane cholesterol less than 50% do not affect the rate of endocytosis but do increase plasma membrane GLUT4 content (Hoffman and Elmendorf 2011).

These later findings suggest that moderate plasma membrane cholesterol lowering augments GSV exocytosis. How these plasma membrane cholesterol-based aspects of GLUT4 regulation intermingle with insulin signaling and/or GSV regulation is unknown, yet coordinated signaling events and/or F-actin reorganization are areas of interest. In fact, plasma membrane cholesterol toxicity has been proposed to cause cortical F-actin disorganization and cellular insulin resistance (Fig. 2, shown in red) (Hoffman and Elmendorf 2011). In direct support of a more distal, perhaps membrane/cytoskeletal defect negatively impinging on GLUT4 translocation, various cell model systems of insulin resistance demonstrate intact proximal insulin signaling to Akt2/AS160.

Membrane Mechanisms of Chromium Action in Health and Disease

Membrane Fluidity Regulation by Chromium

New additions to the molecular details of GLUT4 regulation by insulin add important insight into the antidiabetic mechanism of chromium action. For example, research conducted in the early 1990s found that chromium picolinate increased membrane fluidity and the rate of insulin internalization in cultured rat skeletal muscle cells (Evans and Bowman 1992). Although endocytic internalization of insulin does not seem to enhance its regulation of GLUT4 translocation, studies suggest that this may compartmentalize and efficiently promote interaction of insulin with several of its intracellular substrates (Pattar and Elmendorf 2010). This is consistent with an enhancing effect of chromium on insulin signaling. However, with new data showing that only a small fraction (~5%) of insulin-stimulated Akt2 activity is necessary for a full GLUT4 response, another mechanism of chromium action is suggested to account for chromium-enhanced GLUT4 regulation by insulin (Pattar and Elmendorf 2010). Interestingly, treatment of insulin-resistant adipocytes or skeletal muscle cells with chromium lowers plasma membrane cholesterol, which positively influences insulin-stimulated GLUT4 translocation (Pattar and Elmendorf 2010). It was further demonstrated that reversing this action of chromium by adding back exogenous cholesterol completely rendered the enhancement of insulin action by chromium ineffective in these cells. These studies also showed that chromium action did not result from effects on known mediators of insulin action such as



Chromium and Membrane Cholesterol, Fig. 2 Model of chromium action against plasma membrane cholesterol accrual that induces filamentous actin loss and impaired GSV regulation. See text for abbreviations and details

the IR, IRS-1, PI3K, and Akt2. Although this observed action of chromium suggests a mechanistic basis for chromium action being increased membrane fluidity, the effect on membrane fluidity, per se, may not underlie this nutrient's effect on insulin and GLU4 action. For example, as presented in the preceding section, cholesterol-enriched caveolae microdomains are now appreciated to critically influence cortical F-actin structure that is important in GLUT4 regulation. Therefore, chromium-induced modifications in plasma membrane cholesterol may enhance regulation of GLUT4 translocation by establishing an optimal cortical F-actin environment just beneath the plasma membrane.

Since chromium supplementation has the greatest benefit in overweight, insulin-resistant individuals (Balk et al. 2007), a presumption would also have to be that cells from these individuals possess a cholesterol-laden plasma membrane, whereas the plasma membrane cholesterol content of cells from nondiabetic subjects with normal insulin sensitivity and glucose tolerance would be lower and not affected by chromium. In line with this reasoning, chronic hyperglycemia has been shown to increase cholesterol ester accumulation concomitantly with reduced insulin-stimulated glucose uptake in cultured human skeletal muscle cells (Pattar and Elmendorf 2010). Moreover, skeletal muscle membranes from high-fat fed, insulin-resistant animal models are cholesterol-enriched and display a loss of F-actin. Similarly, human skeletal muscle biopsies reveal an inverse correlation between membrane cholesterol and whole-body glucose disposal (Pattar and Elmendorf 2010). Interestingly, in addition to hyperglycemia inducing cholesterol accrual as presented above, other key derangements of the diabetic milieu, namely, hyperinsulinemia and hyperlipidemia induce plasma membrane cholesterol accrual (Hoffman and Elmendorf 2011). Consistent with clinical data, the beneficial cholesterol-dependent action of chromium to mobilize GLUT4 to the plasma membrane is seen only in cells cultured in diabetic conditions, not in cells cultured in nondiabetic control conditions. These bench findings translate strikingly well to the observation that no significant alteration of chromium on glucose metabolism is seen in nondiabetic individuals, whereas there is a significant effect on chromium supplementation in diabetic patients (Balk et al. 2007). Taken together, chromium appears to display a unique ability to mitigate insulin resistance associated with plasma membrane cholesterol accrual.

Regulatory Cholesterol Metabolism Pathways

Mechanistically, it has been demonstrated that the activity of the AMP-activated protein kinase (AMPK) is enhanced by chromium (Pattar and Elmendorf 2010). This is of interest as a predicted result of AMPK activation is inhibition of energy-consuming biosynthetic pathways, such as fatty acid and cholesterol synthesis, and activation of ATP-producing catabolic pathways, such as fatty acid oxidation. Also, in muscle, AMPK activity can acutely and chronically affect basal and insulin-regulated glucose transport. New data suggest that these pathways that reduce fatty acids and cholesterol synthesis are likely engaged, as both acetyl CoA carboxylase (ACC) and 3-hydroxy-3-methyl-glutaryl coenzyme A reductase (HMGR) are phosphorylated in response to chromium (Pattar and Elmendorf 2010). Based on the observed effect of chromium on plasma membrane cholesterol, chromium-induced HMGR phosphorylation is of interest as this enzyme is the rate-limiting enzyme in the cholesterol biosynthesis pathway, and phosphorylation suppresses its activity (Fig. 2, shown in black). Also, of equal interest and importance is chromium's action on the AMPK/ACC pathway, as ACC catalyzes the conversion of acetyl CoA to malonyl coenzyme A (CoA), an inhibitor of translocation of long-chain fatty acyl (LCFA) groups from the cytosol to the mitochondrial matrix for fatty acid oxidation. Inactivation of ACC by AMPK in insulin-resistant skeletal muscle would be predicted to decrease excess fatty acids and several metabolites including acyl CoAs, ceramides, and diacylglycerol that activate kinases (e.g., *PKC*,

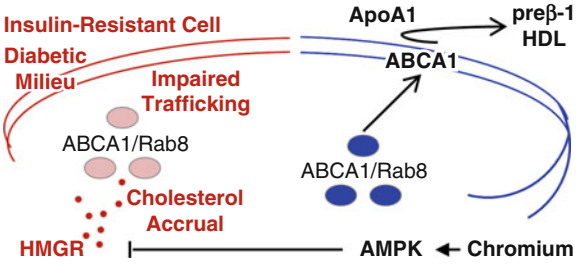
JNK, *IKK*β) that have been demonstrated to increase the inhibitory serine phosphorylation of insulin-signaling cascades, perhaps providing an explanation to the beneficial effects of chromium on insulin signaling. Interestingly, new data show that chromium induces myocardial GLUT4 translocation to caveolar regions rich in caveolin-3 (expressed mainly in skeletal muscle) via activation of Akt, AMPK, and eNOS phosphorylation in streptozotocin-induced diabetic rats (Pattar and Elmendorf 2010). This finding is consistent with the caveolar-localized effect of chromium. Other work has recently shown an activation of AMPK with the chromium complex of D-phenylalanine ($Cr(D\text{-}Phe)_3$) in H9c2 myoblasts (Pattar and Elmendorf 2010). Activation of AMPK in this skeletal muscle cell line sufficiently stimulated glucose transport. Importantly, when AMPK activity was pharmacologically inhibited, the enhanced glucose uptake was blocked. It was suggested that $Cr(D\text{-}Phe)_3$ led to an increase in cellular AMP concentration and a decrease in mitochondrial membrane potential, both of which may account for the activation of AMPK. Finally, increased AMPK activity in chromium-treated 3T3-L1 adipocytes decreased secretion of resistin, an adipokine associated with impaired glucose transport (Pattar and Elmendorf 2010). Taken together, the proposed mechanism that AMPK activity is being increased by chromium may be a feasible explanation for its multiple actions in both relieving glucose and lipid disorders in metabolically challenged individuals.

Cholesterol Within and Beyond the Cell: Connecting Membrane and Circulating Cholesterol Levels

Although evidence relating chromium deficiency and cardiovascular disease is fragmentary, deficiency has been linked to reduced high-density lipoprotein cholesterol (HDL-C) (Simonoff 1984). Nevertheless, a link between chromium supplementation and benefits on raising high-density lipoprotein cholesterol (HDL-C) remains unclear (Balk et al. 2007). However, recent identification of a mechanism by which chromium may positively impact HDL-C generation stresses a plausible role of chromium in regulating circulating cholesterol (Sealls et al. 2011). This work stemmed from findings that membrane cholesterol accumulation in Niemann-Pick disease type C (NPC) cells impairs a rate-limiting step in HDL-C generation entailing cholesterol transporter ABCA1-mediated cholesterol efflux to lipid-poor apolipoprotein A1 (ApoA1). The HDL-C particle formed is preβ-1 HDL-C, a subclass which removes cholesterol from macrophages, representing a cardioprotective event. Thus, a growing appreciation is that this preβ-1 HDL-C particle likely represents the "functional" HDL-C subfraction. Examination of ABCA1 trafficking revealed that plasma membrane ABCA1 was diminished in hyperinsulinemia-induced insulin-resistant cells with plasma membrane cholesterol accrual, yet in the presence of chromium, this was prevented (Sealls et al. 2011). Endosomal membrane ABCA1 was elevated in the insulin-resistant cells and normalized by chromium. Mechanistically, ABCA1 is regulated by the endosomal-to-cytoplasm cycling of the GTPase Rab8. Whereas insulin resistance increased the Rab8 content in the endosomal membrane fraction and decreased this protein in the cytoplasm, these changes were normalized by chromium. This work further showed that similar to plasma membrane cholesterol accrual compromising GLUT4 function, endosomal membrane cholesterol accrual compromises Rab8/ABCA1/ApoA1 functionality, and that chromium, by increasing AMPK activity, diminishes endosomal membrane cholesterol and the cholesterol efflux deficiency (Fig. 3). Therefore, as the serum concentration of the preβ-1 HDL-C accounts for only a small fraction of total HDL-C, trials designed to assess the benefits of chromium on total HDL-C may have had an inherent flaw in understanding chromium's effect. Whether this cell-based model explains the benefits of chromium in humans with diabetes remains to be validated.

Summary and Clinical Perspective

In summary, while chromium is known to be an essential element for animals and humans, much work remains to elucidate the mechanism(s) by which chromium could have nutritional value. Nevertheless, a coherent picture is beginning to emerge from the present sum of experimental and clinical evidence. A model in which membrane cholesterol accrual may represent an unappreciated mechanism leading to insulin resistance and dyslipidemia is of interest, especially in the context of the putative mechanism of chromium action entailing the



Chromium and Membrane Cholesterol, Fig. 3 Model of chromium protection against endosomal membrane cholesterol-associated impairment in ABCA1/Rab8 trafficking and ApoA1-mediated cholesterol efflux. See text for abbreviations and details

stimulation of AMPK that would suppress cellular cholesterol synthesis and offer subsequent improvements in cellular glucose uptake and cholesterol efflux, explaining longstanding health claims that chromium improves glycemic control in type 2 diabetes and that its deficiency may be a primary risk factor in cardiovascular disease. Finally, this membrane cholesterol model may provide an explanation for the existing controversies over the efficacy of chromium in the amelioration of the symptoms and complications of type 2 diabetes. For example, several agents that normalize blood glucose concentrations and/or improve insulin action, including metformin, phenformin, rosiglitazone, and troglitazone, have been shown to activate AMPK. Therefore, a prediction is that the nutritive value of chromium would be masked in patients receiving metformin or one of the other therapies listed above. Similarly, the action of AMPK to combat membrane cholesterol toxicity could explain why exercise, which also activates AMPK, can improve glycemia and dyslipidemia.

Definition

Chromium: Chromium is a common element that exists in the environment in several oxidation states. Trivalent chromium is a component of the natural diet which is thought to be essential for glucose and lipid homeostasis.

Obesity-associated diseases: Obesity is the abnormal or excessive fat accumulation that may impair health. Obesity increase the risk of cardiovascular disease includes insulin resistance, type-2 diabetes, dyslipidemia, stroke, atherosclerosis, and heart failure. Obesity is associated with increased risk of premature death.

Type-2 diabetes: Chronic disease characterized by elevated blood glucose levels caused by either a lack or the inability of the body to efficiently utilize insulin.

The use of nutritional supplements has increased during the past years and it is currently estimated that one half of all Americans used one or other form of nutritional supplements. Chromium is next only to calcium among the minerals sold as nutritional supplements and represents approximately 6% of the nutritional supplement market.

Chromium as an Essential Element

Chromium is an *essential* trace element that is believed to play an important role in carbohydrate and lipid metabolism (Vincent 2007). Way back in 1959, chromium was identified as the active component of "glucose tolerance factor" found in brewer's yeast. The *essentiality* of chromium in carbohydrate metabolism first came to light when chronically ill patients on total parenteral nutrition developed glucose intolerance which was reversed following supplementation of chromium (Anderson 1987). Several human and animal studies that followed demonstrated a beneficial effect of chromium in insulin resistant conditions and type-2 diabetes. However, this notion of the "essentiality" of chromium is now being questioned as recent studies have demonstrated that a "low chromium diet" does not alter glucose metabolism in the body (Di Bona et al. 2011).

Sources of Chromium and Recommended Daily Allowance

Dietary sources of chromium include meat, seafood, green vegetables, fruits, cheese, and wholegrain. A normal diet would therefore help meet the body's chromium requirement and chromium deficiency is therefore rare in normal healthy individuals. However, conditions such as diabetes and insulin resistance, pregnancy and ageing have been associated with depleted levels of chromium in the body. The recommended daily allowances for chromium as suggested by the Institute of Medicine of the National Academy of Sciences ranged from 50 to 200 μg/day for adults (National Research Council FaNB 1989). However, because of the difficulties in reliably assessing chromium levels in the food and in the human body, the Institute of Medicine has recently come up with adequate intakes of chromium rather than the traditional recommended daily allowance. The recommended adequate intake for chromium, which represents the level of chromium consumed by health individuals, is 23–39 μg/day for adult female and 35–50 μg/day for adult males (Institute of Medicine FaNB 2001). These numbers increase in pregnant or lactating women or under disease conditions.

Small-Molecule Organic Chromium Complexes

The poor oral bioavailability of inorganic chromium (0.4–2.5%) and the recognition that the "glucose tolerance factor" represents a chromium complex of amino acids and nicotinic acid prompted the synthesis and characterization of several organic chromium complexes as insulin-potentiating agents. Among them, chromium picolinate and chromium nicotinate have emerged as the most popular forms of organic chromium complexes that are available as nutritional supplements. Today, these chromium complexes are included in multivitamin tablets, breakfast cereals, and energy drinks. Studies have also shown that the absorption of chromium can be enhanced when taken along with vitamin B or C.

Health Benefits of Chromium Supplements

The primary purpose for which chromium supplementation is being used is for its potential beneficial effects to treat diabetes, lipid disorders, and overweight. There have been several clinical trials that have investigated the beneficial effects of nutritional supplementation with chromium in subjects with type-2-diabetes and insulin-resistant conditions. The outcome of these studies were however inconclusive, mainly owing to the small sample sizes, inadequate controls, varying doses used, different patient demographics, concurrent

use of other antidiabetic agents, lack of robust methodologies and/or lack of randomization.

In a recently published meta-analysis, Balk and coworkers performed a systematic review of the major randomized controlled trials involving nutritional supplementation with chromium (Balk et al. 2007). For their analysis, these authors included 41 randomized controlled clinical trials that were performed in individuals with diabetes or glucose intolerance. Their end points were glycemic control and lipid outcomes. In addition, they only included the trials that had ten or more participants and those studies wherein chromium was supplement for at least 3 weeks. The meta-analysis revealed a modest, yet statistically significant beneficial effect of chromium supplementation in subjects with type-2 diabetes. Most of the studies included in this meta-analysis used chromium at doses ranging from 200 to 1,000 μg/day. The beneficial effects of chromium on hyperglycemia and insulin resistance were most prevalent in studies that used doses close to 1,000 μg/day. In type-2 diabetic patients, treatment with chromium caused a lowering of HbA_{1C} by 0.6% and fasting glucose levels by ~1 mmol/L. However, in contrast to glycemic parameters, the lipid levels were not altered following chromium supplementation, except for a significant raise in HDL-cholesterol observed in subjects who received brewer's yeast. In normal subjects (those without type-2 diabetes or insulin resistance), chromium supplementation did not have any effects on either the measures of glycemia or lipid parameters. Despite the smaller, albeit statistically significant favorable effects of chromium on glycemic parameters, the authors of the meta-analysis caution that the poor quality and heterogeneity of the clinical trials warrants further studies before definitive conclusions are made.

Due to the aforementioned conflicting reports, the American Diabetes Association's position statement concludes that there is inconclusive evidence for the benefit of chromium supplementation in diabetes (Bantle et al. 2008). The US Food and Drug Administration has previously issued a statement on similar lines stating that "chromium may reduce the risk of insulin resistance and therefore possibly reduce the risk of type-2 diabetes" and goes on to add, "the existence of such a relationship between chromium picolinate and either insulin resistance or type 2 diabetes is uncertain".

With a view to clear these contradictions, Cefalu and coworkers performed an exhaustive randomized, double-blind, placebo-controlled clinical trial in which they measured insulin-sensitivity, energy expenditure, and muscle and hepatic fat content in type-2 diabetic subjects who were not on any antidiabetic medications (Cefalu et al. 2010). The results of this study indicate that the diabetic population could be categorized as either "responders" and "non-responders" to chromium, and thus the beneficial effects of chromium supplementation may depend on the cohort of individuals tested. However, this claim is refuted by Kleefstra and coworkers who failed to observe any beneficial effect of chromium (at doses of 500 or 1,000 μg) compared to placebo on HbA_{1C} or insulin requirement in diabetic patients (Kleefstra et al. 2010).

In addition to the above human studies, chromium has been shown to reduce body fat, improve cardiovascular parameters, affect fetal-gene programming, regulate obesogenic genes, augment insulin signaling, mobilize glucose transporter, alter lipid metabolism, and affect cholesterol homeostasis in a variety of animal and cellular models suggesting the potential beneficial effects of chromium. However, the jury is till out in the debate over the effectiveness of chromium supplementation in type-2 diabetes and more large-scale, well-controlled trials are warranted to ascertain its benefits as a nutritional supplementation.

Chromium Binding to DNA

Anatoly Zhitkovich
Department of Pathology and Laboratory Medicine, Brown University, Providence, RI, USA

Synonyms

Cr-DNA binding: Cr-DNA adduction; Inner-sphere Cr-DNA complexation

Ternary Cr-DNA adduct: Intermolecular Cr-DNA cross-link; Ligand-Cr-DNA cross-link

Definition

Stable Cr-DNA binding is inner-sphere coordination of Cr(III) atoms with DNA groups. This type of binding can also be described as covalent coordinate bonding.

Cr-DNA Binding

General Characteristics of Chromium-DNA Binding

Human tissues and other biological systems usually encounter Cr in one of its two stable oxidative states, namely, +3 or +6. Although both inorganic Cr(III) and Cr(VI) compounds can cause Cr-DNA binding, the conditions required for this reaction to take place are not identical. At neutral pH, Cr(VI) is completely unreactive toward DNA and requires reductive activation to elicit genetic damage and other forms of biological injury. The reduction process is associated with a transient formation of Cr(V) and Cr(IV) intermediates, organic radicals as by-products, and finally yields thermodynamically stable Cr(III) (Zhitkovich 2005). The most important biological reducers of Cr (VI) in human and other mammalian cells are ascorbate, glutathione, and cysteine (Fig. 1). Although its cellular concentration in vivo is similar to that of glutathione, ascorbate is the most important reducer, accounting for >90% of Cr(VI) metabolism in the main target tissues, such as the lung. This dominant role of ascorbate reflects its very fast rate of Cr(VI) reduction, which at physiological concentrations is up to 60 times faster than that of glutathione (Quievryn et al. 2003).

Initially, the genotoxic activity of carcinogenic Cr(VI) compounds had been largely attributed to oxidative stress and the resulting oxidative DNA damage. However, reduction of Cr(VI) in cultured cells or in vivo has also been known to result in stable Cr-DNA binding that persisted during rigorous, multistep purification procedures employing strong detergents and high-salt and organic solvent extractions. Early studies investigating Cr-DNA binding in the defined reactions in vitro with known biological reducers of Cr(VI) have yielded highly conflicting results, ranging from detecting large amounts of DNA-bound Cr to observing no binding at all. Careful examination of the buffer conditions and aqueous chemistry of Cr(III) led to the realization that the commonly used phosphate buffer was blocking Cr-DNA complexation through the formation of unreactive Cr(III)-phosphate chelates (Zhitkovich 2005). In the organic buffers containing the ionized sulfonate group (MES, MOPS, HEPES), reduction of Cr(VI) with the main biological reducers results in extensive Cr-DNA binding that is readily observed by a progressively decreased electrophoretic mobility

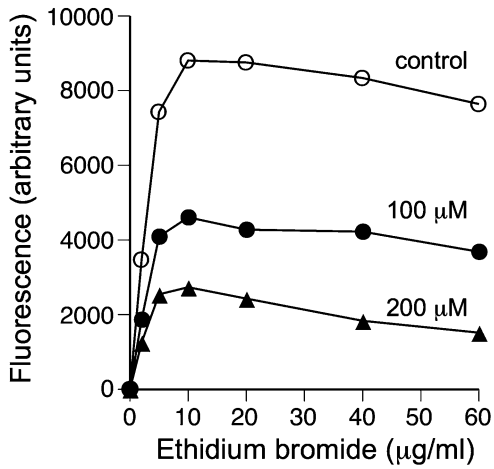
Chromium Binding to DNA, Fig. 2 *Altered electrophoretic mobility of plasmid DNA containing bound Cr.* The ϕX174 plasmids were incubated with 0–200 μM chromate in the presence of 1 mM ascorbate for 30 min at 37°C. DNA bands in agarose gels were visualized by ethidium bromide fluorescence under UV illumination. In contrast to extensive Cr-DNA binding, reduction of Cr(VI) with its main biological reducer did not generate a detectable oxidative damage to the DNA sugar-phosphate backbone as evidenced by a lack of conversion of intact (supercoiled) plasmids into nicked (relaxed) conformation

of the supercoiled plasmid DNA (Fig. 2). This phenomenon reflects unwinding of supercoiled DNA molecules, as the mobility of relaxed plasmids in the same reactions shows little or no changes. At high Cr(VI) concentrations, supercoiled plasmids could be completely unwound, resulting in their comigration with the relaxed DNA molecules. These conditions referred to as the coalescence point were used for the calculations of structural changes in DNA that gave an estimate of 1–2° unwinding by each DNA-bound Cr atom (Blankert et al. 2003). Although this unwinding angle is small in comparison to DNA adducts formed by platinum-based drugs, prolonged exposures of human and other mammalian cells to toxic chromate result in more than 100-fold cellular accumulation of Cr(VI) over its extracellular concentrations, leading to a very large production of Cr-DNA adducts at low doses (Zhitkovich 2005). Thus, a concentrated presence of even mildly duplex-distorting Cr-DNA complexes could elicit sufficiently large structural changes in chromatin loops with significant consequences for transcription and replication that are both known to be affected by the degree of DNA supercoiling.

Another readily detectable change in DNA molecules containing bound Cr atoms is their decreased staining with the commonly used DNA dye ethidium bromide (Fig. 2). The phenomenon of diminished ethidium bromide fluorescence was observed for all Cr(VI) or Cr(III) reactions permitting Cr-DNA binding. Ethidium bromide intercalates between DNA bases, which allows it to become fluorescent through energy transfer from UV radiation that is absorbed by DNA bases. While lower fluorescence of supercoiled DNA after indirect excitation by UV light may have a complex origin, fluorescence of linear DNA molecules after direct excitation of ethidium bromide reflects the amount of intercalated dye and can serve as a test for the degree of duplex distortions. Direct excitation experiments showed that Cr-DNA binding strongly inhibits ethidium bromide intercalation at a wide range of dye concentrations (Fig. 3), which is indicative of distorted DNA duplex that is unable to retain dye molecules. Unstacking of DNA bases is the most likely cause of diminished ethidium bromide intercalation due to the inability of dye molecules to establish strong interactions with top and bottom bases. Other structural changes elicited by Cr-DNA binding include increased stability of duplexes as evidenced by their higher resistance to heat- and alkali-induced denaturation. Positively charged Cr(III) complexes can also interact with DNA ionically, which makes up 40–60% of total DNA-bound Cr in reactions with low ionic strength (Zhitkovich 2005). The ionically bound Cr(III) is easily stripped from DNA by brief incubations with physiological concentrations of Na^+ or Mg^{2+} ions. Nonionic Cr-DNA complexes are largely resistant to dissociation even during prolonged incubations with



Chromium Binding to DNA, Fig. 3 *Diminished binding of ethidium bromide to Cr-adducted DNA*. Sheared chromosomal DNA was treated with Cr(VI) and 2 mM cysteine for 60 min at 37°C (25 mM MOPS, pH 7.0). Ethidium bromide fluorescence was recorded at 595 nm with excitation at 530 nm in the presence of 400 mM KCl and 5 mM EDTA

very high EDTA concentrations. However, smaller and less negatively charged phosphate ions can remove the majority of DNA-bound Cr(III) atoms. Binding of oligomeric Cr(III) products to DNA is more difficult to remove by phosphate and other chelators.

Interactions of Cr(III) with DNA

Cr(III) forms six-coordinate complexes with octahedral arrangement of ligands and displays a strong binding affinity for negatively charged oxygen groups. Direct coordination of Cr(III) to H_2O, SH group, and tertiary N atoms is also strong. Overall, Cr(III) complexes are usually described as kinetically inert that are slow to exchange their ligands, and consequently, are poorly reactive. Another factor impeding interactions of Cr(III) complexes with DNA is their hydrolysis. Dissolution of inorganic Cr(III) salts results in the initial formation of $Cr(H_2O)_6^{3+}$ as the main ionic species. However, these solutions undergo rapid hydrolysis resulting in the conversion of $Cr(H_2O)_6^{3+}$ into $Cr(OH)(H_2O)_5^{2+}$ and $Cr(OH)_2(H_2O)_5^{+}$. The formation of the Cr(III) hydroxo species initiates their polymerization, producing a mixture of low- and high-molecular-weight polymeric products. Monomeric and low oligomeric forms of Cr(III) remain soluble, whereas polymeric products form poorly soluble precipitates. Hydrolysis and polymerization reaction are inhibited at low pH but at neutral pH dissolution of inorganic Cr(III) salts leads to almost immediate formation of insoluble Cr(III) hydroxides and polymeric species. To avoid the solubility and oligomerization problems, the reactions of inorganic Cr(III) with DNA have been frequently performed near pH 6 or lower. Unlike $Cr(H_2O)_6^{3+}$, Cr(III) complexes with multidentate organic ligands are soluble at neutral pH and do not undergo oligomerization (Zhitkovich 2005). A rapid coordination of Cr(III) with the multidentate reducer molecules maintains its solubility in Cr(VI) reduction reactions carried out at neutral pH. Organic buffers containing negatively charged sulfonate group are capable of Cr(III) complexation, which inhibits the production of insoluble hydroxides and permits Cr-DNA binding. Cr^{3+} ions are unable to interact with neutral or positively charged TRIS molecules, and the solubility Cr(III) in diluted TRIS solutions with their very weak buffering capacity at neutral pH results from acidification of the reaction mixtures in the presence of strongly acidic $Cr(H_2O)_6^{3+}$.

Cr-DNA Binding Resulting from Cr(VI) Reduction

As mentioned above, reductive metabolism of Cr(VI) in biological buffers and inside the cells leads to extensive Cr-DNA binding. Cr-DNA complexes are a heterogeneous group including binary Cr-DNA adducts and various cross-links (Zhitkovich 2005). Binary Cr(III)-DNA adducts are usually the most abundant form of DNA-bound Cr produced during in vitro reduction of Cr(VI) with its main biological reducers. For Cr(VI) reduction reactions containing physiological concentrations of ascorbate, Cr-DNA adducts account for approximately 75% of total Cr-DNA binding. The exact amount of binary adducts formed in cells remains unknown due to the indirect methods of their quantitation as a fraction of DNA-bound Cr left after subtracting Cr-DNA cross-links. The purification of chromosomal DNA is associated with a significant loss of Cr-cross-linked ligands, which makes it difficult to get accurate estimates for binary adducts. Based on the limited recovery measurements for Cr-DNA cross-links, it was argued that in contrast to in vitro reactions, binary Cr-DNA adducts in cells probably constitute only a minor fraction of the total Cr-DNA binding (Zhitkovich 2005).

The most abundant form of Cr-DNA cross-links are ternary DNA adducts formed through Cr(III)-mediated DNA cross-linking of histidine and three main Cr(VI) reducers: ascorbate, cysteine, and glutathione (Zhitkovich 2005). Formation of stable complexes with *O*-,*N*-, and *S*-containing groups and the presence of six coordination sites are responsible for the ability of Cr(III) to link multidentate biological ligands to DNA, generating ligand-Cr(III)-DNA cross-links. The most common Cr-DNA modifications in Cr(VI)-treated cells were cysteine-Cr(III)-DNA and glutathione-Cr(III)-DNA cross-links, which in combination with histidine- and some other less frequent amino acid-Cr-DNA cross-links were estimated to constitute ~50% of total DNA-bound Cr even without corrections for losses during purification procedure. The production of ascorbate-Cr(III)-DNA cross-links is readily detectable during in vitro Cr(VI) reduction with physiological levels of ascorbate (1–3 mM in major human tissues) but is progressively decreased at lower concentrations. Formation of ascorbate-DNA cross-links in cells requires restoration of normal concentrations of vitamin C before Cr(VI) exposures. Under standard tissue culture conditions, all human and the vast majority, if not all, rodent cells contain barely detectable concentrations of ascorbate due to its low concentrations in fetal bovine serum and the absence in the commonly used synthetic media (Reynolds et al. 2007). Ternary Cr-DNA cross-links containing glutathione, cysteine, or histidine share the same mechanism of formation (Zhitkovich 2005):

1. Cr(VI) reduction to Cr(III)
2. Formation of binary ligand-Cr(III) complexes
3. Attachment of binary complexes to DNA forming ligand-Cr(III)-DNA cross-links

The last reaction is a rate-limiting step. For ascorbate-Cr(III)-DNA cross-links, the reaction mechanism is very similar with the exception of much higher rates at the final step of DNA conjugation.

In addition to small ligand-Cr-DNA cross-links, Cr(VI)-exposed cells also contain DNA-protein cross-links. These bulky lesions constitute only a small fraction of total DNA adducts in cultured cells, but the availability of a robust methodology for their measurements has led to their frequent use as a biomarker of genetic damage in Cr-exposed human populations and aquatic organisms. Although DNA-protein cross-links have a general structure of ternary adducts (protein-Cr(III)-DNA), their formation mechanism differs from that of small ascorbate/amino acid-Cr-DNA cross-links (Macfie et al. 2010). The three-step protein-DNA cross-linking proceeds as follows:

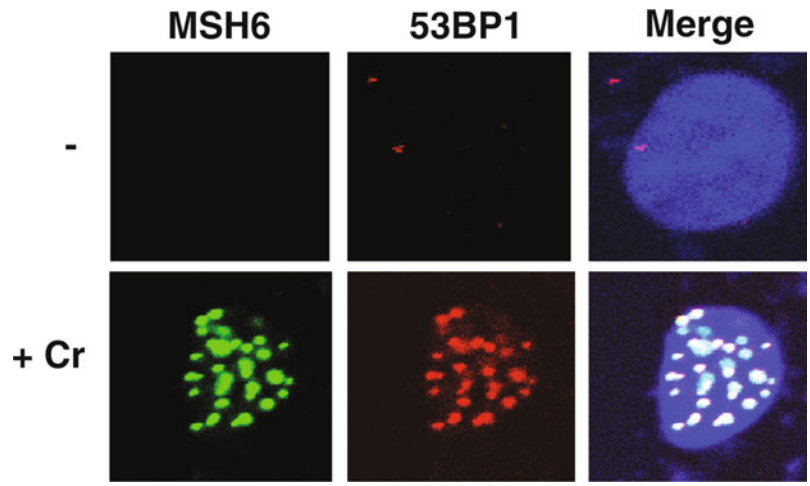
1. Cr(VI) reduction to Cr(III)
2. Cr(III)-DNA binding
3. Protein capture by DNA-bound Cr(III)

The rate-limiting step is protein conjugation by Cr(III)-DNA, which is particularly slow in vivo and explains a delayed buildup of DNA-protein cross-links in Cr(VI)-treated cells with limited DNA repair capacity.

Reduction of Cr(VI) in vitro also generates a small number of Cr(III)-mediated interstrand DNA cross-links (O'Brien et al. 2003). Interstrand cross-linking was promoted in reactions with low ratios of reducer to Cr(VI). At optimal conditions in cysteine-driven reactions, interstrand DNA cross-links made up approximately 1% of total Cr-DNA adducts, but their yield was much lower or even undetectable at more environmentally relevant Cr(VI) concentrations (Zhitkovich 2005). DNA interstrand cross-linking in Cr(VI)-ascorbate reactions was also highly nonlinear, with no cross-linking detected at physiologically relevant ratios of the main reactants. While every DNA nucleotide contains at least one point of attachment for Cr(III), potentially offering multiple opportunities for linkage of the opposite DNA strands, the formation of interstrand cross-links by Cr(III) is difficult to explain when steric factors are taken into consideration (Zhitkovich 2005). It has been therefore suggested that the most likely cause of interstrand DNA cross-linking under in vitro conditions with limited amounts of the Cr(III)-binding multidentate ligands are the oligomeric Cr(III) species, which are unlikely to be formed in cells. There is also strong genetic evidence arguing against the formation of interstrand DNA cross-links by Cr(VI) in mammalian cells (Salnikow and Zhitkovich 2008).

Nucleotide-Specificity of Cr-DNA Binding

As a hard Lewis acid, Cr(III) has a high affinity for the negatively charged oxygen, which predicts that DNA phosphates should act as preferred binding sites. In agreement with this prediction, studies with oligonucleotides of base-specific composition showed nearly identical Cr-DNA binding irrespective of the presence of a particular base and group of bases (Zhitkovich 2005).



Chromium Binding to DNA, Fig. 4 *Presence of the mismatch repair protein MSH6 at the sites of DNA double-strand breaks*. Normal human IMR90 fibroblasts were treated with Cr(VI) and then simultaneously immunostained for MSH6 and 53BP1. 53BP1 is a protein involved in repair of DNA double-stranded breaks and serves as a marker of these lesions

Amino acid-Cr-DNA cross-links could be formed only with mononucleotides but not nucleosides, further supporting a critical role of the phosphate group in the formation of this biologically important class of DNA damage. Nucleotide-level mapping of binary Cr-DNA adducts and three Cr-DNA cross-links found a nearly uniform distribution along a long stretch of duplex DNA, and shielding of DNA phosphates with Mg^{2+} ions blocked Cr-DNA binding. However, all mutagenic events induced by Cr-DNA cross-links targeted G/C pairs with flanking purine bases (Zhitkovich et al. 2001; Quievryn et al. 2003), pointing to the potential presence of additional Cr-base interactions, possibly at N-7 position. Unlike ternary adducts, binary Cr(III) adducts are also formed with dG, indicating that binding at N-7 with possible microchelation at O-6 could be quite strong. An alternative cause for G/C pair specificity of Cr mutagenesis could be biological, such as properties of DNA polymerases and/or selectivity of DNA repair. These and structural factors impacting Cr adduct–induced mutagenesis have been discussed in detail elsewhere (Zhitkovich et al. 2001). At this time, the possibility of microchelate formation between phosphate group and N-7 of purine bases in mutagenic Cr-DNA adducts is neither proven nor disproven.

Indirect Mechanism of Cell Death and Chromosomal Breakage by Cr-DNA Adducts

The presence of ternary ascorbate- or amino acids-Cr-DNA cross-links but not binary Cr-DNA adducts strongly inhibits replication of plasmids in human cells (Zhitkovich et al. 2001; Quievryn et al. 2003). However, in vitro experiments with purified DNA polymerases found no significant replication-blocking activity of ternary Cr-DNA cross-links (O'Brien et al. 2003), indicating that genotoxicity of Cr-DNA damage was not a direct consequence of their direct polymerase-arresting activity. Genetic studies utilizing mutant mouse and human cells identified DNA mismatch repair (MMR) as a cause of cellular toxicity of ternary Cr-DNA adducts (Peterson-Roth et al. 2005). A normal function of MMR is to detect and correct DNA polymerase errors arising during replication. Consistent with plasmid replication experiments in cells, only ternary but not binary adducts were recognized by MMR proteins in binding experiments in vitro, and the loss of MMR components rescued replication blockage of cross-link-containing vectors in cells (Reynolds et al. 2009). "Mistaken identity" binding of ternary Cr-DNA cross-links by MMR proteins followed by aberrant processing causes highly toxic DNA double-stranded breaks, as determined by genetic approaches and confirmed by the presence of MMR proteins at the sites of DNA breakage (Fig. 4). The identification of MMR as a main cause of cell death and chromosomal breakage led to the formulation of the selection model of chromate carcinogenesis involving outgrowth of Cr(VI)-resistant cells with inactivated MMR (Peterson-Roth et al. 2005; Salnikow and Zhitkovich 2008). Cells lacking MMR rapidly accumulate mutations in cancer genes due to their inability to repair spontaneous replication errors. In agreement with this model, the majority of lung

cancers among chromate workers are known to lack functional MMR.

Definition

Chromium(VI) (Cr(VI), hexavalent chromium) is an established human carcinogen and a major occupational and environmental hazard. Toxic properties of Cr(VI) are related to its ability to enter cells easily and to form reactive high-valent (Cr(VI), Cr(V), and Cr(IV)) intermediates on the way to stable Cr(III) products. In recent years, significant progress has been made in the understanding of chemical properties and biological roles of such intermediates, using physicochemical techniques such as electron paramagnetic resonance and X-ray absorption spectroscopies. The potential of biological oxidation of Cr(III) to Cr(VI) (via Cr(IV) and Cr(V)) intermediates has also been recognized as a likely link between the toxicity of Cr(VI) and antidiabetic

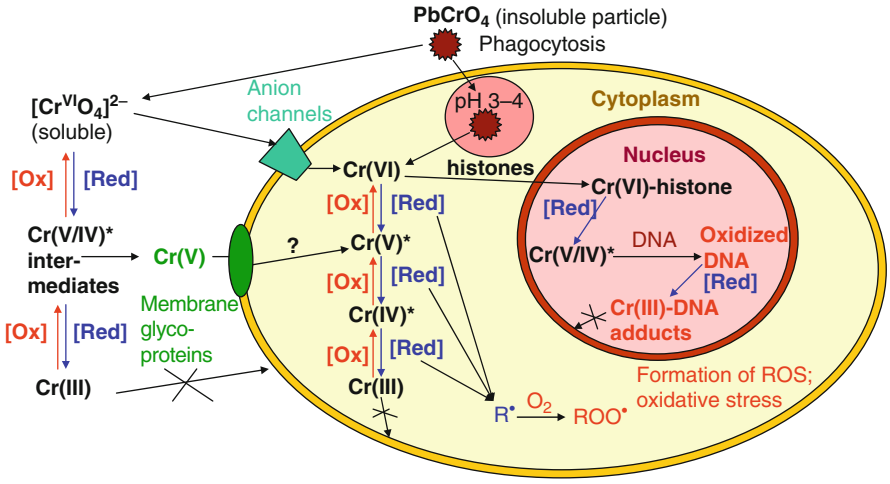
activities of Cr(III), which highlights the potential danger of long-term use of Cr(III) nutritional supplements.

Chromium(VI) Toxicity

Hexavalent chromium (Cr(VI)) compounds, which are well-established (class I) human carcinogens, are among the most common occupational chemical hazards (for a review, see Levina et al. 2003). The most dangerous forms of Cr(VI) exposure are inhalation of insoluble chromate particles ($MCrO_4$, where M = Ca, Sr, Pb, or Zn) and inhalation of chromate fumes from stainless steel welding and electroplating baths, which pose a high risk of respiratory cancers (see section ▶ Hexavalent chromium and cancer (Costa) for details). The health hazards associated with ingestion of Cr(VI)-contaminated water have been extensively studied following the lawsuit against Pacific Gas and Electric, California, in 1993 (Levina et al. 2003). Although micromolar concentrations of Cr(VI) in drinking water are not highly carcinogenic, they are likely to sensitize the organism to other carcinogens, such as UV radiation, and recent studies suggest that oral ingestion of soluble chromates can lead to a range of cancers (section ▶ Hexavalent chromium and cancer (Costa)). A crucial recent finding is the ability of both water-insoluble ($PbCrO_4$) and water-soluble ($K_2Cr_2O_7$) chromates to cause malignant transformation of noncancerous human lung epithelial cells in culture (Xie et al. 2007; Costa et al. 2010). Significant progress has also been achieved in understanding of the roles of altered DNA repair mechanisms and disruptions of cell signaling in Cr(VI)-induced carcinogenicity (see sections ▶ Chromium binding to DNA (Zhitkovich) and ▶ Hexavalent Chromium and DNA, Biological Implications of Interaction (Wise)). This section concentrates on the links between chemical properties and toxicities of Cr(VI) and its metabolic products (Levina et al. 2003; Levina and Lay 2008).

Exposure routes and physical properties of Cr(VI) compounds are among the leading factors that determine their carcinogenic potential (Levina et al. 2003). For instance, inhaled particles of insoluble Cr(VI) salts adhere to the surface of bronchial epithelial cells, where they dissolve slowly, leading to prolonged exposure of cells to small doses of Cr(VI) (Xie et al. 2007). By contrast, ingested soluble forms of Cr(VI) are rapidly reduced to much less toxic Cr(III) in acidic media of the stomach (see section ▶ Chromium, Physical and Chemical Properties (Van Horn) for a review of chemical properties of various oxidation states of Cr), although this protective mechanism can be overwhelmed by exposure to large doses of Cr(VI) (Levina et al. 2003). Absorbed or in vivo-generated Cr(VI) (mainly in the form of $[CrO_4]^{2-}$) has a sufficient lifetime in the blood and other extracellular fluids at pH = 7.4 to be delivered to target cells (Levina et al. 2003). A framework for understanding of Cr(VI) interactions with cells has been provided by the uptake-reduction model (Fig. 1), first proposed by Wetterhahn and coworkers in the 1980s and updated by other researchers (for a review, see Levina et al. 2003).

The well-known ability of cultured mammalian cells to accumulate large amounts of Cr(III) when exposed to low concentrations of Cr(VI) is due to a combination of the following factors (Fig. 1) (Levina et al. 2003; Levina et al. 2007): (1) efficient uptake of $[CrO_4]^{2-}$ through anion channels (based on its structural similarity to essential anions, $[SO_4]^{2-}$ and $[HPO_4]^{2-}$); (2) intracellular reduction of Cr(VI) to Cr(III) (the likely reductants include glutathione, ascorbate, and NAD(P)H-dependent enzymes), which increases the chemical potential (Cr(VI) concentration gradient) for further Cr(VI) uptake; and (3) strong binding of the resultant Cr(III) species to biological macromolecules, which stores Cr(III) in inert forms that are difficult to remove by normal metal efflux mechanisms. Although recent data point to extracellular dissolution of $PbCrO_4$, or other weakly soluble chromates, as the predominant mechanism for intracellular uptake (Xie et al. 2007), their uptake by phagocytosis, followed by intracellular dissolution (assisted by acidic lysosomes that engulf such particles, Fig. 1) cannot be excluded (Levina et al. 2003). Formation of highly reactive Cr(V), Cr(IV), and organic radical intermediates during the cellular reduction of Cr(VI) (Fig. 1) is crucial for its genotoxic action, irrespective of the actual genotoxic agents, since chromate alone does not damage DNA under physiologically relevant conditions (Levina et al. 2003). In addition, biological reoxidation of Cr(III) to Cr(VI) through similar intermediates is also possible (see below). Details of



Chromium Toxicity, High-Valent Chromium, Fig. 1 Uptake-reduction model of Cr(VI) metabolism in mammalian cells (based on data reviewed in Levina et al. (2003), Levina and Lay (2008), Aitken et al. (2011))

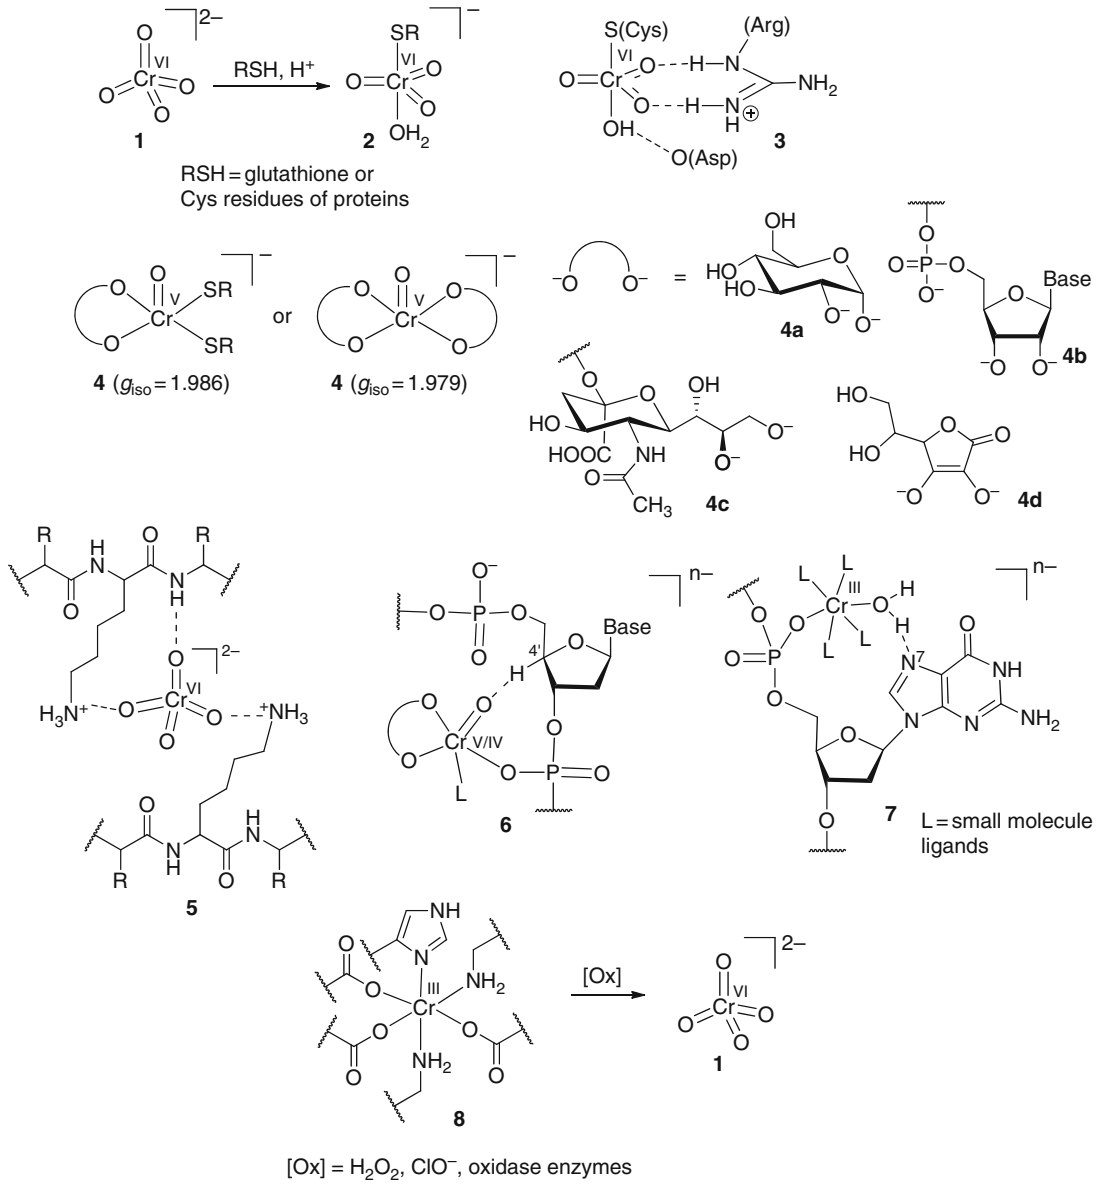
* Reactive Cr(V/IV) intermediates are stabilized by intra- and extracellular ligands, including carbohydrates, glycoproteins, peptides, and 2-hydroxycarboxylates.

biochemical transformations of Cr(VI) within the cell (including the likely structures of reactive intermediates and products that are shown in Fig. 2) were deduced using a combination of electron paramagnetic resonance (EPR) spectroscopy (Levina et al. 2003; Levina et al. 2007), X-ray absorption spectroscopy (XAS) (Levina et al. 2007; Levina and Lay 2004; Aitken et al. 2011), electrospray mass spectrometry (Levina and Lay 2004), and electronic absorption spectroscopy (Levina et al. 2010; Zhitkovich et al. 2001), as well as X-ray fluorescence microscopy (XFM) (Aitken et al. 2011) and kinetic studies that incorporate these techniques, in both cultured cells and model cell-free systems.

Biological thiols, including glutathione, metallothioneins, and cysteine residues of protein tyrosine phosphatases (PTPs), are among the most likely intracellular reactive sites for Cr(VI) (Levina and Lay 2004; Levina et al. 2010). Chromate ($[CrO_4]^{2-}$, **1** in Fig. 2) rapidly reacts with thiols with the formation of five-coordinate Cr(VI) intermediates (**2** in Fig. 2), that have been characterized by XAS (Levina and Lay 2004). Structure **2** is similar to the proposed transition state of phosphate bound to the active sites of PTPs (**3** in Fig. 2, based on X-ray crystallographic studies of a V(V) analog) and is likely to be responsible for the inhibition of PTPs by Cr(VI) (Levina and Lay 2004; Aitken et al. 2011), which can affect the cellular signaling pathways in Cr(VI)-exposed cells. Involvement of thiols in cellular reduction of Cr(VI) is consistent with the EPR signals of thiol-containing Cr(V) species observed shortly after the exposure of cultured cells to Cr(VI) (Levina et al. 2007). Due to the high sensitivity and selectivity of EPR spectroscopy toward Cr(V) species, this method is widely used for the detection and characterization of these highly reactive and potentially DNA-damaging intermediates (Levina et al. 2003). The structures of Cr(V) species corresponding to the two EPR signals observed in Cr(VI)-treated cultured cells or live animals (g_{iso} = 1.986 and 1.979, **4** in Fig. 2; reviewed in (Levina et al. 2003)) were proposed on the basis of detailed EPR spectroscopic and various other kinetic studies of Cr(VI) reactions with model thiols in the presence of Cr(V)-stabilizing ligands (1,2-diols) (Levina et al. 2010).

Efficient stabilization of Cr(V) by ubiquitous biological 1,2-diols, such as carbohydrates (including sugar residues of ribonucleotides, **4a**, **b** in Fig. 2), sialoglycoproteins (**4c**), or ascorbate (**4d**) (Levina et al. 2003), means that significant amounts of these highly reactive species will persist in cells as long as the supply of Cr(VI) lasts or is regenerated by redox recycling of Cr(III) products (Levina et al. 2010).



Chromium Toxicity, High-Valent Chromium, Fig. 2 Proposed structures of intermediates and products of cellular Cr(VI) metabolism (see text for details)

Ascorbate, along with glutathione, is among the most likely of the cellular reductants for Cr(VI) (Levina et al. 2003) (see also section ▶ Chromium binding to DNA (Zhitkovich)), so its role in the stabilization of Cr(V) intermediates is particularly notable. Extracellular reduction of Cr(VI) in the vicinity of the cell is likely to lead to the formation of Cr(V) species bound to sialoglycoproteins on the cell surface (Fig. 1) (Levina et al. 2003). Such binding may be particularly important given that alterations of the cell surface and surrounding areas (extracellular matrix) play a crucial role in malignant transformation of bronchial epithelial cells treated with Cr(VI) (Costa et al. 2010).

By contrast with the biospectroscopic EPR studies on Cr(V), there is currently no reliable technique for the detection of small amounts of Cr(IV) intermediates

formed during the reduction of Cr(VI) in biological systems (several literature reports on the observation of such species are erroneous) (Levina et al. 2003), apart from multiple-linear regressions of Cr K-edge XAS from biological samples (Levina et al. 2007), which is not sensitive to small amounts of Cr(IV) in the presence of much higher concentrations of other Cr oxidation states. A likely reason for lesser biological significance of Cr(IV) compared with Cr(V) is its inability to form stable complexes with carbohydrate ligands, although stabilization by 2-hydroxycarboxylato and peptide ligands is possible (Levina et al. 2003). Model Cr(IV) 2-hydroxycarboxylato complexes cause oxidative DNA damage to a similar extent as Cr(V) complexes with the same ligands, and evidence was gained for Cr(IV) peptide complexes as being more reactive toward DNA than their Cr(V) analogs (Levina et al. 2003).

A significant proportion of Cr(VI) taken up by cells reaches the nucleus and binds to genomic DNA (Levina et al. 2003; Levina et al. 2007) (in the form of Cr(III), Fig. 1, see section ▶ Chromium binding to DNA (Zhitkovich) for details). By contrast with intact cells, isolated cell nuclei do not take up $[CrO_4]^{2-}$, so an active transport mechanism is likely to exist for the nuclear uptake of Cr in live cells (Levina et al. 2006). One possibility is the electrostatic binding of $[CrO_4]^{2-}$ to the positively charged residues of histones (**5** in Fig. 2, characterized by XAS) (Levina et al. 2006) that are synthesized in the cytoplasm and then transported across the nuclear membrane via the protein transport mechanism (Fig. 1), as is the case with phosphate and sulfate (Levina et al. 2006). Once in the nucleus, Cr(VI) is likely to dissociate from the histone protein due to thermodynamically more favorable histone binding to DNA polyanions during the formation of chromatin (Levina et al. 2006). Reduction of Cr(VI) in the vicinity of DNA can lead to the formation of Cr(V/IV) species bound to the phosphate backbone of DNA (**6** in Fig. 2) (Levina et al. 2003). Structure **6** was proposed based on kinetic and product studies of the reactions of isolated DNA with model Cr(V/IV) complexes (for a review, see Levina et al. 2003). Intramolecular electron transfer in **6**, involving the C4′ atom of the sugar ring (Fig. 2), will lead to the formation of stable DNA-bound Cr(III) species (due to the kinetic inertness of Cr(III)) (Fig. 1) (Levina et al. 2003). Such species can further interact with the N-donors of nucleic bases via linkage isomerization reactions or cross-linking, particularly with the N7 atom of guanine (**7** in Fig. 2), which would lead to distortions in DNA structure and to mutagenicity (Zhitkovich et al. 2001).

The mutagenic potential of the ternary DNA-Cr(III)-L_n adducts, such as **7** (where L are small molecule ligands, such as ascorbate, glutathione, or cysteine), has been demonstrated experimentally (Zhitkovich et al. 2001), but the roles of more bulky DNA-Cr(III)-DNA and DNA-Cr(III)-protein cross-links remain unclear (section ▶ Chromium binding to DNA (Zhitkovich)). An alternative route to Cr(III)-DNA intermediates involves the formation of relatively labile low-molecular-weight Cr(III) species during the reduction of Cr(VI) in the nucleus, followed by their binding to DNA (Levina and Lay 2008; Zhitkovich et al. 2001), but the structures of the final products are likely to be similar. In addition to Cr(III)-DNA binding, oxidative DNA and protein damage by peroxo radicals ($ROO^{\bullet}$) formed as by-products of cellular Cr(VI) reduction (Fig. 1) is also possible, but it is more likely to be repaired by the existing cellular protection mechanisms (Levina et al. 2003).

Detailed XAS studies of Cr(III) products formed in cultured human lung epithelial cells treated with Cr(VI) (Levina et al. 2007) have shown that a major proportion of the Cr(III) is protein-bound, with a likely average coordination environment represented by the structure **8** (Fig. 2). The XAS results indicated that this environment was independent of whether the cells were ascorbate-deficient or ascorbate-saturated (with glutathione or ascorbate as the main Cr(VI) reductants, respectively, as shown by EPR spectroscopy) (Levina et al. 2007), which means that binding of the primary reductants to final Cr(III) products is insignificant. This work also highlighted the problem of aquation, hydrolysis, and redistribution of Cr(III) (as well as of other metal ions) during the cell lysis and subcellular fractionation, which greatly complicates the biospeciation studies of metal ions (Levina et al. 2007; Aitken et al. 2011). The use of XAS gives a unique opportunity to compare the metal coordination environments in intact cells and tissues with those in subcellular fractions, and thus detect if any such changes take place (Levina et al. 2007; Aitken et al. 2011). Given this information, Cr(III)-biomolecule adducts isolated from Cr(VI)-treated cells can be separated by gel electrophoresis and further analyzed by a combination of XAS and

XFM (Aitken et al. 2011); this work is currently in progress. Another highly promising research direction is the study of spatial distribution of Cr in organelles of single cultured Cr(VI)-treated cells, using XFM with submicron lateral resolution, and the determination of Cr coordination environments in single cells by micro-XAS (Aitken et al. 2011).

Biological oxidation of Cr(III) to Cr(VI) has long been considered highly unlikely, but recent studies (reviewed in Levina and Lay 2008) have shown that this process can occur in blood factions, particularly in the presence of the relatively high concentrations of H_2O_2 and ClO^- produced by macrophages at the sites of inflammation. These results may be crucial to explain the antidiabetic action of some Cr(III) complexes, such as a popular nutritional supplement, Cr(III) picolinate (see sections ▶ Chromium and Nutritional Supplement (Nair) and ▶ Chromium and human nutrition (Stoecker); for the discussion of biological roles of Cr(III)) (Levina and Lay 2008). Ligand-exchange reactions of this compound with blood serum proteins lead to the formation of Cr(III)-protein complexes similar to **8** (characterized by XAS) (Levina and Lay 2008; Aitken et al. 2011), which can be more readily oxidized to Cr(VI) by biologically relevant concentrations of H_2O_2 at pH = 7.4 (Fig. 2; Cr(III) picolinate itself is relatively unreactive toward H_2O_2) (Levina and Lay 2008). Such oxidation is likely to be facilitated in patients and animals with poorly controlled diabetes who suffer from chronic oxidative stress (Levina and Lay 2008; Aitken et al. 2011). The $[CrO_4]^{2-}$ oxidation product is efficiently taken up by cells, while cellular uptake of Cr(III) is several orders of magnitude slower (Fig. 1) (Levina et al. 2003). If the amounts of Cr(VI) product are small, Cr(VI) likely to be reduced by thiol-containing molecules (including PTPs) in the cell membrane and cytoplasm, which can lead to potentiation of the insulin signaling cascade (Levina and Lay 2008; Aitken et al. 2011). On the other hand, prolonged use of high doses of Cr(III)-containing supplements could possibly overwhelm the cellular protective mechanisms and lead to Cr(VI)-induced mutagenicity and/or other toxic effects (Levina and Lay 2008). Recent studies by a combination of XAS and XFM techniques (Aitken et al. 2011) revealed the formation of intracellular Cr(V)- and Cr(VI)-containing hotspots in cultured adipocytes (fat cells, crucial for insulin signaling) treated with another Cr(III) antidiabetic (trinuclear Cr(III) propionate), which means that reoxidation of Cr(III) can also occur within the cells (Fig. 1). In summary, toxicity of Cr(VI) and antidiabetic activity of Cr(III) are likely to arise from the same biochemical mechanisms involving the formation of reactive Cr(V) and Cr(IV) intermediates (Fig. 1), which enhances the current concern over the safety of Cr(III) nutritional supplements (Levina and Lay 2008).

Chromium; Cytokines; Immune responses; Stress; T & B lymphocytes

Definition

Chromium (III) is an essential trace mineral that potentiates the action of insulin. A number of different chemical forms of chromium have been utilized as dietary chromium supplements. Various studies have reported beneficial effects of supplemental chromium on the immune system function as well as exacerbation of disease pathogenesis. It is well documented that chromium exerts its effects on immune responses either by immunostimulatory or by immunosuppressive mechanisms. These mechanisms have been shown to be mediated by its effects on T and B lymphocytes, antigen-presenting cells like macrophages, or via cytokine production.

Introduction

The common valance states (III and VI) of chromium differ widely in their biological activity. Trivalent chromium is the form of chromium supplemented to humans and animals and is the form that occurs naturally in foods. Chromium (III) is considered an essential trace mineral for mammals and functions by potentiating the action of insulin. In chromium deficiency, glucose metabolism is impaired due to insulin-sensitive tissues becoming resistant to insulin. Chromium (III) is poorly absorbed from the diet, and is relatively nontoxic. In contrast, chromium (VI) is produced almost entirely by industrial processes and is highly toxic to mammalian cells.

Numerous studies in both animals and cultured immune cells have indicated that chromium can affect an array of immune responses. Many studies evaluating the effects of dietary chromium on immunity and disease resistance have involved animals exposed to various types of stress. Stress increases losses of chromium from the body and also impairs immune responses. Reports in the early to mid-1990s indicating that chromium supplementation could increase immunity and reduce incidence of respiratory disease in stressed calves generated considerable interest in the role of chromium in immunity and disease resistance (Spears 2000). The mechanism(s) whereby chromium alters immune responses is unclear. Chromium effects on immune responses may relate to increased insulin sensitivity by immune cells or the ability of chromium to minimize physiological responses to stress.

Immune responses to chromium supplementation have been variable with some studies showing no response to chromium supplementation. The control diet fed in some studies may have contained adequate bioavailable chromium prior to chromium supplementation. Supplemental chromium sources can differ in their absorption and postabsorptive utilization. A number of different chromium sources including chromium chloride, chromium picolinate, chromium nicotinate, chromium yeast, chromium propionate, chromium amino acid chelate, and chromium nanoparticles have been studied in regard to their ability to modulate immune processes. All of these chromium sources have enhanced immune response in one or more studies. In studies that have compared different chromium sources, organic chromium sources have generally been more effective than inorganic chromium chloride in enhancing immune response.

Overview of the Immune System

A brief overview of the immune system will be presented before discussing the effects of chromium on immunity. The immune system protects host via a two-tiered defense system that involves innate and acquired or adaptive immune responses. Innate immunity is the first line of defense against foreign pathogens and includes physical barriers such as skin, cellular mediators (complement, cytokines), and phagocytic cells (neutrophils, monocytes, and macrophages) that are capable of ingesting and killing pathogenic microorganisms by complement fixation or reactive oxygen and reactive nitrogen species. Neutrophils and monocytes function in blood, while

macrophages function in tissues to engulf and subsequently destroy pathogens. The innate immune system is nonspecific for a particular pathogen and functions to prevent the entry of foreign pathogens into the body, and to attempt to rapidly eliminate organisms that do enter the body. This system does not confer long-term immunity against a given pathogen.

The acquired immune system involves T and B lymphocytes which exhibit a high degree of specificity against a particular antigen. An antigen is a foreign molecule/substance present on pathogens or other foreign invaders that causes activation and proliferation of lymphocytes, resulting in the production of cytokines or antibodies. T lymphocytes are involved in providing cell-mediated immunity, while B lymphocytes generate humoral immunity.

Cell-mediated immunity is conferred by T lymphocytes and is involved in destruction of intracellular pathogens and tumor cells, assisting with activating and directing other immune cells and antibody class switch. T cell receptors bind to fragments of antigen presented to them by macrophages or immune cells, and also to antigen fragments on the surface of infected body cells.

Humoral immunity results from the ability of B lymphocytes to proliferate and produce antibodies against a specific antigen. Antibodies produced by B lymphocytes neutralize pathogens by binding them and preventing their attachment to host cells. Antibodies are also involved in activating complement proteins that enhance the destruction of bacteria by phagocytic cells. Humoral immunity is an important defense mechanism against extracellular pathogens and their secreted toxins.

The innate immune response occurs rapidly, while the acquired immune response is slower to develop after activation by a foreign substance but is of sustained duration. The persistence or sustained duration of the acquired immune response results in immunological memory, resulting in an enhanced immune response on reexposure to the same pathogen or antigen.

A functional immune system is dependent on communication among cells within the acquired immune system and also between cells in the innate and acquired immune system. For example, macrophages process antigen and present it to effector cells in the cell-mediated immune system. B lymphocytes also require T helper cell help to start producing antibodies. A variety of immune cells also produce small soluble cell-signaling proteins called cytokines that promote inter- and intracellular communication among various immune cell types, resulting in immunomodulation. Interleukin 1 (IL-1), IL-6, and tumor necrosis factor α (TNF-α) are important cytokines produced by monocytes and macrophages. These cytokines stimulate T and B lymphocyte proliferation, activate phagocytic cells to kill microorganisms, and initiate production of a number of other cytokines. However, these cytokines are also responsible for many of the clinical signs of infectious disease including fever, anorexia, and inflammation as their effect is not only local but also systemic in nature.

Chromium and Immunity

The effect of chromium supplementation on adaptive immune responses has been explored utilizing various serologic- and immune-based assays. Several important studies are discussed here in an attempt to understand the role of chromium in potentiating humoral (B lymphocyte) and cell-mediated (T lymphocyte) adaptive immune responses against viral or bacterial pathogens.

Chromium supplementation to animal diets has increased humoral immune responses in a number of studies. Humoral immune response has been assessed in these studies by measuring antibodies produced following vaccination against viral and bacterial organisms or after injection of a foreign protein. In chicks, chromium has increased antibody responses following immunization against Newcastle virus and influenza virus. Chromium supplementation has increased antibody responses following vaccination against tetanus toxoid and infectious bovine rhinotracheitis virus in cattle. Chromium has also increased humoral immune response following injection of pigs with sheep red blood cells and cattle with ovalbumin or human red blood cells.

The ability of lymphocytes, isolated from blood or spleen of animals, to proliferate in vitro following mitogen stimulation has been used to evaluate the effect of dietary chromium on cell-mediated immune response. Mitogens stimulate DNA synthesis and induce lymphocyte transformation and cell division by mitosis. The plant-derived mitogens concanavalin A (ConA) and phytohemagglutinin (PHA) stimulate

T lymphocytes, while pokeweed mitogen stimulates T and B lymphocytes. Lipopolysaccharide from the cell wall of gram-negative bacteria is a mitogen that stimulates only B lymphocytes. Blood lymphocytes isolated from cattle supplemented with 0.4–0.5 mg chromium/kg of diet had greater proliferation responses to T cell mitogens than lymphocytes obtained from cattle not supplemented with chromium. Addition of blood serum from chromium-supplemented cattle to lymphocytes isolated from control cattle also increased ConA–induced lymphocyte proliferation. In pigs, the addition of 0.2 mg chromium/kg diet enhanced pokeweed mitogen–induced proliferation. Chromium supplementation, from chromium nanoparticles, at levels of 0.15–0.45 mg/kg diet increased responsiveness of T and B lymphocytes, isolated from blood and spleen, to mitogen stimulation in rats exposed to heat stress (Zha et al. 2009).

Adding chromium directly to lymphocyte cultures has also increased T lymphocyte proliferation from nonstimulated and ConA–stimulated cells. Chromium addition (from chromium chloride) at a concentration of 0.0045 μg/ml of culture medium increased proliferation of blood lymphocytes from cattle not receiving supplemental chromium. Adding a combination of chromium (0.005 μg/ml) and insulin (0.05 or 0.5 ng/ml) to culture medium also increased ConA–induced proliferation of blood lymphocytes from cattle. Fetal calf serum is added to medium used to grow lymphocytes in culture. However, when lymphocytes are grown in serum-free media, insulin addition stimulates mitogen-induced proliferation.

Glucose is the major energy source used by immune cells. Energy requirements of resting (nonactivated) immune cells are very low. Activation of immune cells enhances cell proliferation by a factor of several magnitudes, thus greatly increasing their glucose demand. Insulin receptors are found on the surface of resting and activated monocytes and B lymphocytes. T lymphocytes do not have insulin receptors in a resting state, but activation of T lymphocytes causes development of insulin receptors, especially in cells exposed to high glucose concentrations (Stentz and Kitabchi 2005). Glucose uptake by cells occurs via glucose transporters (GLUT). Glucose transporter 1 (GLUT 1) is not affected by insulin, while GLUT 4 and GLUT 3 are insulin responsive. Human monocytes and T and B lymphocytes express GLUT 1, GLUT 3, and GLUT 4, and expression of all three glucose transporters is increased when cells are activated (Maratou et al. 2007). Insulin addition to culture medium increases expression of GLUT 3 and GLUT 4 in monocytes and B lymphocytes, both in a resting and activated state. Insulin increases expression of GLUT 4 in activated T lymphocytes but not in resting T lymphocytes. Increased expression of GLUT 4 and GLUT 3 by insulin is consistent with a role for insulin in enhancing glucose uptake by activated immune cells when energy demands are high for cell proliferation. Chromium may increase lymphocyte proliferation and antibody production by increasing responsiveness of immune cells to insulin.

The effect of dietary chromium on cell-mediated immunity has also been assessed in vivo using intradermal injection of PHA (Kegley et al. 1996). Following administration of PHA, swelling response at the injection site is measured over 24–48 h as an indicator of the inflammatory response. Chromium supplementation has increased inflammatory response following intradermal administration of PHA in a number of animal species.

From the studies discussed here, we can conclude that chromium appears to assist the immune system by increasing antibody production against foreign agents and by driving the proliferation and cytokine production by T lymphocytes. Chromium may increase proliferation of T and B lymphocytes by enhancing their responsiveness to insulin.

Chromium and Cytokine Production

Chromium has been shown to alter cytokine production both in vivo and in vitro. Mononuclear cells isolated from cattle supplemented with 0.5 mg chromium/kg of diet had lower production of TNF-α, IL-2, and IFN-γ following stimulation with ConA than cells from nonchromium-supplemented animals (Burton et al. 1996).

Addition of 100 μM of chromium (from chromium chloride) to activated monocytes from a human cell line reduced TNF-α secretion. Exposure of monocyte cultures to high glucose concentrations results in increased secretion of proinflammatory cytokines, such as TNF-α, and increases oxidative stress. Oxidative stress is caused due to an imbalance in the production and removal of the reactive oxygen species which leads to protein, lipid, and DNA damage within

the host. Activated monocytes, neutrophils, and macrophages produce high quantities of reactive oxygen species during the destruction of pathogens. Oxidative stress is usually assessed by measuring malondialdehyde, an end product of lipid peroxidation. Jain et al. (2007a) compared the effects of different chromium sources and levels on oxidative stress and secretion of IL-6 and IL-8 from monocytes exposed to high glucose concentration. Chromium chloride, chromium picolinate, and chromium niacinate were evaluated at chromium concentrations of 0.5, 1, and 10 μM. While all concentrations of chromium reduced IL-6 and IL-8 secretion, the 10 μM level was generally most effective. Chromium niacinate was also more effective than chromium chloride or picolinate in reducing IL-6 and IL-8 secretion in this study. Oxidative stress of monocytes exposed to high glucose was reduced by chromium chloride and chromium niacinate but not by chromium picolinate. Concentrations of chromium used in monocyte culture studies probably exceed physiological concentrations. Chromium is poorly absorbed and is usually found in blood and tissues at nM concentrations.

Monocytes and other immune cells can be exposed to elevated glucose concentrations in humans with diabetes. Diabetes is often associated with elevated circulating levels of proinflammatory cytokines and increased oxidative stress. Proinflammatory cytokines and oxidative stress are markers of vascular inflammation in diabetic patients. Diabetic rats have higher plasma levels of TNF-α, IL-6, and malondialdehyde than normal rats. Streptozotocin administration was used to induce diabetes. Supplementation of 400 μg of chromium/kg of body weight from either chromium niacinate or chromium picolinate for 7 weeks prevented the elevation of plasma TNF-α, IL-6, and malondialdehyde in diabetic rats (Jain et al. 2007b). The level of chromium supplemented in this study would be considered pharmacological relative to doses of chromium that would be supplemented to humans or animals.

Lipopolysaccharide (*E. coli*) injection has been used to study the effect of dietary chromium on release of proinflammatory cytokines in pigs. Lipopolysaccharide stimulates mononuclear phagocytes, causing a large elevation of TNF-α concentration within 2 h post–LPS dosing. The increase in TNF-α rapidly stimulates mononuclear cells to produce and release IL-1 and IL-6 into the blood. In pigs injected with a low dose of LPS (20 μg/kg body weight) intravenously, chromium picolinate supplementation (0.3 mg chromium/kg diet) reduced plasma TNF-α concentration at 1 and 2 h postinjection. Plasma IL-6 concentrations were not affected by chromium in this study. Injection of high doses of LPS can cause death due to septic shock which results from extremely high production of TNF-α and other proinflammatory cytokines. Supplementing 0.4 mg chromium/kg diet (from chromium propionate) reduced mortality in pigs injected intravenously with 200 μg LPS/kg body weight from 83% to 42%. This suggests a protective effect of chromium against septic shock.

Chromium supplementation at 0.4 or 0.8 mg/kg diet reduced liver malondialdehyde and plasma malondialdehyde, TNF-α, and IL-6 concentrations in Japanese quails housed at thermoneutral (22°C) or heat stress (34°C) environmental temperatures (Sahin et al. 2010). Responses to chromium were greater in heat-stressed quails. Reduced levels of proinflammatory cytokines in chromium-supplemented animals could indicate that chromium curtails the subsequent inflammatory signaling cascades that might occur. IFN-γ mRNA expression was enhanced at 1 and 3 days following vaccination against Newcastle disease virus in chicks supplemented with 0.5 mg chromium/kg diet. Supplementation with higher concentrations of chromium (1.0 or 1.5 mg/kg diet) downregulated IFN-γ mRNA compared to nonchromium-supplemented chicks. IFN-γ is the key cytokine that interferes with viral replication, and chromium may assist with initiating the antiviral cytokine responses following vaccinations.

Interaction Between Chromium, Stress, and Immunity

Humans and domestic animals are exposed to various stressors during their lifetime. Acute stress results in the release of adrenocorticotropin hormone (ACTH) from the pituitary gland which subsequently increases release of cortisol from the adrenal gland. Common stressors in humans include exercise, emotional stress, trauma, and surgical procedures. Stressors that animals may encounter include heat, cold, weaning from their dams, and shipping from one location to another. In humans, stress associated with physical trauma, acute exercise, and lactation increases urinary losses of chromium and may lead to chromium deficiency (Anderson 1994). A positive correlation exists between serum cortisol concentrations following exercise stress and urinary chromium excretion in humans.

Corticosteroid treatment in humans also increases urinary chromium excretion, and corticosteroid treatment can lead to impaired glucose tolerance due to insulin resistance. Chromium supplementation has been reported to improve glucose tolerance in humans with steroid-induced diabetes. This suggests that chromium deficiency is at least partially responsible for insulin resistance observed in steroid-induced diabetes.

It is well documented that cortisol and other glucocorticoids suppress a variety of immune responses. Depletion of chromium due to increased urinary losses during stress may further compromise immune responses. Studies with calves that have been stressed due to weaning from their dams, shipping to a new environment, and feed restriction during transportation indicate that chromium supplementation can increase immunity and health. The incidence of respiratory disease is frequently high in stressed calves. In calves stressed by weaning and shipping, chromium supplementation at 0.2–0.5 mg/kg diet has reduced morbidity in some studies (Spears 2000). Calves supplemented with 0.4 mg/kg diet (as chromium nicotinate or chromium chloride) tended to have lower body temperature at certain time points after intranasal inoculation with infectious bovine rhinotracheitis virus followed by intratracheal inoculation with *Pasteurella haemolytica* 5 days later (Kegley et al. 1996). In guinea pigs, chromium supplementation reduced mortality during pregnancy. Chromium addition to diets of laying hens has also reduced mortality rate.

Providing adequate dietary chromium can reduce blood cortisol concentrations during stress. In calves stressed via weaning and shipping, chromium supplementation has decreased serum cortisol in some studies. Following a respiratory disease challenge, calves supplemented with chromium had lower serum cortisol concentrations than control calves (Kegley et al. 1996). Chromium supplementation has also reduced circulating cortisol concentrations in heat-stressed rats and LPS-challenged pigs.

Chromium(III) and Low Molecular Weight Peptides

John B. Vincent
Department of Chemistry, The University of Alabama, Tuscaloosa, AL, USA

Synonyms

Chromodulin; Low-molecular-weight chromium-binding substance (LMWCr)

Definition

Low-molecular-weight chromium-binding substance is a carboxylate-rich peptide isolated from the urine and tissues of higher animals that tightly binds Cr^{3+} ions. The peptide has been suggested to have a role in chromium detoxification and to potentially have a role in improving insulin sensitivity when animals are supplemented with high doses of chromium(III) compounds.

Chromium is absorbed by passive diffusion and then binds to the iron-transport protein in the blood. Transferrin delivers chromium to the tissues where it binds to a low-molecular-weight organic species that is cleared from the tissues. The chromium is ultimately eliminated from the body in the urine as a low-molecular-weight organic complex. This organic complex is called low-molecular-weight chromium-binding substance (LMWCr) and has also been coined chromodulin (Vincent and Stearns 2011).

Discovery of LMWCr

LMWCr was first reported by the toxicology group of Osamu Wada in 1981 (Yamamoto et al. 1981), who investigated the compound for about a decade (Vincent and Stearns 2011). Although other higher molecular weight species that bound chromium were present, a low-molecular-weight chromium compound(s) was identified by size exclusion chromatography of the cytosol of liver cells of male mice injected with a single dose of potassium dichromate (50 or 200 μg/kg body mass). In contrast to the higher molecular weight molecules that bound chromium, LMWCr could be detected for 7 days. A similar low-molecular-weight compound was found in the feces and urine and 2 h after injection in the plasma. The researchers suggested that a low-molecular-weight chromium-binding substance (LMWCr) was formed in the liver and participates in retention and excretion of chromium in the body. The material from the livers of rabbits treated similarly with dichromate (200 μg/kg body mass) was partially purified and found to apparently be an anionic organic-chromium complex containing amino acids with a molecular weight under 3,000 and a component that absorbed ultraviolet light at 260 nm (Yamamoto et al. 1981). Subsequently, LMWCr was found to occur in urine normally, although the amounts were greatly increased after rats were injected with chromate (Wu and Wada 1981). Normal human and rat urine LMWCr was found not be saturated with chromium; addition of Cr^{3+} to urine would result in increased amounts of the chromium-containing species that eluted in a particular band upon size-exclusion chromatography. The LMWCr was believed to be similar to that of the liver and other organs of rabbits and dogs and to be involved in removing excess chromium from the body. Wada and coworkers (Yamamoto et al. 1984) followed the initial studies by examining the distribution of LMWCr. LMWCr was found in liver, kidney, spleen, intestine, testicle, brain, and blood plasma, with the greatest amount in liver followed by kidney. The organs were obtained from mice 2 h after injection with potassium dichromate. Supernatants of homogenates of the organs were found to possess more chromium bound to LMWCr when dichromate was added to the homogenate than when the mice were injected with dichromate. The time course of chromium binding to LMWCr after injection of dichromate was also examined. Chromium was found to be associated with liver and kidney LMWCr in just 2 min after injection and reached a maximum of 1–2 h after treatment. Repetitive treatments of mice with dichromate (150 μmol/kg daily for each of 4 days) had no effect on LMWCr levels in the liver; thus, no induction of formation of LMWCr was observed. LMWCr had greater affinity for chromium than transferrin or albumin. LMWCr was proposed to play a role in chromium detoxification.

In these studies, LMWCr was identified by its elution behavior in size exclusion chromatography and its Cr-binding ability. In other words, to identify LMWCr, chromium had to be added to the animal, tissue homogenate, or body fluid, and then the fraction of appropriate molecular from designated solution has to be separated by size exclusion chromatography. Thus, LMWCr refers to a low-molecular-weight organic species containing amino acids and able to bind chromium. These initial studies also leave questions as to whether LMWCr is a single species as no single well-characterized species was isolated, purified, and characterized, bringing back memories of the artifact first proposed as the biologically active form of chromium, glucose tolerance factor (Vincent and Stearns 2011).

Isolation and Characterization of LMWCr

Organic Composition

Efforts to isolate and characterize LMWCr continued. LMWCr has been isolated and purified from alligator liver, chicken liver, rabbit liver, bovine liver, porcine kidney, and porcine kidney powder and partially purified from dog and mouse liver. Inclusion of protease inhibitors in buffers during the isolation of bovine liver LMWCr does not affect the amount of oligopeptide isolated, suggesting it is not a proteolytic artifact generated during the isolation procedure. The materials from rabbit and dog liver were loaded with Cr by injection of the animal with chromate (or Cr(III) which provides lower yields). For the other tissues, chromate was added to the homogenized liver or kidney or suspended kidney powder. Cr(III) could also be added to the bovine liver homogenate to load LMWCr with chromium, but the loading was not as efficient as when chromate was utilized. A Cr-loading procedure is required so that the material can be followed by its chromium content during the isolation and purification procedures. The isolation procedures are similar involving an ethanol precipitation, anion exchange chromatography, and finally, size exclusion chromatography (Vincent and Stearns 2011).

The first purification was from rabbit liver by Wada and coworkers (Yamamoto et al. 1987). LMWCr was found to be an anionic organic chromium compound with an approximate molecular weight of 1,500 and to be composed of a peptide of glutamate (and/or glutamine), cysteine, glycine, and aspartate (and/or asparagine) and chromium (four Cr: amino terminus). Interestingly, the addition of purified LMWCr to isolated rat adipocytes in the presence of insulin (5 μU/mL) stimulated the conversion of glucose into carbon dioxide and the incorporation of hydrogen from glucose into lipids in a concentration-dependent manner. Increased incorporation of hydrogen into lipids also occurred in a concentration-dependent fashion in the absence of insulin, although to a lesser degree. Activation required LMWCr in Cr concentrations of 0.2–6 μM (Yamamoto et al. 1987). The biological activity is dependent on the chromium content. Removal of chromium decreases the production of glucose and incorporation of hydrogen from glucose into lipids, while most of the activity can be restored by addition of chromium (Yamamoto et al. 1989).

The amino acid composition of the LMWCr from mammalian sources is presented in Table 1. From the table, LMWCr appears to be an oligopeptide composed of glycine, cysteine, aspartate, and glutamate with the carboxylates comprising more than half of the total amino acid residues (Table 1). The amino acid composition data for the rabbit liver LMWCr (injected with dichromate) and bovine liver (dichromate added to homogenate) are extremely similar, indicating that the type of Cr-loading procedure utilized is probably not critical to the composition of the isolated material. Amino acid sequence data has only appeared most recently. Treatment of LMWCr from bovine liver, human urine, chicken liver, and alligator liver with trifluoroacetic acid in an attempt to remove the chromium in a more gentle fashion than used previously resulted in the production of a heptapeptide fragment of LMWCr with a mass/charge ratio of 802 as determined by matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) and electrospray ionization (ESI) mass spectrometry (MS) (Vincent and Stearns 2011). Postsource decay (POD) MALDI-TOF MS suggested the sequence was either pEEEEGDD (where pE is pyroglutamate) or pEEEGEDD. Use of collision-induced dissociation (CID) MS/MS or MS/MS/MS experiments allowed the sequence of the heptapeptide from the treatment of the bovine liver LMWCr to be confirmed as pEEEEGDD by comparison of spectra with those of synthetic peptides of the proposed sequences. The composition of the isolated heptapeptide was also confirmed by amino acid analysis. The treatment with trifluoroacetic acid in addition to removing the chromium cyclized the terminal glutamate residue while also dissociating some cysteine and glycine from the isolated LMWCr. The sequence of the heptapeptide explains why LMWCr could not be sequenced by Edman degradation as exposed N-terminal glutamates tend to cyclize under the Edman conditions; previous efforts at Edman sequencing had observed a low yield of glutamate at the N-terminus and essentially no yield at subsequent steps. Searches of sequence databases reveal a small number of possible sources for the heptapeptide; however, none have cysteine and glycine residues adjacent to the sequence. The ability of cysteine and glycine to be cleaved by the acid treatment and the lack of an appropriate sequence suggest these residues are

Chromium(III) and Low Molecular Weight Peptides, Table 1 Amino acid composition data for isolated LMWCr

Source	Glycine	Glutamic acid	Aspartic acid	Cysteine
Rabbit liver	3.22	3.91	1.98	1.75
Bovine liver	2.47	4.47	2.15	2.19
Bovine colostrum	1.98	5.0	4.12	0.93
Porcine kidney	1.45	4.05	2.31	0.622

associated with the heptapeptide through a nonstandard linkage (Vincent and Stearns 2011). Unfortunately to date, LMWCr has not proven to be particularly antigenic, preventing its presence to be detected using immunological techniques. Antibodies raised against the heptapeptide will recognize bovine liver LMWCr; however, the binding of the antibodies is not sufficient for use in techniques such as Western blotting (Vincent and Stearns 2011).

Three laboratories have reported not being able to isolate bovine liver LMWCr. One made the statement as a footnote in an article; one reported isolating instead a material they identified as containing Cr(IV) or Cr(V). Much of the work in this paper has been refuted, and the existence of such a Cr(IV) or Cr(V) species with the stability necessary to be isolated under these conditions is difficult to fathom. Another observed at least four species that bound chromium and isolated an approximately 15.6-kDa protein. As would only be expected by adding chromate to a liver homogenate, these researchers suggested that chromium binding was nonspecific. The other three Cr-containing species were not characterized (Vincent and Stearns 2011).

Metal-Binding Sites

Despite its small size (approximately 1,500 molecular weight; 1438 by MALDI-TOF mass spectrometry for bovine liver LMWCr), the molecule from rabbit and bovine liver tightly binds four equivalents of chromic ions. The binding is quite tight (K_a approximately 10^{21} M^{-4} for bovine liver LMWCr) and highly cooperative (Hill coefficient, $n = 3.47$); thus, the large value of the Hill coefficient indicates essentially only apoLMWCr and holoLMWCr (Cr_4-LMWCr) coexist in solution. The binding of chromium to synthetic heptapeptide pEEEEGDD is tight and cooperative, with four chromic ions binding with an essentially identical binding constant and Hill coefficient (Vincent and Stearns 2011).

Spectroscopic and magnetic studies suggest that the chromic ions comprise an anion-bridged multinuclear assembly supported by carboxylates from the oligopeptide. Electronic spectroscopic studies reveal that the Cr bound to LMWCr exists in the trivalent oxidation state; for the bovine liver material, 10Dq and the Racah parameter B were found to be 1.74×10^3 and 847 cm^{-1}, respectively, an indication of predominately oxygen-based coordination. In the ultraviolet region, the spectra of LMWCr possess a maximum or shoulder at approximately 260 nm; this feature may arise from a disulfide linkage. Paramagnetic ^{1}H NMR spectroscopy of the bovine liver reveals a downfield-shifted resonance at approximately +45 ppm, suggestive of the protons of a methylene carbon bound adjacent to a carboxylate bridging two chromic centers. The presence of a bridging ligand suggests the existence of a multinuclear assembly. Charge balance also suggests the existence of an anion-bridged multinuclear assembly. Four Cr^{3+} have a combined charge of +12, while holoLMWCr is anionic. The organic components cannot provide sufficient negative charge to compensate, indicating the need for additional anionic components. Also, the four chromium(III) centers require six coordination. How the organic composition could fill these 24 sites is difficult to envision (Davis and Vincent 1997b).

X-ray absorption spectroscopic studies on the bovine liver LMWCr have shown that the chromium atoms are surrounded by six oxygen atoms at an average distance of 1.98 Å and are consistent with a lack of sulfur-based ligands. A long Cr...Cr interaction at approximately 3.79 Å is present, and another such interaction may be present at 2.79 Å. This is also consistent with the presence of a multinuclear chromium assembly. As holoLMWCr can be prepared simply by addition of chromic ions to aqueous solutions of apoLMWCr, anionic bridges to the chromium assembly are probably hydroxide ions; the X-ray absorption studies failed to detect any short Cr-oxo interactions. The nature of the assembly has been narrowed to a few possibilities from electron paramagnetic resonance (EPR) spectroscopy to variable temperature magnetic susceptibility measurements. X-band EPR studies indicate that at least three chromic ions are coupled to give a species with an $S = 1/2$ ground state giving rise to a broad signal at $g \sim 2$; this signal appears to be

broadened by interaction with another chromium species, giving rise to a complex EPR signal centered about g ~ 5. The g ~ 2 EPR signal sharpens as the temperature is raised from 5 to 30 K, suggesting that dipolar coupling exists between the two chromium species giving rise to the EPR signal. Finally, magnetic susceptibility studies are consistent with the presence of a mononuclear chromic center and an unsymmetric trinuclear chromic assembly (Jacquamet et al. 2003).

Put together, the spectroscopic and magnetic data on bovine LMWCr suggest the occurrence of a Cr_4 assembly in LMWCr. The chromium environment is mostly, if not exclusively, composed of O atoms, and the assembly is comprised of a single chromic ion and a trinuclear unit. Additionally, the sulfur atoms of the two cysteine residues of LMWCr appear to be involved in a disulfide linkage and not to be involved in binding chromium. Similarly, the N-terminal amine group can be derivatized, suggested it is not coordinated to chromium. Thus, oligopeptide-provided ligands appear to be limited to carboxylates from the side chains of the aspartate and glutamate residues and possibly the carboxy terminus.

Function

As described above, insulin dose–response studies using rat adipocytes have indicated a potential intrinsic biological function for LMWCr. Isolated rat adipocytes in the presence of LMWCr and insulin display an increased ability to metabolize glucose to produce carbon dioxide or total lipids; this increase occurs without a change in the insulin concentration required for half-maximal stimulation. This lack of change in half-maximal insulin concentration suggests a role for LMWCr inside the insulin-sensitive cells after insulin binds externally to the insulin receptor. The stimulation of glucose metabolism by LMWCr is proportional to the chromium content of the oligopeptide.

Because the primary events between insulin binding to its receptor and glucose transport are signal transduction events, a role for LMWCr in these events has been probed. LMWCr has been shown to activate the tyrosine kinase activity of insulin-activated insulin receptor and to activate a membrane phosphotyrosine phosphatase in adipocyte membranes. For example, the addition of bovine liver LMWCr to rat adipocytic membranes in the presence of 100-nM insulin results in a concentration dependent on up to eightfold stimulation of insulin-dependent protein tyrosine kinase activity, while no activation of kinase activity is observed in the absence of insulin. The dependence of the kinase activation on the concentration of LMWCr can be fit to a hyperbolic curve to give dissociation constants (K_m) of approximately 875 pM, indicating extremely tight binding. Blocking the insulin-binding site on the external β subunit with antibodies whose epitope lies in this region results in the loss of the ability to activate insulin receptor kinase activity. Examining the potential activation of isolated rat insulin receptor by bovine liver LMWCr in the presence of insulin indicates that LMWCr can amplify the isolated receptor protein tyrosine kinase activity by approximately sevenfold with an apparent dissociation constant of approximately 250 pM, suggesting that the receptor is the site of interaction with LMWCr (Davis and Vincent 1997a). The site of LMWCr binding on insulin receptor can be further refined. Studies with a catalytically active fragment (residues 941–1,343) of the β-subunit of human insulin receptor (which does not require insulin for kinase activity) reveal that LMWCr can stimulate kinase activity threefold with a dissociation constant. Thus, LMWCr apparently binds at or near the kinase active site.

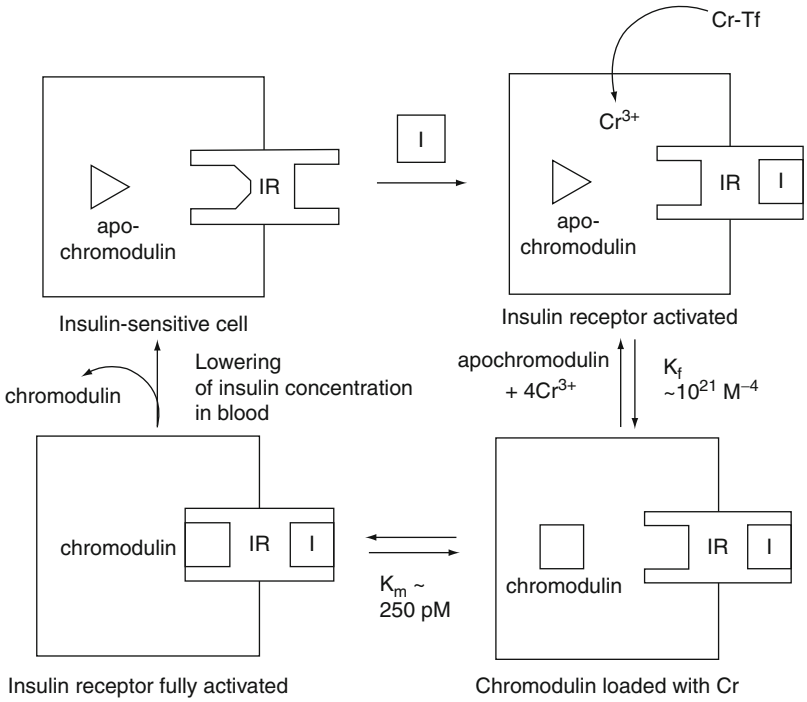
As noted above, chromium plays a crucial role in the in vitro activation of insulin receptor kinase activity by LMWCr. ApoLMWCr is unable to activate insulin-dependent tyrosine kinase activity in the rat adipocyte membranes. Titration of apoLMWCr with Cr^{3+} results in the restoration of the enhancement of kinase activity; approximately four Cr^{3+} per oligopeptide are required for maximal activity, consistent with the number of chromium (four per oligopeptide) reported to be bound to holoLMWCr from liver sources. This reconstitution is specific to chromium. Transition metal ions other than chromium which are commonly associated with biological systems (V, Mn, Fe, Co, Ni, Cu, Zn, and Mo) are ineffective in potentiating the ability of apoLMWCr to activate kinase activity. In fact, all the ions except Cr^{3+} resulted in loss of activation potential relative to apoLMWCr (Davis and Vincent 1997a). Thus, the ability of LMWCr to potentiate the effects of insulin in stimulating the insulin-dependent protein tyrosine kinase activity of insulin receptor is specific to chromium and is directly dependent on the chromium content of LMWCr.

The activation of a membrane-associated phosphotyrosine protein phosphatase (PTP) by LMWCr has been little explored. Studies with isolated LAR and PTP1B have shown that chromodulin has no effect on these phosphatases (Vincent and Stearns 2011).

Based on these results, LMWCr has been proposed to function as part of a unique autoamplification system for insulin signaling (Fig. 1) and a new (and shorter) name, chromodulin, has been put forward (Vincent 2000). In this mechanism, apoLMWCr is stored in insulin-sensitive cells. In response to increases in blood insulin concentrations (as would result from increasing blood sugar concentrations after a meal), insulin binds to its receptor, bringing about a conformation change which results in the autophosphorylation of tyrosine residues on the internal side of the receptor. This transforms the receptor into an active tyrosine kinase and transmits the signal from insulin into the cell. In response to insulin, chromium is moved from the blood where it is maintained in the iron transport protein transferrin to insulin-sensitive cells. Here, the chromium flux results in the loading of apoLMWCr with chromium. The holoLMWCr then binds to the receptor, presumably assisting to maintain the receptor in its active conformation, amplifying its kinase activity. When the signaling is to be turned off, a drop in blood insulin levels facilitates relaxation of the conformation of the receptor, and the holoLMWCr is excreted from the cell into the blood. Ultimately, LMWCr is efficiently excreted in the urine. The basis of the alternative name chromodulin is the similarity of the proposed mechanism of action to that of the calcium-binding protein calmodulin. Both bind four equivalents of metal ions in response to a metal ion flux; however, the four calcium ions which bind to the larger protein calmodulin rest in mononuclear sites. Both holoproteins selectively bind to kinases and phosphatases, stimulating their activity (Vincent 2000).

Noting that all the studies on LMWCr and insulin receptor are in vitro studies is important. This proposed mechanism of action of chromium needs to be supported by in vivo studies. In other words, does LMWCr bind to insulin receptor in vivo and is insulin receptor kinase activity affected in vivo by interaction directly with LMWCr in vivo? As recent studies indicate that chromium is probably not an essential trace element, then LMWCr would not normally have a role in carbohydrate and lipid metabolism. However, studies using pharmacological doses of Cr^{3+} have generated beneficial effects on insulin sensitivity and blood lipid parameters in rodent models of diabetes (Vincent and Stearns 2011). This raises the question of whether pharmacological doses of chromium, orders of magnitude above the amount of chromium obtained in the diet, could result in a loading of LMWCr with chromium above normal levels, allowing for holoLMWCr to interact with insulin receptor to an appreciable effect and to increase insulin sensitivity.

The other suggested role for LMWCr is in detoxification of chromium. As noted above, chromium is absorbed by passive diffusion and maintained in the blood bound to transferrin. The movement of transferrin to tissues results in the transfer of chromium to LMWCr, and the holoLMWCr is eliminated in the urine. Thus, LMWCr appears to provide an efficient mechanism for elimination of chromium from the tissues and ultimately the body. ApoLMWCr is maintained in the soluble portion of tissue cells examined to date and in the nucleus of at least hepatocytes. ApoLMWCr levels are not increased in response to multiple intravenous administrations of chromium. However, the levels appear to not be diminished by administration of a chromium load; consequently, levels of apoLMWCr have been suggested to be under homeostatic control (Vincent and Stearns 2011). This is not typical for biomolecules whose primary role is detoxification. The efficiency of this clearance can be observed from the LD_{50} and mean tubular reabsorption rates of LMWCr. The mean tubular reabsorption rate for LMWCr of 23.5% in contrast to rates of 85.7% and 92.5% for chromate and chromium chloride, respectively; this is probably also responsible for the extremely high LD_{50} for LMWCr injected into mice of 135 mg/kg body mass (Yamamoto et al. 1984). Given a role for LMWCr under physiological circumstances does not appear to have a role in carbohydrate metabolism; a detoxification role would appear to be its natural function. Given that dietary intake of chromium is very low (approximately 30 μg/day), and lack of toxic from Cr^{3+} intakes several orders of magnitude higher, perhaps an inducible detoxification system for chromium, has not proven necessary.



Chromium(III) and Low Molecular Weight Peptides, Fig. 1 Proposed mechanism for the activation of insulin receptor kinase activity by chromodulin in response to insulin (Vincent 2000). The inactive form of the insulin receptor (*IR*) is converted to the active form by binding insulin (*I*). This triggers a movement of chromium (presumably in the form of chromium transferrin, *Cr-Tf*) from the blood into insulin-dependent cells, which in turn results in a binding of chromium to apochromodulin (apoLMWCr) (*triangle*). Finally, the holochromodulin (*square*) binds to the insulin receptor, further activating the receptor kinase activity. Apochromodulin is unable to bind to the insulin receptor and activate kinase activity. When the insulin concentration drops, holochromodulin is released from the cell to relieve its effects (Reproduced with the permission of the copyright holder)

Bovine Colostrum LMWCr

A related chromium-containing oligopeptide from bovine colostrum (M-LMWCr) is comprised of the same amino acids but in distinctly different ratios and also stimulates insulin-dependent glucose metabolism in rat adipocytes. Whether the oligopeptide is present in other forms of milk is unknown. The significance of these differences between the liver and colostrum oligopeptides is essentially unexplored. The existence of multiple forms of LMWCr in cows raises concerns about identifying LMWCr in tissues or body fluids from only its apparent molecular weight and chromium-binding ability (Vincent and Stearns 2011). For example, are blood and urine LMWCr fractions comprised of one or more of these oligopeptides?

Conclusion

Overall, these studies show that chromium is transferred to a low-molecular-weight species in tissues and is subsequently lost in the urine as a low-molecular-weight species. These species are similar, if not identical, and can serve as a detoxification mechanism for chromium. An isolated species from liver and urine treated with chromium has been characterized and called LMWCr or chromodulin. While it is logical and likely that this species that tightly binds chromium is the same species that occurs naturally in tissues and urine, the chromium-loading process required to isolate the biomolecule does not allow this to be determined with certainty as it could represent an artifact generated during chromium loading. As chromium is probably not an essential element,

LMWCr (if the natural chromium-binding biomolecule) should not have a role in insulin signaling during normal conditions. The activity observed in test tube studies could reflect a mechanism for altering carbohydrate and lipid metabolism when excess chromium is present, as when rodents are treated with high doses of chromium(III) supplements. However, this will require in vivo evidence. Additional research on LMWCr and on the molecules in insulin signaling affected by chromium in vivo is needed to address these questions.

Definition

Transferrins comprise a class of proteins with molecular weights of approximately 80,000 that reversibly bind two equivalents of metal ions. The proteins selectively bind ferric ions in a biological environment because the metal-binding sites are adapted to bind ions with large charge-to-size ratios. Transferrin is a blood serum protein, a β-globulin, although other forms of the protein are found in milk (lactoferrin) and avian egg white (conalbumin or ovotransferrin). Transferrin is the major iron transport protein in the bloodstream, while lactoferrin and conalbumin are believed to have antibacterial roles by depriving bacteria of iron. Because of its similarity in size and charge to ferric ion, Cr^{3+} is transported and stored in the bloodstream by transferrin.

Transferrins are a class of proteins of approximately 80 kDa (kilodaltons) that reversibly bind two equivalents of metal ions (Brock 1985). The protein exhibits amazing selectivity for Fe^{3+} in a biological environment because the metal sites are adapted to bind ions with large charge-to-size ratios. Transferrin is a blood serum protein, a β-globulin, although other forms of the protein are found in milk, lactoferrin, and avian egg white (conalbumin or ovotransferrin). Transferrin is the major iron transport protein in the bloodstream, while lactoferrin and conalbumin are believed to have antibacterial roles by depriving bacteria of iron. In humans, the protein is present at a concentration of approximately 3 mg/ml in serum and is normally about 30% saturated with iron (Brock 1985), allowing it to potentially bind and transport other metal ions. Consequently, transferrin has been proposed to serve as a chromium(III) transport agent, given the similar

charge and relatively similar size of this ion to iron(III) (Vincent and Stearns 2011).

The transferrin molecule is composed of two lobes with approximately 40% sequence homology; the three-dimensional structures of the lobes are nearly superimposable (Baker 1994). Each lobe possesses an iron-binding site. Each Fe^{3+} binds concomitantly with a synergistic anion, usually bicarbonate or carbonate. The iron coordination is essentially identical in each site, being distorted octahedral and composed of two tyrosine residues, a histidine residue, an aspartate residue, and a chelating (bi)carbonate ion. The presence of the anion is essential for iron binding. The transferrin molecule undergoes a significant conformational change when binding and releasing iron. The apoprotein possesses a more open confirmation (Baker 1994). In the metal-loaded confirmation, transferrin binds to transferring receptor, a transmembrane protein of the cell membrane. Transferrin is brought into the cell by endocytosis. Acidification of resulting endosome releases the Fe^{3+}, and subsequent fusion of the endosome with the cell membrane releases and recycles the apotransferrin (Brock 1985).

Physical Characterization of Chromium Transferrins

In vitro studies have shown that Cr^{3+} readily binds to the two metal-binding sites of transferrin and concomitantly also binds two equivalents of bicarbonate, resulting in intense changes in the protein's ultraviolet spectrum. The changes in the ultraviolet spectrum suggest that each chromic ion binds to two tyrosine residues, suggesting that chromium binds specifically in the two iron-binding sites. The involvement of tyrosine ligands has been confirmed by Raman spectroscopy (Ainscough et al. 1980). Human Cr_2 transferrin has been described as pale blue in color with visible maxima at 440 and 635 nm (Aisen et al. 1969), while Cr_2 lactoferrin has been described as gray-green with maxima at 442 and 612 nm ($\varepsilon = 520$ and 280 $M^{-1}\,cm^{-1}$, respectively) (Ainscough et al. 1979). The visible spectra are typical for Cr(III) centers in a pseudooctahedral environment. The oxidation state of the bound chromium has been confirmed by variable temperature magnetic susceptibility studies, whose results are consistent with the presence of $S = 3/2$ centers, and by electron paramagnetic resonance (EPR) studies (Aisen et al. 1969). The two Cr-binding sites can readily be distinguished by EPR (frozen solutions at 77 K) (Aisen et al. 1969). At approximately pH 7.7, chromium binds to both sites on the protein. At pH 4.8–5.9, chromium only binds to one site. This tighter binding site possesses an EPR signal at $g = 5.43$. At near neutral pH, the Cr^{3+} in the tighter binding site that binds chromium at the lower pH cannot be displaced by Fe^{3+}, while Fe^{3+} readily displaces Cr^{3+} from the other site (Ainscough et al. 1980). The weaker binding site Cr^{3+} gives rise to EPR signals at $g = 5.62$, 5.15, and 2.42 (Ainscough et al. 1980).

The effective thermodynamic binding constants for chromium transferrin, actually using conalbumin, have been determined (Sun et al. 2000). The addition of chromic ions to apoconalbumin was monitored by following the enhancement of the intensity of the ultraviolet absorption bands at circa 240 and 290 nm. The value of $\Delta\varepsilon$ increased rapidly upon the initial additions of chromium but rapidly levels off after the addition of approximately 1.5 chromic ions, indicating the chromium was occupying both metal-binding sites. At a given pH and carbonate concentration, effective equilibrium constants can be written such that

$$K_1 = [CrT_f]/([Cr][T_f]) \tag{1}$$

and

$$K_2 = [Cr_2T_f]/([Cr][CrT_f]), \tag{2}$$

where [Cr] represents the concentration of all chromium not bound to transferrin. Based on these equations, the total concentration of Cr and of transferrin becomes

$$[Cr]_{total} = [Cr] + K_1[Cr][T_f] + 2K_1K_2[Cr]^2[T_f] \tag{3}$$

and

$$[T_f]_{total} = [T_f] + K_1[Cr][T_f] + K_1K_2[Cr]^2[T_f] \tag{4}$$

Using these equations, the $\Delta\varepsilon$ at any point of the titration, $\Delta\varepsilon_{calcd}$, can be calculated as

$$\Delta\varepsilon_{calcd} = \left(\Delta\varepsilon_{Cr}K_1[Cr] + 2\Delta\varepsilon_{Cr}K_1K_2[Cr]^2\right) / \left(1 + K_1[Cr] + K_1K_2[Cr]^2\right). \tag{5}$$

where $\Delta\varepsilon_{Cr}$ is the molar absorptivity per bound chromium at 245 nm. $\Delta\varepsilon_{Cr}$ can be determined by the slope of the linear portion of the curve in Fig. 2 at low Cr-to-transferrin ratios and is $7.94 \times 10^3\ M^{-1}\ cm^{-1}$. Fitting the data to (5) gave the effective binding constants of $K_1 = 1.42 \times 10^{10}\ M^{-1}$ and $K_2 = 2.06 \times 10^5\ M^{-1}$. This gives the overall effective binding constant $K = K_1 \times K_2$ to be $2.92 \times 10^{15}\ M^{-2}$ (Sun et al. 2000). The difference in the binding constant for the two metal-binding sites is consistent with previous studies with chromium and transferrin. Given the binding constants for Cr^{3+}, the inability Fe^{3+} to displace Cr^{3+} from one of the binding sites, and that transferrin is maintained on average only 30% loaded with ferric ions, the protein appears to be primed to be able to transport chromium through the bloodstream.

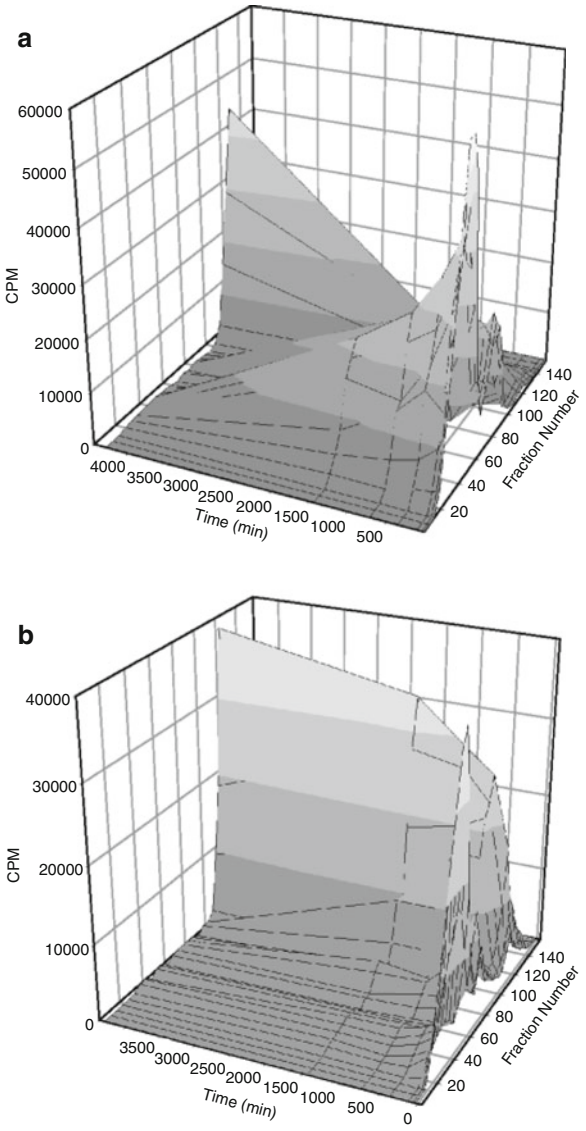
In Vivo Studies

The first demonstration of the potential importance of transferrin in the transport of chromium resulted from in vivo administration of chromic ions to mammals; this results in the appearance of chromic ions in transferrin. $^{51}CrCl_3$ given by stomach tube to rats resulted in $\geq$99% of the chromium in blood being associated with noncellular components (Hopkins and Schwarz 1964). Ninety percent of the Cr in blood serum was associated with the β-globulin fractions; 80% immunoprecipitated with transferrin (Hopkins and Schwarz 1964). In vivo and in vitro studies of the addition of chromium sources to blood or blood plasma also result in the loading of transferrin with Cr(III), although under these conditions, albumin and some degradation products also bind chromium; in fact, in vitro, more Cr may bind to albumin than transferrin. One must be careful to distinguish experimental design when examining chromium binding to serum proteins. When given orally, absorbed chromium appears in the blood essentially only as transferrin and a low-molecular-weight species; when given intravenously or added in vitro to blood or blood serum or plasma, nonphysiologically relevant binding of chromium to other species occurs. The results of the latter studies must be viewed with caution (Vincent and Stearns 2011).

Recent reports on the effects of insulin on iron transport support transferrin being the major physiological chromium transport agent. Plasma membrane recycling of transferrin receptors is sensitive to insulin as increases in insulin result in a stimulation of the movement of transferrin receptors from vesicles to the plasma membrane. The most detailed studies of Cr transferrin movement have been reported in the last few years using ^{51}Cr-labeled transferrin administered intravenously to rats. Injection of ^{51}Cr-labeled transferrin into the bloodstream resulted in a rapid and insulin-sensitive movement of chromium into the tissues as Cr transferrin; greater than 50% of the chromium is transported to the tissues within 30 min. Tissue levels of chromium were maximal 30 min after injection; decreases in tissue chromium with time were mirrored by increases in urine chromium. Thus, transferrin, in an insulin-dependent fashion, can transfer Cr to tissues from which Cr is excreted in the urine (Clodfelder and Vincent 2005).

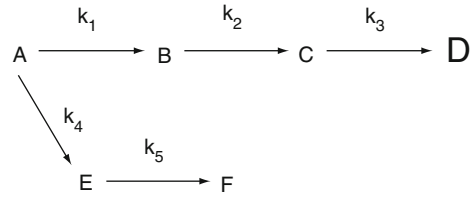
Approximately 50% of the ^{51}Cr appeared in the urine within 360 min of injection of Cr transferrin into the tail vein of rats in the absence of added insulin; insulin treatment concurrent with injection of ^{51}Cr-labeled transferrin results in approximately 80% of the label appearing in the urine within 180 min. The removal of ^{51}Cr from the blood was faster than the appearance of ^{51}Cr in the urine; the lag in time indicates that the Cr transferrin in the blood and chromium in the urine are not in direct equilibrium and that intermediates in the transport of chromium must be involved. Separation of the urine components by G-25 size exclusion chromatography revealed that chromium occurred in the urine as apparently a single low-molecular-weight species, assumed to be low-molecular-weight chromium-binding substance (LMWCr, also called chromodulin). LMWCr when added to the urine comigrated with the urine chromium (Clodfelder and Vincent 2005).

When the species of chromium in the blood plasma as a function of time were examined by S-200 size exclusion chromatography, two primary features were observed (Fig. 1). The first was Cr transferrin, which disappeared quickly from the bloodstream. With time, a low-molecular-weight species, also proposed to be LMWCr, appeared. (Two species of intermediate molecular weight are also observable in Fig. 1, but they account for $<$10% of the applied chromium and probably were degradation products of transferrin) (Clodfelder and Vincent 2005).



Chromium(III) and Transferrin, Fig. 1 Elution profiles of ^{51}Cr in blood plasma from adult rats from an S-200 column as a function of time. (**a**) Rats not receiving insulin. (**b**) Rats receiving insulin (Reproduced from Clodfelder and Vincent 2005 with the permission of the copyright holder)

This work established a clear pathway of transport of chromium starting from transport by transferrin from the bloodstream into the tissues, followed by release and processing in the tissues to form a low-molecular-weight chromium-binding species, excretion into the bloodstream, rapid clearance of the low-molecular-weight species or a similar species into the urine, and ultimately excretion as this species.



Chromium(III) and Transferrin, Fig. 2 Proposed mechanism of distribution of chromium from Cr transferrin (Reproduced from Clodfelder and Vincent 2005 with permission of the copyright holder)

Insulin stimulates the processing of chromium in the tissues. The rates of chromium movement were estimated, and on the basis of these results, a kinetic model for the movement of chromium from transferrin in the blood to LMWCr-like species in the urine was proposed (Fig. 2). The model assumes the presence of six major types of chromium: (a) Cr transferrin in the blood plasma, (b) chromium in the tissues, (c) LMWCr-like species in the plasma, (d) LMWCr-like species in the urine, (e) the larger unidentified species in the plasma, and (f) the smaller unidentified species in the plasma. Two pathways were required to fit the movement of Cr from transferrin to the urine and the Cr-binding species in the bloodstream. The first involves the transport of chromium by transferrin to the tissues (k_1), followed by the release of chromium and production and release of LMWCr-like species into the blood (k_2), and the movement of chromium as LMWCr-like species from the blood to the urine (k_3). The presence of LMWCr-like species in the tissues and in the urine necessitates the presence of LMWCr-like species in the blood plasma, although its presence appears to be masked by the smaller unidentified species. Hence, the LMWCr-like species is assumed to be kept at low steady-state levels in the blood, and k_3 is assumed to be much larger than k_1 and k_2. The second pathway includes the appearance of the larger unidentified species (k_4), which in turn is either metabolized to generate the smaller unidentified species or gives up its Cr to the smaller species (k_5). This kinetic model fit the experimental data well at the early time points but failed to simulate the gradual loss of chromium from the tissues to the urine. This failure arose because the model did not incorporate the processing and loss of chromium from the various tissues occurring at different rates. This manifested itself, for example, in a requirement for at least

a biphasic function to fit to the appearance of LMWCr-like species in the urine as a function of time (Clodfelder and Vincent 2005).

Transferrin and LMWCr

While the studies of the movement of chromium from Cr transferrin to the tissues and ultimately the urine indicated that Cr chromium from transferrin was transferred to the tissues and then to a low-molecular-weight species for clearance in the urine, the relative ability of transferrin, LMWCr, and other biomolecules have been examined. Yamamoto and coworkers have previously investigated the ability of equal molar amounts of LMWCr, transferrin, and albumin to compete for chromic ions and found that LMWCr accepted more chromium than the two serum proteins (Yamamoto et al. 1984). These investigators also examined the ability of Cr_2 transferrin to donate chromium to apoLMWCr and for LMWCr to donate chromium to transferrin. These workers reported that approximately 10% of the chromic ions in Cr_2 transferrin were transferred to apoLMWCr and that 25% of the chromic ions in LMWCr were transferred to apotransferrin (Yamamoto et al. 1984). However, the data were collected after a single time interval (60 min) at an elevated temperature (37°C). LMWCr is highly susceptible to hydrolysis, particularly at elevated temperature. In light of this, the exchange of Cr^{3+} between transferrin and LMWCr has been reexamined. Within detection limits, LMWCr with its full complement of four chromium does not release its chromium to apotransferrin over greater than 25,000 min incubation (in pH 6.5 buffer at ~4°C) (Sun et al. 2000). However, over the same time period, chromium migration from Cr_2 transferrin is significant (approximately half the chromium), consistent with the larger chromium-binding constant of apoLMWCr versus halfapotransferrin. Although a direct transfer of chromium between transferrin and LMWCr is unlikely to be physiologically relevant (as metal-containing transferrin enters the cell through receptor-mediated endocytosis and releases metal during the lowering of pH that occurs with endosomal maturation), these results illustrate the ability of LMWCr to sequester chromic ions in the presence of other metal-binding species (Sun et al. 2000).

Significance of Chromium Transport by Transferrin

While chromium has generally been believed to be an essential trace element for approximately 50 years, recent research has not supported a role for chromium (Vincent and Stearns 2011). This has implications for the significance of chromium transport by transferrin. The ability of transferrin to bind chromium in vivo and transport chromium to tissues, particularly muscle, in an insulin-sensitive fashion is supportive of suggestions that chromium played a role in optimization of insulin signaling. Alternatively, transferrin could serve a role in detoxification of chromium. Transferrin, in such a role, could be viewed as scavenging absorbed dietary chromium from the bloodstream and delivering the metal to the tissues where it is ultimately bound to a low-molecular-weight peptide and rapidly cleared from the body via the urine.

Definition

Chromium (III) is a transition metal, and its trivalent state is the form most prevalent in organic complexes (Vincent 2004; Cefalu and Hu 2004). Chromium (III) supplements are widely consumed worldwide. Most chromium (III) in the diet is chromium (III), and any hexavalent chromium in food or water is reduced to chromium (III) in the acidic environment of the stomach.

Background

Various studies have reported lower levels of chromium (III) in the blood, lenses, and toenails of diabetic patients compared with those of the normal population (Rajpathak et al. 2004). Thus, subclinical chromium (III) deficiency may be a contributor to glucose intolerance, insulin resistance, and cardiovascular disease, particularly in aging populations or in populations that have increased chromium (III) requirements because of high sugar diets. Epidemiological data concerning chromium (III) intake and the risk of CVD are limited. Results from two case–control studies suggest an inverse association between chromium (III) levels in toenails and the risk of myocardial infarction in the general population. Similarly, a recent report within the Health Professionals Follow-up Study has found lower levels of toenail chromium (III) among men with diabetes and CVD compared with healthy control subjects (Rajpathak et al. 2004).

Chromium Content of Food

Foods with high chromium (III) concentrations include whole grain products, green beans, broccoli, and bran cereals. The chromium (III) content of meats, poultry, and fish varies widely since chromium (III) may be introduced during transport, processing, and fortification of foods. Not only are foods rich in refined sugars low in chromium (III), they actually promote chromium (III) loss. Based on the chromium (III) content of well-balanced diets, adequate intake values for chromium (III) in adults have been established at 35 μg/day in men and 25 μg/day in women. Although there are no national survey data available on chromium (III) intake, a study of self-selected diets of US adults indicates that the chromium (III) intake of a substantial proportion of subjects may be well below the adequate intake values; similar results have been shown in the United Kingdom, Finland, Canada, and New Zealand.

Cytokines and Chromium (III)

Cytokines interact with cells of the immune system to regulate the body's response to disease and infection. The cytokines locate target immune cells and interact with receptors on the target immune cells by binding to them. Overproduction of certain cytokines, such as interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF-α), is involved in inflammation and insulin resistance that can contribute to the development of CVD. The levels of pro-inflammatory cytokines are elevated in the blood of many subjects with CVD and diabetes (Jain et al. 2007a; Jain and Kannan 2001). An increase in circulating levels of TNF-α and IL-6 decreases insulin sensitivity. Elevated circulating levels of TNF-α and IL-6 can induce expression of adhesion molecules and thus monocyte-endothelial cell adhesion, now recognized as an early and rate-limiting

step in vascular inflammation and the development of vascular disease.

Chromium (III) supplementation decreased secretion of IL-8, IL-6, and TNF-α in U937 monocyte cells exposed to high levels of glucose (Jain and Kannan 2001). Similarly, secretion of TNF-α and IL-6 was inhibited when isolated monocytes from human volunteers were used. These studies provide evidence that chromium (III) supplementation inhibits the increase in pro-inflammatory cytokine secretion and oxidative stress levels caused by exposure to high levels of glucose or ketosis (mimicking diabetes) in cultured monocytes (Jain and Kannan 2001; Jain et al. 2007b). Myers et al. (1997) determined the effect of growth hormone or chromium picolinate (CP) on swine metabolism and inflammatory cytokine production after endotoxin challenge and showed that IL-6 was not affected by CP or recombinant porcine somatotropin (PST) treatments. However, both CP and PST lowered the TNF-α response to lipopolysaccharide (LPS), similar to results observed in isolated monocytes exposed to high glucose levels in a cell culture model.

Studies using cobalt chromium alloy particles did not show any effect on TNF-α, IFN-α, IL-6, or IL-12 secretion or on mRNA expression of cytokines in a J774A.1 cell line exposed to chromium. In contrast, A549 human lung carcinoma cells pretreated with chromium showed inhibition of TNF-α stimulated expression of IL-8 and NFkB. Chromium (III) did not inhibit the TNF-α-stimulated IKB-alpha degradation or the translocation of the NFkB-binding protein to the nucleus. Both chromium chloride and CP showed a beneficial effect in reducing oxygen radical production and increasing glucose uptake and phagocytosis of *Escherichia coli* in the presence and absence of insulin using pulmonary alveolar macrophages.

The inhibitory effects of chromium (III) on pro-inflammatory cytokines were also observed in vivo in diabetic rats supplemented with chromium (III) compounds (Jain et al. 2007a, 2010). The levels of TNF-α, IL-6, IL-8 and MCP-1, and ICAM-1 were significantly lower in diabetic rats supplemented with chromium (III). It appears that the effects of chromium (III) on the secretion or expression of different cytokines may be dependent on the chromium (III) concentration and the specific cells. The effect of chromium (III) supplementation on lowering pro-inflammatory cytokines in the blood was associated with a beneficial effect in lowering elevated blood levels of glycemia, cholesterol, and triglycerides, as well as lowering oxidative stress in streptozotocin-treated diabetic rats. These animal studies suggest that chromium (III) supplementation can lower the level of vascular inflammation associated with diabetes.

The influence of chromium (III) on cytokines and inflammatory markers in cell culture and in vivo studies may be mediated by different mechanisms. One potential mechanism is the antioxidant effect of chromium (III). Several investigators have reported that chromium (III) supplementation lowers the blood levels of oxidative stress markers in an animal model as well as in diabetic patients (Jain et al. 2010). Chromium (III) activates glutathione reductase activity in a red blood cell model. Thus, it is possible that chromium (III) reduces oxidative stress by increasing the detoxification of oxygen radicals and the maintenance of cellular GSH. Whether chromium (III) supplementation has beneficial effects on oxidative stress, on pro-inflammatory cytokines, or on GSH in all of the cells crucial to atherogenesis, such as monocytes and endothelial cells, is not known. Chromium (III) may influence the immune system by modulating anti-inflammatory cytokines.

Hormones and Chromium (III)

Insulin is a major hormone that is critical to the metabolism and storage of carbohydrate, fat, and protein in the body. The role of chromium (III) in glucose metabolism has been known since 1955 when Metz identified chromium (III) containing glucose tolerance factor (GTF). GTF is a complex of chromium (III), glutathione, and nicotinate. Glutathione, a tripeptide of glutamate, glycine, and cysteine, is known to bind insulin tightly. The oligopeptide known as low-molecular-weight chromium (III)-binding substance is composed of glycine, cysteine, aspartate, and glutamate coordinated by chromic ions (Vincent 2004). The effects of chromium (III) on Zucker diabetic fatty (ZDF) rats, a genetic model of type 2 diabetes, was examined using 1,000 μg chromium (III)/kg body mass (Bennett et al. 2006). Treatment with chromium (III) caused significantly lower concentrations of blood insulin along with low levels of cholesterol and triglycerides. Similarly, a diet containing 5 mg chromium (III)/kg diet for 10 weeks caused a nearly 16% reduction in blood

insulin concentrations in normal Wistar rats. It has been proposed that chromium (III) insulin complexes enhance the action of insulin on glucose metabolism and lower blood sugar levels. The crystallographic analyses of chromium (III)-Salen-soaked cubic insulin crystals revealed B21 glucose to be binding site for chromium (III) (Sreekanth et al. 2008). Bennett et al. (2006) also found a significant decrease in blood concentrations of leptin in ZDF rats supplemented for 4 weeks with chromium (III) (250–100 μg/kg BW).

The effects of a variety of dietary chromium (III) sources on adrenal steroid hormones have been investigated, but results have been inconclusive. Dietary chromium (III) decreased circulating adrenal steroids in stressed young calves, in epinephrine challenged lambs, in stressed dairy cows, and in postmenopausal women. Other studies have shown no effect of chromium (III) supplementation on adrenal hormones. Chromium (III) has a significant effect on insulin secretion from the islets of Langerhans and on catecholamine secretion from bovine medullary cells. Chromium (III) supplementation decreased the secretion of both cortisol and dehydroepiandrosterone in H259 R cells. The inhibition of steroid genesis by chromium (III) may explain the decreased blood cortisol concentration in chromium (III)-supplemented stressed calves and cows. However, other studies did not report any change in cortisol levels in chromium (III)-supplemented immune-stressed or thermally stressed pigs. The discrepancy of cortisol responses in chromium (III)-supplemented animals may be attributed to the dosage, source of chromium (III) or duration of dietary treatment, source and intensity of stress, and animal species. However, blood levels of cortisol were consistently lower when high-dose supplementation with chromium (III) (>0.4 mg/kg) was used in different studies.

Transthyretin (TTR) binds and transports thyroxin (T4) in human plasma. In vitro studies demonstrate that chromium (III) increased the T4-binding capacity of wild-type and amyloidogenic V30M-TTR. Chromium (III) and T4 cooperatively suppressed in vitro fibril formation due to the stabilization of wild-type TTR and V30M-TTR. Thus, transthyretin amyloid fibril formation, which is triggered by the dissociation of tetrameric TTR, is suppressed by chromium (III) in vitro (Sato et al. 2006). Other studies have also reported that the distribution of chromium (III) in the body is influenced by thyroid hormone activity but not by calcitonin or parathyroid hormone. This suggests that thyroid hormone controls cellular chromium (III) transport. Recent studies suggest that supplementation with chromium (III) nanoparticles significantly lowers serum concentrations of insulin, cortisol, insulin-like growth factor 1, and IgG after chromium (III) supplementation (150–450 μg/kg BW for 8 weeks in Sprague–Dawley rats.

The studies of Vincent et al. (2004) have shown that LMW chromium (III) is stored in the cytosol of insulin-sensitive cells in an apo (unbound form) that is activated by binding four chromium (III) ions. This activation is the result of a series of steps stimulated by insulin signaling. LMW chromium (III) potentiates the action of insulin once insulin has bound to its receptor. This insulin potentiating or autoamplification action stems from the ability of LMW chromium (III) to maintain stimulation of tyrosine kinase activity. Once insulin is bound to its receptor, LMW chromium (III) binds to the activated receptor on the inner side of the cell membrane and increases the insulin-activated protein kinase activity by eightfold. There is also evidence that the autoamplification effect of LMW chromium may be enhanced by the inhibition of phosphotyrosine phosphatase, which inactivates tyrosine kinase. LMW chromium (III) actually activates membrane-associated phosphotyrosine phosphatase in insulin-sensitive cells. As insulin levels drop and receptor activity diminishes, LMW chromium (III) is transported from the cell to the blood and excreted in the urine.

Trivalent chromium, the form found in foods and dietary supplements, is believed to be safe. The most popular complexed form is chromium picolinate, although chromium niacinate and chromium citrate are also used as nutritional supplements. Absorption of chromium (III) is low, as is common for other polyvalent minerals, ranging from less than 1% for chromium (III) chloride to above 1% for chromium (III)-niacinate to 1–3% for chromium (III) picolinate in rat studies. Human absorption from food is estimated at about 2–3% and 5–10% from brewer's yeast. In animal studies, the retention of chromium (III) from supplementation occurred chiefly in the kidneys, followed by liver and heart muscle. The order of retention was chromium (III) picolinate > chromium (III) niacinate > chromium (III) chloride, which varies from the order of absorption. No disturbances in the

organ systems showing high concentrations of chromium (III) have yet been detected.

In conclusion, trivalent chromium can lower oxidative stress by improving glucose and lipid metabolism. It has been proposed that chromium (III) supplementation increases the amount of a chromium (III)-containing oligopeptide present in the insulin-sensitive cells that bind to the insulin receptor, markedly increasing the activity of the insulin-stimulated tyrosine kinase and phosphorylation of insulin receptor substrate-1 and glucose transporter (Jain et al. 2010). Oxidative stress associated with diabetes activates NFkB, which then activates the insulin resistance cascade. Hyperglycemia is known to increase reactive oxygen species generation and oxidative stress in diabetic rats and patients. Oxidative stress is a known activator of NFkB, which undergoes nuclear translocation and serine phosphorylation at residue 276 in its p65 subunit. It then associates with surrounding chromatin components and binds with DNA, which promotes the transcription of pro-inflammatory cytokines that mediate the insulin resistance cascade. Thus, the effect of chromium (III) on glucose and lipid metabolism is likely to be mediated by lowering levels of the pro-inflammatory cytokines TNF-α, IL-6, and MCP-1, which are known to cause insulin resistance.

Concluding Remarks

Chromium (III) supplementation in the form of commercially available chromium dinicotinate (CDN) or chromium picolinate (CP) is widely used by the public. Subclinical chromium (III) deficiency may contribute to insulin resistance and CVD, particularly in aging and diabetic populations. Although not in all studies, some studies of diabetic patients and diabetic animals have reported decreased blood glucose or decreased insulin requirements after chromium (III) supplementation (Cefalu and Hu 2004). A number of animal studies have demonstrated beneficial effects of chromium (III) supplementation on circulating levels of cytokines and hormones, which in turn may influence biological functions and diseases such as diabetes and cardiovascular disease (CVD). However, studies on the effect of chromium (III) supplementation on cytokines and hormones in humans have yet to be done.

Definition

Hexavalent chromium (Cr(VI)) is a highly reactive metal capable of causing cellular oxidative damage through the generation of intracellular reactive oxygen species (ROS). ROS refers to a diverse group of reactive, short-lived, oxygen-containing species such as $O_2^{\bullet -}$, H_2O_2, and $^{\bullet}OH$. Overproduction or decreased removal of ROS leads to oxidative stress in tissues and cells. Cr(VI) can be reduced by various cellular reductants to its lower oxidation states, such as Cr(V) and Cr(VI). During the reduction process, molecular oxygen is reduced to $O_2^{\bullet -}$, which reduces to H_2O_2 upon dismutation. H_2O_2 reacts with Cr(V) or Cr(IV) to generate $^{\bullet}OH$ radicals. Thus, Cr(VI) is able to generate a spectrum of ROS. Biological systems are normally protected against oxidative injury caused by free radical reactions due to enzymatic and nonenzymatic antioxidants. When the balance between prooxidants and antioxidants shifts in favor of prooxidants, chromium-induced oxidative cell damage occurs.

Introduction

Cr(VI) compounds are known to cause serious toxic and carcinogenic effects. Intensive epidemiological studies of industrially exposed chromium workers have identified chrome plating, chrome pigment manufacturing, leather tanning, and stainless steel production as sources of potential exposure to this metal. Because of its wide industrial application, environmental contamination is considered to be an additional source of human exposure to Cr(VI). However, the biological mechanisms responsible for the initiation and progression of diseases resulting from exposure to Cr(VI) are not fully understood. A growing body of evidence reveals the correlation between Cr(VI)-induced generation of reactive oxygen species and cytotoxicity, or carcinogenesis.

Hexavalent chromium (Cr(VI)) and trivalent chromium (Cr(III)) are two stable chromium oxidation states found in nature. Cr(VI) is able to enter into cells through an anion transport system. If Cr(VI) enters cells, it is reduced by cellular reductants to its lower oxidation states, pentavalent chromium (Cr(V)) and tetravalent chromium Cr(IV). These intermediate states of chromium are reactive and capable of producing ROS. ROS are known to cause oxidative damage including DNA strand breaks, base modification, and lipid peroxidation (Ding and Shi 2002; Yao et al. 2008). Thus, it is generally believed that Cr(VI) can induce cell death by oxidative stress (Son et al. 2010).

Recent studies have suggested that the reduction of Cr(VI) to its lower oxidation states and related free radical reactions play an important role in Cr(VI)-induced carcinogenesis. Cr(VI) has been demonstrated to induce a variety of DNA lesions, such as single-strand breaks, alkali-labile sites, and DNA-protein cross-links. In contrast, most Cr(III) compounds are relatively nontoxic, noncarcinogenic, and nonmutagenic due to Cr(III)'s difficulty in entering the cells. Since Cr(VI) does not react with isolated DNA, the reduction of Cr(VI) by cellular reductants to lower oxidation states has been considered an important step in the mechanism of Cr(VI)-induced carcinogenesis (Kortenkamp et al. 1996).

Cr(VI)-Induced ROS Generation

In general, there are two pathways in the mechanism of Cr(VI)-mediated ROS generation. Cr(VI) is able to

directly generate ROS during its reduction and subsequent reaction with cellular small molecules such as glutathione (GSH) and H_2O_2. A second, indirect pathway involves the stimulation of cells by Cr(VI). Cr(VI)-stimulated cells may increase the activity of NAD(P)H oxidase and generate ROS.

Direct Generation of ROS

Reaction of Cr(VI) with GSH generates glutathione-derived thiyl radical ($GS^{\bullet}$). An increase in GSH concentration enhances the $GS^{\bullet}$ generation. Reaction of Cr(VI) with cysteine or penicillamine also generates a corresponding thiyl radical (Shi et al. 1994a). The reaction equation is

$$\mathrm{Cr(VI)} + \mathrm{GSH} \rightarrow \mathrm{Cr(V)} + \mathrm{GS}^{\bullet} \qquad (1)$$

The thiyl radicals generated by this reaction may cause direct cellular damage. These radicals may also react with other thiol molecules to generate a $O_2^{\bullet-}$ radical (Ding and Shi 2002; Yao et al. 2008) as

$$\mathrm{GS}^{\bullet} + \mathrm{RSH} \rightarrow \mathrm{ESSR}^{\bullet-} + \mathrm{OH}^{-} \qquad (2)$$

$$\mathrm{ESSR}^{\bullet-} + \mathrm{O_2} \rightarrow \mathrm{RSSR} + \mathrm{O_2}^{\bullet-} \qquad (3)$$

The generation of $O_2^{\bullet-}$ radicals leads to the formation of H_2O_2 through a dismutation reaction. $O_2^{\bullet-}$ is able to cause additional oxygen radical generation by reducing Cr(VI) to Cr(V). Cr(V) can react with H_2O_2 to generate $^{\bullet}OH$ radical through a Fenton-like reaction. Reaction of Cr(V) or Cr(IV) with H_2O_2 generates $^{\bullet}OH$ radicals (Shi and Dalal 1992):

$$\mathrm{Cr(IV)} + \mathrm{H_2O_2} \rightarrow \mathrm{Cr(V)} + {}^{\bullet}\mathrm{OH} \qquad (4)$$

$$\mathrm{Cr(V)} + \mathrm{H_2O_2} \rightarrow \mathrm{Cr(VI)} + {}^{\bullet}\mathrm{OH} \qquad (5)$$

These reactions are similar to the Fenton reaction $Fe(II) + H_2O_2 \rightarrow Fe(III) + {}^{\bullet}OH$; the reactions of Cr(IV) or Cr(V) with H_2O_2 are called Fenton-like reactions. Using xanthine and xanthine oxidase as a source of $O_2^{\bullet-}$ radicals, it has been demonstrated that Cr(VI) can be reduced to Cr(V) by $O_2^{\bullet-}$ (Shi and Dalal 1992):

$$\mathrm{Cr(VI)} + \mathrm{O_2}^{\bullet-} \rightarrow \mathrm{Cr(V)} + \mathrm{O_2} \qquad (6)$$

A combination of reaction Eqs. (5) and (6) leads to

$$\mathrm{O_2}^{\bullet-} + \mathrm{H_2O_2} \xrightarrow{\mathrm{Cr(VI)/Cr(V)}} {}^{\bullet}\mathrm{OH} + \mathrm{O_2} + \mathrm{OH}^{-} \qquad (7)$$

Reaction Eq. (7) is similar to the Fe(II)/Fe(III) Haber-Weiss reaction, and thus reaction (7) can be called a Haber-Weiss-like reaction. This reaction could become particularly significant during phagocytosis, when macrophages and other cellular constituents generate large quantities of $O_2^{\bullet-}$ radicals in the so-called respiratory burst. It has been reported that a significant portion of oxygen consumed by phagocytes is first converted to $O_2^{\bullet-}$ radicals (Yao et al. 2008). However, further conversion of $O_2^{\bullet-}$ to $^{\bullet}OH$ is too slow to be physiologically significant, unless a suitable metal ion is present as a Haber-Weiss catalyst. The finding that Cr(VI) can function as a Haber-Weiss catalyst may provide a basis for the known critical role of molecular oxygen in the genotoxic and carcinogenic reaction of Cr(VI)-containing particles. Using electron spin resonance (ESR) spin trapping, it has been demonstrated that both $^{\bullet}OH$ and Cr(V) were generated in Cr(VI)-stimulated cells (Wang et al. 2000). The Cr(V) generated was identified as a Cr(V)-NADPH complex. Addition of NADPH enhanced the generation of these two kinds of reactive species. Addition of H_2O_2 enhanced the $^{\bullet}OH$ generation, while catalase inhibited it, indicating that a Fenton-like reaction was involved.

Indirect Generation of ROS

Although the mechanisms of Cr(VI)-induced $^{\bullet}OH$ generation may involve the direct interaction of Cr(VI) with cellular small molecules, such as GSH and glutathione reductase, an indirect mechanism may also occur. This indirect mechanism may involve activation of a certain signal transduction pathway to upregulate certain ROS-generating enzymes, such as NADPH oxidase. Treatment of cells with Cr(VI) increases oxygen consumption and increases the level of intracellular $O_2^{\bullet-}$. NADPH oxidase is one of the major enzymes that consumes most of the oxygen and converts it to $O_2^{\bullet-}$ during respiratory burst (Shi and Dalal 1990). It is the enzyme that catalyzes the transfer of one electron from NADPH to oxygen, leading to the formation of $O_2^{\bullet-}$.

Oxidative DNA Damage

Oxidative DNA lesions are one of the primary factors underlying Cr(VI)-induced apoptosis and carcinogenesis, the topics of the following two sections. Cr(VI) is able to cause DNA damage in both cell-free and cellular system. Studies utilizing the λ Hind III DNA digest have found that DNA damage was induced by free radical generation system consisting of a mixture of Cr(VI) and ascorbate, with and without H_2O_2 (Shi et al. 1994b). A significant amount of DNA strand breaks occur when DNA is incubated with Cr(VI) and ascorbate. The amount of DNA strand breaks is dependent upon the relative concentrations of Cr(VI) and ascorbate, which facilitates Cr(VI) reduction to Cr(V). Addition of H_2O_2 has been found to drastically enhance the DNA damage. Alternatively, addition of Mn(II) reduces DNA damage through the removal of Cr(IV) and inhibition of the Cr(IV)-mediated Fenton-like reaction.

The amount of DNA strand breaks present following Cr(VI) administration correlate with the amount of free radicals generated. $^{\bullet}OH$ radical can interact with guanine residues at several positions to generate a range of products, of which the most studied one is 8-hydroxy-deoxyguanosine (8-OHdG). The formation of this adduct is considered a marker to implicate ROS in the mechanism of toxicity and carcinogenicity of a variety of agents. Using single-cell gel electrophoresis, Cr(VI) has been shown to cause DNA damage in the human prostate cell line, LNCaP. Cr(VI)-induced ROS generation and, accordingly, DNA damage, is stronger in Ras protein–overexpressing LNCaP than in wild type (Liu et al. 2001). This indicates that Cr(VI)-generated ROS are capable of generating characteristic oxidative DNA lesions, including 8-OHdG.

Cr(VI)-Induced Apoptosis by Oxidative Stress

Apoptosis is a well-recognized form of cell death with some typical hallmarks, such as changes in nuclear morphology, chromatin condensation, and fragmentation of chromosomal DNA. During the last decade, there has been an overwhelming interest in apoptosis and the elucidation of mechanisms controlling this process. Apoptosis is an essential process required for development, morphogenesis, immune regulation, tissue remodeling, and some pathological reactions.

Under normal circumstances, the cell cycle proceeds without interruptions. However, when damage occurs particularly to DNA, most normal cells have the capacity to arrest proliferation in the G1/S or G2/M phase and then resume proliferation after the damage is repaired. The cell cycle controls the onset of DNA replication and mitosis in order to ensure the integrity of the genome. Lack of fidelity in DNA replication and maintenance can result in mutations, leading to cell death or, in multicellular organisms, cancer. Using flow cytometric analysis of DNA content, Cr(VI) is able to induce cell cycle arrest at the G2/M phase in human lung epithelial A549 cells; while at relatively low concentrations Cr(VI) causes cell cycle arrest, at relatively high concentrations Cr(VI) induces apoptosis, and ROS generated by Cr(VI)-stimulated cells are involved in Cr(VI)-induced cell cycle arrest and among the ROS H_2O_2 plays a key role (Zhang et al. 2001).

Since apoptosis is an important factor influencing the malignant transformation of cells, the regulation of cell apoptosis may be critical in metal-induced carcinogenesis. Cr(VI) itself is incapable of reacting with macromolecules such as DNA, RNA, proteins, and lipids (Shi et al. 2000). Instead, Cr(V) or Cr(III), intermediates of Cr(VI) reduction, can form covalent interactions with DNA and other macromolecules, a process that activates DNA-dependent protein kinases (DNA-PKs) and induces subsequent p53 activation and cell apoptosis (Singh et al. 1998). The DNA-damaging effect of Cr(VI) may also be through ROS generated during Cr(VI) reduction.

Activation of the p53 tumor suppressor protein is considered to be a major step in apoptosis induced by Cr(VI) (Son et al. 2010; Wang et al. 2000). p53 is considered an oxidative stress response transcription factor and can be activated in response to a variety of stimuli, such as UV, γ radiation, and nucleotide deprivation. Several mechanisms are involved in Cr(VI)-induced p53 activation. First, direct DNA damage by Cr(VI) or ROS generated during cellular Cr(VI) reduction activates upstream kinases, including DNA-PK, ATM, ATR, and others, for p53 phosphorylation and activation (Yao et al. 2008). Second, the p53 protein contains several redox-sensitive cysteines critical for the DNA binding activity of p53 (Meplan et al. 2000).

Evidence indicates that Cr(VI)-dependent p53 activation is ROS-mediated. Several recent studies have highlighted the importance of H_2O_2 and hydroxyl radical in Cr(VI)-induced p53 activation and cell death (Son et al. 2010; Wang et al. 2000; Ye et al. 1999;

Ye et al. 1995). SOD has been shown to increase p53 activity by enhancing the production of H_2O_2 from $O_2^{\bullet -}$. Alternatively, catalase, a H_2O_2 scavenger, inhibits p53 activation through elimination of $^{\bullet}OH$ radical generation. Sodium formate and aspirin, $^{\bullet}OH$ radical scavengers, also suppress p53 activation. Deferoxamine, a metal chelator, inhibits p53 activation by chelating Cr(V) to make it incapable of generating radicals from H_2O_2. NADPH, which accelerates the one-electron reduction of Cr(VI) to Cr(V) and increased $^{\bullet}OH$ radical generation, enhances p53 activation. Thus, $^{\bullet}OH$ radicals generated from Cr(VI) reduction are primarily responsible for Cr(VI)-induced p53 activation. The activation of p53 is at the protein level instead of the transcriptional level (Wang and Shi 2001).

As a transcription factor, p53 is able to upregulate the expression of genes involved in either ROS production or metabolism, including quinone oxidoreductase (Pig3), proline oxidase (Pig6) homologues, glutathione transferase (Pig12), and glutathione peroxidase (GPx) (Polyak et al. 1997). Moreover, p53 also activates the expression of several genes that directly control or regulate the process of apoptosis.

It has been shown that Cr(VI)-derived ROS initiate early apoptosis prior to activation of p53 protein (Ye et al. 1999). Alternate pathways have been implicated in activation of Cr(VI)-induced apoptosis, including MAPK-dependent signaling pathways and direct mitochondrial damage (Son et al. 2011). Although p53 is not necessarily required for initiation of Cr(VI)-induced apoptosis, it has been shown to significantly enhance late-stage apoptosis by transcriptional activation of p53-mediated apoptotic cascades. Therefore, Cr(VI) induces apoptosis through both p53-dependent and p53-independent pathways through a common ROS-mediated pathway.

Cr(VI)-Induced Carcinogenesis by Oxidative Stress

Cr(VI) is a known human carcinogen. The mechanisms underlying Cr(VI)-induced carcinogenesis are multifold. These include direct and indirect DNA damage, as discussed previously, as well as activation of oncogenic cell signaling proteins. These oncogenic proteins, or oncoproteins, typically promote cell survival, growth, and proliferation. Tumor suppressors, as their name suggests, repress carcinogenesis and tumorigenesis through causing cell senescence and/or apoptosis. These oncogenic pathways will be discussed in detail next.

NF-κB

NF-κB is considered to be a primary oxidative stress response transcription factor. NF-κB promotes cell survival by stimulating the transcription of a variety of cell survival genes. Cr(VI) stimulates NF-κB activation in vitro, an effect which is attenuated by the inhibition of IκB kinase (IKK), an upstream promoter of NF-κB phosphorylation. The reduction of Cr(VI) to lower oxidation states is required for Cr(VI)-induced NF-κB activation. The cotreatment of aspirin, an antioxidant, has been shown to attenuate NF-κB activation by Cr(VI). This indicates that hydroxyl radicals generated by Cr(V)- and Cr(IV)-mediated Fenton-like reactions likely play a prominent role in the mechanism of Cr(VI)-induced NF-κB activation. The inhibition of IKK, an upstream NF-κB activator, attenuates NF-κB activation by Cr(VI). This indicates that ROS acts as the ultimate upstream signal regulating NF-κB activation by Cr(VI), with IKK acting as a downstream terminal kinase.

NF-κB binding sites serve as an enhancer element in c-myc, a gene associated with the formation of Burkitt's lymphoma (Ji et al. 1994). Cr(VI) could induce expression of c-myc proto-oncogene via NF-κB activation. It is possible that NF-κB activation and a subsequent expression of NF-κB-regulated proto-oncogenes, such as c-myc, may play a role in the induction of neoplastic transformation by Cr(VI).

AP-1

Another important transcription factor whose activity is stimulated by Cr(VI) is AP-1. AP-1 is a multimeric protein consisting of Jun (c-Jun, JunB, and JunD) and Fos (c-Fos, FosB, Fra1, and Fra2) subunits. AP-1 binds to the TRE/AP-1 DNA response elements and regulates many kinds of early response gene expression (Munoz et al. 1996). Activation of AP-1 results in the overexpression of c-Jun and other proto-oncogenes. A number of mitogen-activated protein kinases (MAPK) members participate in the activation of AP-1 hierarchically through divergent kinase cascades. MAPKs, such as c-Jun-N-terminal kinase (JNK) and p38, are activated by a specific MAPK kinase (MAPKK) through phosphorylation of conserved threonine and tyrosine residues. In turn, a MAPKK is activated by a specific MAPKK kinase (MAPKKK) through phosphorylation of conserved threonine and/or serine residues.

Cr(VI) is capable of inducing AP-1 activation (Chen et al. 2000). The induction of AP-1 by Cr(VI)

is associated with phosphorylation of the MAPKs p38 and JNK but not that of the extracellular-signal-regulated kinase (ERK). Cotreatment with aspirin has been shown to attenuate AP-1 activation by Cr(VI). Inhibition of p38 also decreases Cr(VI)-induced AP-1 activation. These results suggest that ROS serves as the ultimate upstream signal initiating activation of AP-1, with p38 acting as the downstream executive kinase.

HIF-1 and VEGF

Hypoxia-inducible factor 1(HIF-1) is a heterodimeric basic helix-loop-helix transcription factor, composed of HIF-1α and HIF-1β/ARNT subunits. HIF-1α is unique to HIF-1 and is induced exponentially in response to a decrease in cellular O_2 concentration. In contrast, HIF-1β is identical to the aryl hydrocarbon nuclear translocator (ARNT) that heterodimerizes with an aryl hydrocarbon receptor and is not regulated by cellular oxygen tension.

HIF-1 regulates the expression of many genes including vascular endothelial growth factor (VEGF), erythropoietin (EPO), heme oxygenase 1, aldolase, enolase, and lactate dehydrogenase A. High levels of HIF-1 activity in cells are correlated with tumorigenicity and angiogenesis in nude mice. HIF-1 is induced by the expression of oncogenes, such as v-Src and Ras, and is overexpressed in many human cancers. HIF-1 activates the expression of VEGF gene at the transcriptional level.

Vascular endothelial growth factor (VEGF) is an essential protein for tumor angiogenesis. VEGF plays a key role in tumor progression and angiogenesis. Inhibition of VEGF expression and function of its receptor dramatically decreases tumor growth, invasion, and metastasis in animal models. Tissue hypoxia is a major inducer for the expression of VEGF in tumors. Somatic mutations, such as oncogene Ras activation and tumor suppressor gene p53 inactivation, also increased VEGF expression.

Cr(VI) induces HIF-1 activity through the specific expression of HIF-1α, but not the HIF-1β subunit, and increases the level of VEGF expression in DU145 human prostate carcinoma cells (Gao et al. 2002). To dissect the signaling pathways involved in Cr(VI)-induced HIF-1 expression, p38 MAP kinase signaling was required for HIF-1α expression induced by Cr(VI). Neither PI3K nor ERK activity was required for Cr(VI)-induced HIF-1 expression. Cr(VI) induced expression of HIF-1 and VEGF through the production of ROS in DU145 cells. The major species of ROS for the induction of HIF-1 and VEGF expression is H_2O_2. These results suggest that the expression of HIF-1 and VEGF induced by Cr(VI) may be an important signaling pathway in Cr(VI)-induced carcinogenesis.

Tyrosine Phosphorylation

Tyrosine phosphorylation is an important step in the regulation of many key cellular functions. It is involved in control of cell proliferation, differentiation, cell-cycle regulation, cell signal transduction, metabolism, transcription, morphology, adhesion, ion channels, and cancer development. Cr(VI) increased tyrosine phosphorylation in human epithelial A549 cells in a time-dependent manner (Qian et al. 2001). N-acetyl-cysteine (NAC), a general antioxidant, inhibited Cr(VI)-induced tyrosine phosphorylation. Catalase (a scavenger of H_2O_2), sodium formate, and aspirin (scavengers of $^{\bullet}OH$ radical) also inhibited the increased tyrosine phosphorylation induced by Cr(VI). H_2O_2 and $^{\bullet}OH$ radicals generated by cellular reduction of Cr(VI) are responsible for the increased tyrosine phosphorylation induced by Cr(VI).

Summary

Cr(VI) is able to generate ROS in various biological systems. Reduction of Cr(VI) to its low oxidation states, such as Cr(V) and Cr(IV), is an important step. Fenton-like and Haber-Weiss-type reactions are common pathways for Cr(VI)-induced ROS generation. Cr(VI) may also be able to generate ROS through stimulation of the cells and upregulation of certain ROS generating proteins, such as NADPH oxidase. When the ROS present in the cellular system overpower the defense systems, oxidative stress will occur. The persistent oxidative stress caused by Cr(VI) exposure may play a key role in activation of transcription factors NF-κB, AP-1, p53, and HIF-1; regulation of cell cycle; and induction of apoptosis. All of these processes could be involved in the Cr(VI)-induced carcinogenic activation.

Synonyms

Cr, Element 24, [7440-47-3]

Definition

Chromium is a metallic element in the first transition series, Group IVB (6).

General Chromium Chemistry and Biochemistry

Chromium (Cr, atomic weight, 51.996; atomic number, 24) is an abundant metallic element usually found associated with iron-containing minerals and ores; chromite ($FeCr_2O_4$) is the most important source. The name "chromium" is derived from the Greek, $\chi\rho\acute{\omega}\mu\alpha$ (color), referring to the intense coloration of many Cr compounds, such as $PbCrO_4$ (crocoite), a yellow pigment. Cr metal resists corrosion due to the formation of an oxide layer that passivates its surface (*cf.* aluminum). Cr metal is used in iron and stainless steel alloys for its hardening and anticorrosion properties; it is also used to electroplate surfaces.

Cr belongs to the first transition series, possesses an [Ar] $3d^5$ $4s^1$ electronic configuration, and can form compounds in every oxidation state from −2 to +6. The biologically important oxidation states include those from +2 to +6. The most prevalent oxidation states encountered are Cr(III) and Cr(VI); Cr(III) is the most thermodynamically stable state. While the highly charged Cr(VI) ([Ar] $3d^0$) metal center is unstable, it is kinetically stabilized by the presence of the oxo (O^{-2}) ligands. Thus, the chemistry of the higher oxidation states is dominated by the tetrahedral oxyanions of Cr(VI), namely, chromate (CrO_4^{-2}), hydrogen chromate ($HCrO_4^{-1}$), and dichromate ($Cr_2O_7^{-2}$). These three oxyanions are in equilibrium in a pH- and concentration-dependent manner. Therefore, oxyanions of Cr(IV) exist and are soluble over the entire range of pH. The structures and oxyanion chemistry of chromium trioxide (CrO_3), chromate, and dichromate are analogous to those of sulfur trioxide (SO_3), sulfate (SO_4^{-2}), and pyrosulfate ($S_2O_7^{-2}$), respectively. The Cr(VI) oxyanions are important as strong oxidants in analytical chemistry and in industry, and because of the health hazards they pose to biological organisms. The ability of chromium to pass through various biological compartments as a −2 oxyanion contributes to its hazardous properties. Cr(IV) and Cr(V) compounds readily undergo disproportionation, which may impede their characterization. Cr(III) and the higher oxidation states are hard Lewis acids and prefer oxygen, fluoride, or other hard donors; Cr(II) and lower states are softer acids and may accept nitrogen, carbon, and sulfur donors.

Chromium, Physical and Chemical Properties, Table 1 Comparison of M(III) hydroxide solubility products; a larger pK_{sp} indicates a more favorable reaction (Lide 2009)

M(III) hydroxide	K_{sp}	pK_{sp}
$Fe(OH)_3$	2.79×10^{-39}	38.5
$Ga(OH)_3$	7.28×10^{-36}	35.1
$Al(OH)_3$	3×10^{-34}	33.5
$Cr(OH)_3$	6.7×10^{-31}	*30.2*
$Nd(OH)_3$	1.1×10^{-26}	25.9
$Ce(OH)_3$[a]	2×10^{-20}	19.7

[a]Ce(III) hydrolysis is complicated by the extraordinarily stable Ce(IV) oxidation state

The extensive redox chemistry of chromium is reminiscent of that of manganese, but Cr does not play such an extensive and essential biological role as Mn. The standard reduction potentials of Cr(III) to Cr metal are −0.77 and −1.33 V in acidic and in basic conditions, respectively. The corresponding reduction potentials of Mn(II) to Mn metal are −1.18 and −1.56 V, respectively. The standard reduction potential for $Cr_2O_7^{-2}$ to Cr(III) (*aq*) in acidic solution is 1.38 V; the analogous three-electron-step reduction of permanganate (MnO_4^{-1}) to manganese dioxide (MnO_2) is 1.70 V. Redox reactions of the Cr(V) and Cr(IV) states are more typically observed in acidic conditions.

Cr(III) coordination chemistry is characterized by substitutional inertness and an essentially octahedral (O_h) geometric preference. In addition to extensive mononuclear examples, the types of Cr(III) compounds include numerous multinuclear clusters, such as $Cr_3O(O_2CCH_3)$ and $[Cr_8(OH)_8(O_2CCH_3)_{16}]$ (Eshel 2001). Many Cr(III) complexes are stable and soluble at neutral to high pH but are susceptible to hydrolysis and may precipitate as pure or mixed Cr(III) hydroxides. Cr(III) coordination and redox chemistry is sometimes compared to that of Fe(III). However, the biological redox chemistry of Fe is limited to the +2 and +3 states, and the comparable reduction reactions are quite different: The M(III) to M(II) potentials for Cr and Fe are −0.424 and 0.771 V, respectively. Chemical differences for Cr(III) may also be compared using the M(III) hydroxide solubility products (Lide 2009) of a range of +3 cations (Table 1). Thus, Cr(III) is less susceptible to hydrolysis than Fe and is more comparable to Al(III) or the

Chromium, Physical and Chemical Properties, Table 2 Comparison of Cr (III) to Fe(III), Mn(III), and cations with similar charge/ionic radius ratios. Charge/I.R. is proportional to cation surface charge (Shannon 1976)

Cation	Coordination number	Ionic radius (Å)	Charge/I.R. ($Å^{-1}$)
Fe(III) *or* Mn(III) (high spin)	6	0.645	4.65
. . .			
Hf(IV)	8	0.83	4.82
Ga(III)	6	0.62	4.84
In(III)	4	0.62	4.84
Cr(III)	*6*	*0.615*	*4.89*
Co(III) (high spin)	6	0.61	4.92
Sn(IV)	8	0.81	4.94
. . .			
Fe(III) or Mn(III)	5	0.58	5.17

lanthanides, e.g., Nd(III). A comparison of ionic radii, and charge-to-radius ratios (Table 2) also indicates some metal ions that are more similar to Cr(III) than Fe(III) or Mn(III) (Shannon 1976).

While the [Ar] d^0 closed-shell configuration of Cr(VI) should not be colored due to lack of *d* electrons for *d–d* transitions, chromate and dichromate are colored yellow and orange, respectively, due to charge transfer between the metal center and oxo ligands. Most other Cr compounds are colored due to *d–d* orbital electronic transitions and thus available to spectroscopic analysis.

Chromates and chromium compounds are amenable to a wide variety of spectroscopic analysis and standard methods of metal analysis, including titrimetry, atomic absorbance, neutron activation, and X-ray fluorescence. Potassium dichromate ($K_2Cr_2O_7$) is a primary standard for redox titrimetry. Electron paramagnetic resonance is utilized in characterizing paramagnetic Cr(I, III, or V) compounds and in following the stages of redox reactions of biochemical interest from Cr(VI) to Cr(III); EPR analysis is typically done in the X band (~9.5 GHz) at liquid N_2 or He temperatures. In radiochemistry, Cr-51 is a gamma-emitting radioisotope with a half-life of 28 days; it is used as a radiotracer in analytical and biochemical experiments.

Cr(III) has not been identified in any biological redox system or enzyme, and a role for Cr(III) as a trace element in biological systems, especially in humans, has not been definitively described for healthy individuals. Some Cr(III) compounds have been evaluated as possible insulin mimetic agents or therapeutic agents for glucose metabolism or lipid maintenance in Type II diabetes and associated cardiovascular disease (Levina 2008). Cr(III) compounds generally do not pose an acute hazard due to the inability of Cr(III) salts, e.g., $CrCl_3$, to adequately pass through biological membranes. The oral bioavailability of Cr(III) as the chloride salt is less than 1%. Other compounds, notably, Cr(III) picolinate, have an oral bioavailability of about 10%. Chronic disease caused by Cr(III) has not been definitively determined, though the compounds that may access two-electron Cr(II)/Cr(IV) redox cycles may pose a potential hazard related to having Cr(III) present in the human body.

Cr(VI) is a significant anthropogenic environmental hazard in certain locations and in industrial settings and represents an acute or chronic health hazard. Cr(V) and Cr(IV) compounds participate in direct mechanisms of carcinogenesis. The most affected organs are the lungs and associated airways. Ingestion and absorption through the skin are the major routes of Cr(VI) contamination from contaminated water supplies or from contact with compounds or solutions in industrial settings. Other diseases caused by high-oxidation-state Cr compounds include gastroenteritis, liver damage, and acute renal failure.

Cobalamin; Methionine amino peptidase; Nitrile hydratase; Non-corrin cobalt; Radical rearrangement; Vitamin B_{12}

Definition

Cobalt is relatively rare among essential trace elements but plays important roles in various living organisms. For instance, cobalamin cofactor comprising a cobalt ion coordinated in a substituted corrin macrocycle is known as vitamin B_{12}, and its deficiency may cause severe damage to mammals. In this entry, the structure and function of vitamin B_{12}-dependent enzymes and non-corrin cobalt enzymes are reviewed.

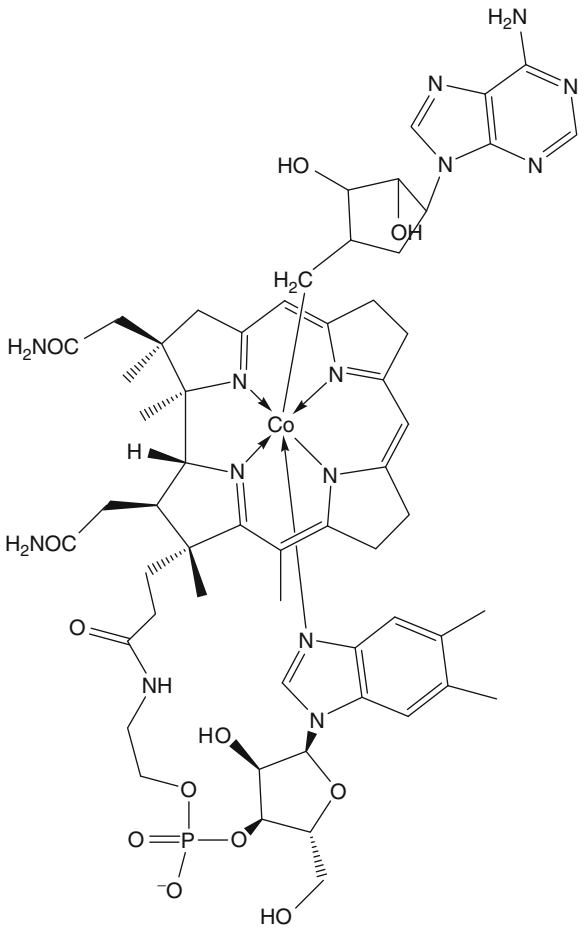
Introduction

Cobalt is the 27th element in the periodic table and a transition metal with seven d electrons. It can take oxidation states from –I to + IV and preferably exists as Co^{2+} and Co^{3+}. Cobalt is relatively rare among essential trace elements, and its concentrations in seawater and the cytosol are 10^{-11} and 10^{-9} mol dm^{-3}, respectively. Geochemistry of trace metals suggests that the cobalt ion existed in ancient sea in relatively high concentrations, but it decreased after the generation of molecular oxygen through photosynthesis started. This view is consistent with the fact that most cobalt-containing enzymes are found in Archaea and Bacteria. Among the first-row transition metals, cobalt is less frequently used in a metalloenzyme than other elements such as iron, copper, zinc, and manganese. However, cobalamin cofactor, comprising a cobalt ion coordinated in a substituted corrin macrocycle, is essential for mammals, and a deficiency of it may cause severe damage to the brain and nerve system and lead to pernicious anemia (Matthews et al. 2008; Randaccio et al. 2007). Cobalamin is also known as vitamin B_{12}, and the biochemistry of the B_{12}-dependent enzymes has been extensively investigated. In addition, there are some enzymes as well as proteins that have been indicated to possess non-corrin cobalt cofactors (Kobayashi and Shimizu 1999). In particular, a mononuclear non-corrin cobalt enzyme, nitrile hydratase, has been biotechnologically very important because of its industrial use for acrylamide and nicotinamide production. This entry first overviews the biochemistry of and recent progress regarding B_{12}-dependent enzymes and then those for other cobalt-containing proteins.

Vitamin B_{12}-Dependent Enzymes

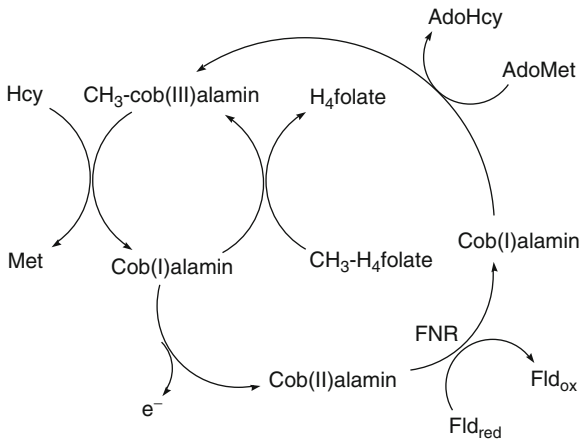
The biosynthesis of vitamin B_{12} compounds is performed only by some microorganisms and algae (Escalante-Semerena and Warren 2008), and thus, mammals have to take them up via food (Matthews et al. 2008; Randaccio et al. 2007). Figure 1 shows the structure of adenosylcobalamin (AdoCbl). The cobalt is six-coordinated. Four ligands are provided by a corrin macrocycle, and the fifth ligand is the nitrogen atom of a 5,6-dimethylbenzimidazole nucleotide substituent covalently bonded to the corrin ring or a histidine from the enzyme. The sixth ligand is the C1 methylene group of 5′-deoxyadenosine which is a very unique example of a naturally occurred organic metal compound. The other B_{12} cofactor is methyl cobalamin (MeCbl), in which the sixth ligand is substituted by a methyl group. Usually, B_{12} compounds are taken as aquacobalamin, hydroxocobalamin, or cyanocobalamin through specific import and transport systems and then transformed into AdoCbl or MeCbl after binding to the catalytic site of the B_{12}-dependent enzymes.

There are two B_{12}-depndent enzymes in humans (Randaccio et al. 2007). One is methionine synthase (MS), which catalyzes the transfer of a methyl group from *N*-methyl-tetrahydrofolate (CH_4-H_4Folate) to homocysteine (Hcy), which produces methionine. Human MS is pathologically important because a dysfunction of it results in homocysteine accumulation in the blood, which causes homocystinuria. Although the structure of human MS has not been determined, the crystal structures of the N-terminal and C-terminal halves of methionine synthases (MetH) from *Thermotoga maritima* and *Escherichia coli* provide significant insights into the catalytic mechanism (Fig. 2). Human MS and bacterial MetHs share four modular structures. The N-terminus two modules are the Hcy-binding and CH_4-H_4Folate-binding domains (Hcy and Fol domains, respectively). The third module is composed of the Cap and Cob (B_{12}-binding) domains, and the C-terminus module comprises the AdoMet domain, which contains *S*-adenosyl-L-methionine (AdoMet). When MetH is activated, a strong nucleophile, cob(I)alamin, in the Cob domain extracts the methyl group from CH_4-H_4Folate to yield methyl-cob(III)alamin. Then, the Cob domain interacts with the Hcy-domain to



Cobalt Proteins, Overview, Fig. 1 Structure of adenosylcobalamin

methylate Hcy into methionine. It is known that both human MS and bacterial MetHs lose their catalytic activity in every 1,700–2,000 turnovers because the highly reactive cob(I)alamin is occasionally oxidized into an inert cob(II)alamin form under aerobic conditions. Therefore, organisms have intrinsic reactivation systems. The cob(II)alamin in MetH is reduced to cob(I)alamin by FAD-dependent ferredoxin-$NADP^+$ reductase (FNR) with flavodoxin, while that of human MS is reduced by methionine synthase reductase, which is the fusion protein of FNR and flavodoxin. The regenerated cob(I)alamin accepts the methyl group from an AdoMet molecule in the AdoMet domain to become methyl-cob(III)alamin again. Recent biochemical studies indicated that methionine synthase reductase not only reactivates



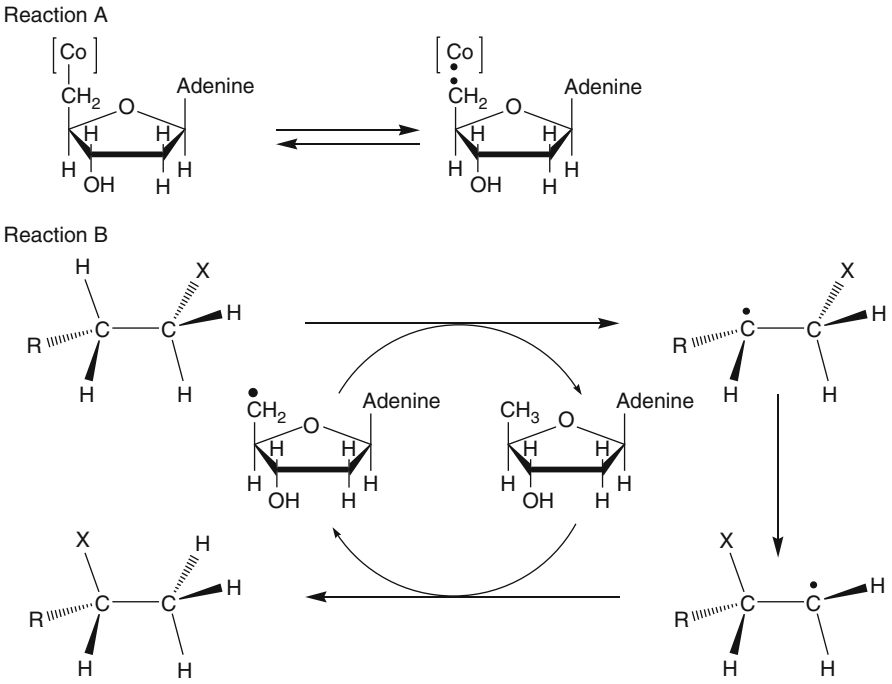
Cobalt Proteins, Overview, Fig. 2 Scheme of proposed reaction mechanism of methyltransferase. *Hcy* homocysteine, *AdoHcy* adenosylhomocysteine, *AdoMet* adenosylmethionine, *Fld* flavodoxin, *FNR* FAD-dependent ferredoxin-$NADP^+$ reductase

the cob(II)alamin in MS but also enhances the incorporation of cobalamin into the apo-form of MS through a specific protein-protein interaction (Wolthers and Scrutton 2009).

Some anaerobic organisms such as hydrogenogenic, acetogenic, and methanogenic bacteria and Archaea can convert CO and CO_2 into acetyl-CoA via the reductive acetyl-CoA pathway, the methyl group being transferred from CH_4-H_4Folate to the cob(I)alamin of the corrinoid iron-sulfur protein (CoFeSP) by its partner enzyme, methyltransferase (MeTr), and then, using the methyl group, acetyl-CoA is synthesized from CO and CoA by acetyl-CoA synthase (Matthews et al. 2008). Very recently, Goetzl et al. (2011) elucidated the crystal structures of CoFeSP and MeTr from *Carboxydothermus hydrogenoformans* and proposed a catalytic mechanism based on their conformational flexibility. Methanol:coenzyme M methyltransferase transfers a methyl group from methanol to CoM through a similar mechanism (Matthews et al. 2008). The enzyme is composed of three subunits, MtaA, MtaB, and MtaC. The cob(I)alamin in MtaC nucleophilically attacks the C-O bond of methanol activated by the zinc (II) ion of MtaB and cleaves it heterolytically to produce methyl-cob(III)alamin. Then the methyl group is transferred to CoM by MtaA. MtaC is structurally related to the cobalamin-binding domain of MetH.

Another human B_{12}-dependent enzyme is methyl malonyl-CoA mutase (MUT), which possesses AdoCbl at its catalytic site (Randaccio et al. 2007). MUT catalyzes isomerization of methylmalonyl-CoA into succinyl-CoA. The catalytic activity of MUT is explained as 1,2-radical rearrangement (Fig. 3). When a substrate binds to the enzyme, the Co(III)-C bond is cleaved homolytically to produce a Co(II) radical and an adenosyl radical. The adenosyl radical subtracts the hydrogen atom from the C1 site of the substrate to generate the substrate radical (reaction A). The product radical generated on the transfer of the X group from C2 to C1 subtracts the hydrogen atom from 5′-deoxyadenosine to yield the product and to regenerate the adenosyl radical (reaction B). The activities of the bacterial AdoCbl-dependent enzymes, 1,2-diol dehydratase, glycerol dehydratase, and ethanolamine ammonia lyase, can be explained similarly. 1,2-diol dehydratase and ethanolamine ammonia lyase produce 1,1-diol and 1-hydroxy-1-amine radicals as intermediates, respectively. Because of their chemical instabilities, the intermediates self-react immediately to produce water and ammonia in addition to the corresponding aldehydes.

A rare genetic disorder, isolated methylmalonic aciduria, mainly results from a deficiency of one of the three genes, *cbl*A, *cbl*B, and *mut*, which correspond to mitochondrial proteins MMNA, MMNB, and MUT. MMNB is an ATP: cob(I)alamin adenosyltransferase (ATR) that converts the inactive cob(II)alamin form into the active AdoCbl and delivers it to MUT. Banerjee and his colleagues (Padovani and Banerjee 2009) found that MeaB from *Methylobacterium extorquens* AM1, the ortholog of human MMNA, is a GTP-binding protein that functions as a chaperone editing the release of the inactive cob(II)alamin from MUT and gating the insertion of AdoCbl into the corresponding MUT. Since MUT is occasionally inactivated through loss of the deoxyadenosine moiety at the end of catalysis, MeaB is likely to rescue the removal of cob(II)alamin from the inactivated MUT. Recently, the crystal structures of a GTP-bound form of human MMNA and apo-, holo-, and substrate-bound forms of human MUT were determined (Froese et al. 2010). By combining crystal structural and kinetic studies, the authors demonstrated the guanine nucleotide-dependent interaction of human MMNA and human MUT and the gating function of human MMNA as to AdoCbl binding to human MUT.

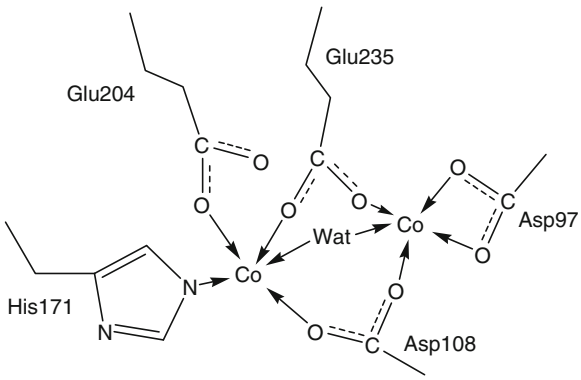


Cobalt Proteins, Overview, Fig. 3 Scheme of proposed reaction mechanism of AdoCbl-dependent enzymes. Reaction A represents the hemolysis of adenosylcobalamin. Reaction B is the scheme of the radical rearrangement reaction of AdoCbl-dependent enzymes

Methionine Aminopeptidase

Methionine aminopeptidase (MetAP) is a ubiquitous enzyme that catalyzes the cleavage of the N-terminal methionine from newly translated polypeptide chains in eukaryotes as well as prokaryotes (Lowther and Matthews 2000). MetAP from *Escherichia coli* was reported as the first non-corrin cobalt protein whose crystal structure had been determined. Pseudo twofold-related N-terminal and C-terminal domains form the "pita bread" structure and contribute to hold a dinulcear cobalt center. Two cobalt ions are coordinated with His171 and Glu104 as monodentate ligands and Asp97, Asp108, and Glu235 as bidentate ones (residue numbers are based on MetAP from *E. coli*) (Fig. 4). A water ligand bridging two cobalt ions is considered as the nucleophile in the catalysis. These structures are conserved among all structurally known MetAPs.

Based on amino acid sequence similarities, MetAP is classified into two subfamilies. MetAP type 1 (MetAP1) is found in bacteria, while type 2 (MetAP2) is found in Archaea. MetAP2 has an inserted region that forms a helical surface subdomain. Eukaryotes possess both types of MetAPs. But each type has a specific N-terminal extension domain. Namely, eukaryotic MetAP1s have zinc-finger domains,



Cobalt Proteins, Overview, Fig. 4 Structure of the bimetallic catalytic center of MetAP from *Escherichia coli*

whereas eukaryotic MetAP2s have polybasic and polyacidic regions. These N-terminal extensions are not necessary for the catalysis because the truncated enzymes retain the catalytic activities. Interaction between the N-terminal regions and DNA and/or RNA has been suggested, but their biological functions remain unclear.

Deletion of both types of MetAPs in *Saccharomyces cerevisiae* is lethal. Since deletion of either of the two MetAPs results in slow growth, each enzyme can partly compensate for the biological function.

Also, MetAP is important as a target not only for antimicrobial agents but also for antitumor agents. Human MetAP2 was identified as the target of fumagillin family compounds that act as potent angiogenesis inhibitors. A synthetic analog of fumagillin, TNP-470, has entered clinical trials for a variety of cancers (Satchi-Fainaro et al. 2005). The crystal structure of hMetAP2 in complex with fumagillin has been determined. Fumagillin is covalently bound to the imidazole ring of His231 via C2, the carbon atom in the epoxide group in fumagillin, and occupies the substrate-binding pocket. The higher affinities of fumagillin compounds to MetAP2 rather than MetAP1 can be explained by the size of their substrate-binding pockets. TNP-470 induces the activation of p53 and p21CIP/WAF in endothelial cells to inhibit their proliferation in the G1 phase. Downregulation of MetAP2 by RNAi results in inhibition of the proliferation of germ cells in *Caenorhabditis elegans*. These findings suggest that MetAP2 plays an important role in the proliferation of specific cell lines. On the other hand, an inhibitor specific for MetAP1 causes a significant delay in the G2/M phase (Hu et al. 2006). Also, silencing of the human MetAP1 gene induces a delay in the G2/M phase in cell cycle progression (Hu et al. 2006). Although many of the details of the function of each type of MetAP remain unknown, it will serve as a promising target for drug designs.

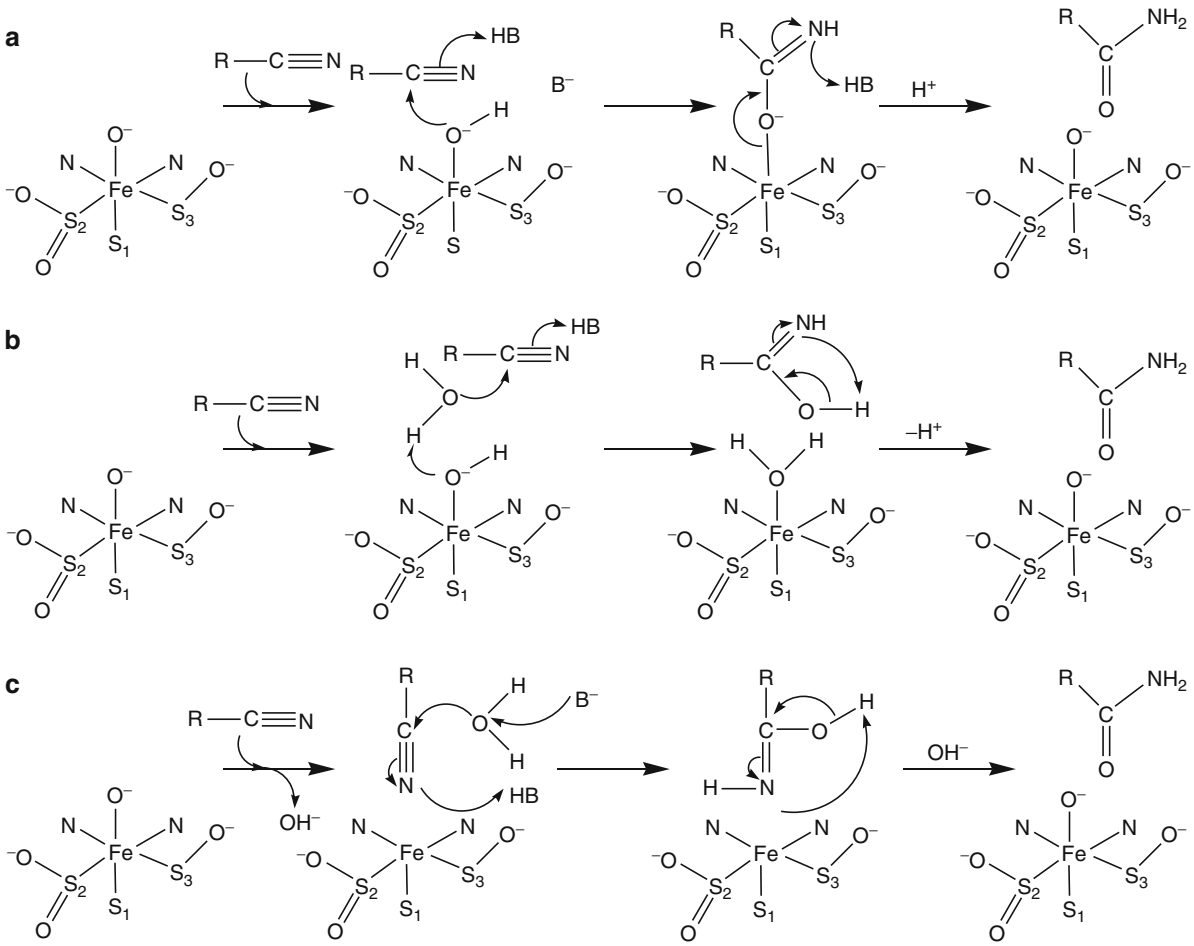
MetAPs coordinate metals loosely because native MetAP1 from *Salmonella typhimurium* contains no metals when it is purified. *S. typhimurium* MetAP1 is activated by Co^{2+}, but not by Mg^{2+}, Mn^{2+}, or Zn^{2+}. But, generally, MetAP is sensitive to divalent cations such as Co^{2+}, Mn^{2+}, Zn^{2+}, and Fe^{2+}. Although MetAP1 from *E. coli* was determined to be a cobalt-containing enzyme, studies on the inhibitory effects of metal-selective MetAP inhibitors in vivo suggested that Fe^{2+} is the likely metal used by MetAP in *E. coli* and other bacterial cells (Chai et al. 2008). Likewise, hMetAP2 is suggested to function as a manganese enzyme in vivo. Thus, the physiologically relevant metals in MetAPs have not firmly established.

Nitrile Hydratase

Nitrile hydratase (NHase) catalyzes hydration of aromatic and small aliphatic nitriles into the corresponding amides (R-CN + H_2O → R-$CONH_2$). It is composed of two distinct subunits, α and β, and was originally identified as a nonheme iron enzyme. *Rhodococcus rhodochrous* J1 possesses two kinds of NHase genes, and both enzymes contain a non-corrin cobalt center in place of the nonheme iron one as the catalytic center. NHase is industrially very important because it has been used for kiloton scale production of acrylamide. Physiologically, NHase is considered to be involved in the aldoxime-nitrile pathway (Oinuma et al. 2003). Briefly, aldoxime compounds are converted into nitriles by aldoxime dehydratase. Then, the produced nitriles are hydrated into amides by NHase. Finally, the amides are hydrolyzed into the corresponding carboxylic acids and ammonia by amidase. The details of the characteristics of NHases are dealt with in a separate section.

Structural and functional studies have mostly concentrated on iron-type NHases. Nagashima et al. determined the crystal structure of *Rhodococcus* sp. N774 NHase at 1.7 Å resolution. The combination of high-resolution structure and mass spectrometric analyses revealed the unusual structure of the catalytic center at the α-subunit. Two main chain amide nitrogens and three cysteine sulfurs are coordinated to the iron, and two out of the three cysteine ligands are posttranslationally modified to cysteine sulfenic acid (Cys-SOH) and cysteine sulfinic acid (Cys-SO_2H), respectively. NHase is the first example of a metalloenzyme that has two cysteine ligands with different oxidation states. The crystal structure of the cobalt-type NHase from *Pseudonocardia thermophila* JCM 3095 is very similar to that of the iron-type one including two posttranslational oxidations of cysteine ligands. The sixth ligand site is occupied by a solvent water ligand. Some difference was observed in the β-subunit. In particular, the region of β111–β125 formed a helix and interacted with a helix in the α-subunit (α36–α49) in the cobalt-type NHase. The additional interaction is likely to contribute to the thermostability of the cobalt-type NHase.

Based on the crystal structure, three reaction mechanisms are proposed (Fig. 5). (a) A coordinated water molecule (or a hydroxide ion) provided nucleophilicity from the metal attacks the nitrile in the substrate-binding pocket. (b) A water molecule in the pocket is activated by the coordinated water molecule (or hydroxide ion) and makes a nucleophilic attack on the substrate. (c) A nitrile substrate activated through coordination to the metal is attacked by a water molecule in the pocket. Various studies



Cobalt Proteins, Overview, Fig. 5 Proposed catalytic mechanism of nitrile hydratase

involving model complexes mimicking the metallocenter of NHases, site-directed mutagenesis, specific inhibitors, and theoretical calculations have been conducted to understand the reaction mechanism of NHase. One of the authors has performed time-resolved X-ray crystallography of Fe-type NHase using a novel substrate, *tert*-butyl isonitrile (tBuNC). The nitrosylated inactive iron-type NHase from *Rhodococcus* sp. N771 soaked in tBuNC in the dark was activated by light illumination, and then its crystal structure was determined. After 120-min illumination, tBuNC coordinated to the sixth site of the iron center. Then, the shape of the electron density for the substrate changed, suggesting that a solvent water molecule activated by the oxygen atom of the cysteine sulfenic acid makes a nucleophilic attack on the nitrile carbon.

Thiocyanate Hydrolase

Thiocyanate hydrolase (SCNase) catalyzes the hydration and subsequent hydrolysis of thiocyanate (SCN^-) to produce carbonyl sulfide and ammonia ($SCN^- + 2H_2O \rightarrow COS + NH_3 + OH^-$). SCNase was identified in a sulfur-oxidizing bacterium, *Thiobacillus thioparus* THI115, isolated from active sludge for the treatment of factory wastewater for the gasification of coal. Based on amino acid sequence similarities, SCNase was found to belong to the same protein family as NHases. SCNase is composed of three subunits, α, β, and γ. The γ-subunit corresponds to the NHase α-subunit, while the α- and β-subunits correspond to the C-terminal and N-terminal halves of the NHase β-subunit. The crystal structure of SCNase shows that

four αβγ-hetero-trimers comprise the dodecameric structure and that each γ-subunit possesses one non-corrin cobalt center. The structure of the αβγ-hetero-trimer of SCNase is very similar to that of NHase including two posttranslationally modified cysteine ligands, Cys-SOH, and Cys-SO_2H, respectively. The structural as well as biochemical characterization of SCNase will be discussed in a separate section.

Other Cobalt Proteins

Prolidase There are few proteases that cleave a peptide bond adjacent to a proline residue. This is because the cyclic structure of proline puts a conformational constraint in the polypeptide chain. Prolidase can hydrolyze dipeptides containing proline at the C-terminus, Xaa-Pro. Prolidase is widespread in nature from bacteria to mammalian tissues. Prolidase from *Pyrococcus furiosus* is homo-dimeric enzyme, and each subunit has a bimetallic catalytic center (Ghosh et al. 1998). The two sites exhibit distinct metal-binding affinities. The tightly binding site is occupied by a Co^{2+} ion. The second site binds Co^{2+} or Mn^{2+} (with a 25% decrease in activity) with a K_d of 0.24 mM, but does not bind Mg^{2+}, Fe^{2+}, Zn^{2+}, Cu^{2+}, and Ni^{2+}. The crystal structure of Pfprolidase has been determined. Unexpectedly, the enzyme in the crystal contains two Zn^{2+} ions, not Co^{2+} ones (Maher et al. 2004). This may be due to metal exchange during its crystallization. The fold of Pfprolidase is similar to those of two functionally related enzymes, aminopeptidase P and creatinase. Interestingly, Pfprolidase exhibited the highest activity when the metals were substituted by Fe^{2+}. Recently, human prolidase was shown to possess a Zn^{2+} ion and a Mn^{2+} one at the catalytic site (Besio et al. 2010). The difference in their metal composition may affect their substrate selectivities.

D-Xylose Isomerase D-Xylose isomerases catalyze conversion of D-xylose and D-glucose into D-xylulose and D-fructose, respectively, and have attracted considerable interest as to the production of high-fructose corn syrup. D-Xylose isomerase is dependent on a bivalent cation, Co^{2+}, Mg^{2+}, or Mn^{2+}. D-Xylose isomerases bind two metal ions per monomer with different binding affinities. The binding constant of the high-affinity site for Co^{2+} was estimated to $> 3.3 \times 10^6$ M^{-1} and that for the low-affinity site to be 4×10^4 M^{-1}. The crystal structure of D-xylose isomerase from *Streptomyces diastaticus* No. 7 strain M1033 showed that it had a homo-tetrameric structure. Two Co^{2+} ions exist in the catalytic site, revealing that *Sd* D-xylose isomerase prefers Co^{2+} ions to Mg^{2+} ones (Zhu et al. 2004).

Methylmalonyl-CoA Carboxytransferase Methylmalonyl-CoA carboxytransferase (MMCT) is a biotin-containing enzyme and also is known as transcarboxylase. MMCT from *Propionibacterium shermanii* is a 26S huge multi-subunit enzyme of 1.2 million Da, which is composed of three kinds of subunits, 1.3S, 5S, and 12S. 1.3S has twelve 12-kDa biotnylated linkers; 5S, six catalytic 116-kDa dimmers; and 12S, a catalytic 336-kDa hexameric core, respectively. The overall transcarboxylation reaction consists of two half reactions. In the first half reaction, 12S transfers CO_2^- from MMCoA to biotin to generate propionyl-CoA on 1.3S. 5S transfers the CO_2^- from the 1.3S biotin to pyruvate to produce oxaloacetate in the second half reaction. The 5S subunit is a dimer of $\beta_8\alpha_8$ barrel monomers (Hall et al. 2004). Each monomer contains one Co^{2+} ion at its catalytic site. Although the 5S subunit had been thought to contain one Co^{2+} and one Zn^{2+} per subunit, no Zn^{2+} ion was observed. The Co^{2+} is octahedrally coordinated by two imidazole groups of His215 and His217, one carboxyl group of Asp23, a solvent water molecule, and the CO_2^- from the carbamylated Lys184. The coordination is likely to be tight because the average ligand distance is 2.15 Å. The coordination sphere is unchanged in a complex with the substrate, pyruvate, but when the product, oxaloacetate, is co-crystallized, the carboxylate group of oxaloacetate is coordinated to Co^{2+} in place of the carbamylated Lys184.

Aldehyde Decarboxylase The final step of fatty acid synthesis is the decarboxylation of aldehyde catalyzed by a membrane protein, aldehyde decarboxylase (AD). The enzyme is attracting increasing attention because it will be applicable to biofuel production. However, information on its biochemical characteristics has been rather limited because of the difficulty in its solubilization and purification. AD purified from a green algae, *Botryococcus braunii*, exhibits a visible absorption spectrum characteristic of a porphyrin and contains 1.37 mole of cobalt per enzyme. This is the first example of a non-corrin cobalt-containing protein in a plant. Later, AD was purified from a higher plant, *Pisum sativum*. Interestingly, the higher plant AD

contains a copper ion, probably with a porphyrin, despite that the enzyme reconstituted with cobalt showed about 70% of the activity of the wild type. Most recently, soluble aldehyde decarboxylase (cAD) was purified from cyanobacteria, *Prochlorococcus marinus* MIT9313 (Das et al. 2011). Surprisingly, cAD does not have a porphyrin-like cofactor, but has a nonheme di-iron center. AD may use a variety of prosthetic groups as the catalytic center.

Bromoperoxidase-esterase Haloperoxidase is classified into three groups: eukaryotic and bacterial heme-type, eukaryotic vanadium-containing-type, and bacterial nonmetal-type enzymes. Based on amino acid sequence homology, bromoperoxidase-esterase (BPO-EST) from *Pseudomonas putida* is grouped as a nonmetal-type enzyme, but its BPO activity was activated by ca. 300% in the presence of Co^{2+} (Itoh et al. 2001). The interaction between the enzyme and Co^{2+} is rather weak because Co^{2+} is easily eliminated on dialysis against the buffer. Interestingly, the EST activity was inhibited by Co^{2+}. Despite detailed kinetic analyses, the enzyme reaction mechanism and the role of Co^{2+} remain unclear because its crystal structure has not been determined.

Concluding Remarks

Cobalt ions are used much less frequently in living organisms than other transition metals. As overviewed here, however, most cobalt-containing enzymes catalyze very unique reactions. Therefore, they are very important from medical aspects as well as from industrial ones. Metal ions such as Mn^{2+}, Fe^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} involved in enzymes can often be substituted by Co^{2+} as in MetAP. In fact, cobalt substitution is one of the useful tools for studying the functions of other metal-containing proteins.

The concentrations of transition metals are strictly regulated in living organisms. The free cobalt ion is highly toxic because it may produce reactive oxygen species and because it may occupy the binding sites of proteins containing other metals. Therefore, the concentration of free cobalt ions is kept very low in cytosol. It is very important to understand the transport system controlling the uptake and transfer of cobalt. Future research will provide major clues as to the biological functions as well as to the industrial applications of cobalt proteins.

Definition

Import systems that transport the transition metal ion across cell membranes in order to provide it for synthesis of coenzyme B_{12} and for incorporation into cobalt-containing enzymes.

Background

Cobalt is a trace nutrient for prokaryotes and utilized for biosynthesis of the cobalt-containing coenzyme B_{12} (see also ▶ Vitamin B_{12}), and for incorporation into noncorrin ▶ Co-containing enzymes. Animals must take up vitamin B_{12} with their diet or from intestinal prokaryotic producers. In higher plants, physiological roles for corrin and noncorrin cobalt enzymes have so far not been established. Nevertheless, beneficial effects of Co^{2+} for plant growth are known (Pilon-Smits et al. 2009). These effects may be due to stimulating growth of bacteria in the rhizosphere and of root-nodulating bacterial endosymbionts.

The focus of this short survey is on import systems in prokaryotes that transport Co^{2+} ions with high affinity and specificity under physiologically relevant conditions into the cells. Many of the transporters discussed here have closely related counterparts among the ▶ nickel transporters that function in the uptake of Ni^{2+} ions. From a bioenergetic point of view, cobalt importers can be classified into primary and secondary active transport systems (Eitinger et al. 2005; Rodionov et al. 2006) (Table 1). The latter include the long-known nickel/cobalt transporter (NiCoT) family and the weakly related HupE/UreJ systems. Primary active cobalt importers (CbiMNQO) belong to the more recently identified energy-coupling factor (ECF) transporter family of micronutrient importers and are driven by ATP hydrolysis. These systems are widespread in bacteria and archaea and represent a novel type of ABC (ATP-binding cassette) transporter (Rodionov et al. 2009; Eitinger et al. 2011).

CorA proteins form a huge group of Mg^{2+} channels in both prokaryotes and eukaryotes. It has long been known that CorA – in addition to Mg^{2+} – can transport Co^{2+} (and Ni^{2+}), however only at unphysiologically high concentrations of the transition metal ions in the micromolar range, underlining the primary role of CorA as a Mg^{2+} transporter. Very recently, however, CorA of the hyperthermophilic bacterium *Thermotoga maritima* was identified as a selective Co^{2+} transporter (Xia et al. 2011).

Another recent observation is energy-dependent transport of cobalt ions across the outer membrane of Gram-negative bacteria, and available data is included in the short overview.

Cobalt Transporters, Table 1 Classification and distribution of cobalt-uptake systems

System	Mechanistic type	Occurrence
CbiMNQO	Primary, ECF type	Prokaryotes
NiCoT	Secondary	Prokaryotes, fungi
HupE/UreJ	Secondary	Prokaryotes
CorA	Channel	Prokaryotes, eukaryotes
TBDT	TonB-dependent outer-membrane transporter	Gram-negative bacteria

NiCoT

Members of the NiCoT family are known since the early 1990s. They were originally identified as nickel transport systems in ▶ NiFe hydrogenase- or ▶ urease-producing bacteria. A Co^{2+} transporter within the NiCoT family was identified during sequence analysis of the gene cluster encoding a cobalt-containing ▶ nitrile hydratase in the actinobacterium *Rhodococcus rhodochrous* J1. This transporter, named NhlF, was later shown to transport both Ni^{2+} and Co^{2+} ions but to prefer the latter (reviewed in Eitinger et al. 2005). Similar properties, i.e., the capability to transport the two transition metal ions but to prefer one or the other, were reported for a couple of additional NiCoTs (reviewed in Eitinger et al. 2005).

Functional genomics proved a powerful method to predict the substrate preference of NiCoTs. The analyses uncovered that colocalization and/or coregulation of NiCoT genes with genes implicated in nickel or cobalt metabolism is a reliable indicator of a NiCoT's preference for Ni^{2+} or Co^{2+} (Rodionov et al. 2006).

Analyses of NiCoT sequences predict 2 four-helix segments formed by the N-terminal and C-terminal parts of the proteins (Fig. 1). The two halves are connected by a large and highly charged cytoplasmic loop. A couple of conserved sequence motifs mainly located within the TMDs have been found to be essential for transport activity. Of special importance is TMD II harboring the +HAXDADH (+, R or K; X, V, F, or L) motif which serves as the signature sequence for NiCoTs. This segment interacts spatially with a histidine- or asparagine-containing region in TMD I, together forming a central part of the selectivity filter that controls velocity and ion selectivity of the transport process (Degen and Eitinger 2002). Site-directed mutagenesis was applied to investigate the consequences of amino acid replacements introduced into a cobalt- and a nickel-preferring NiCoT. These experiments showed that an increase of transport velocity results in a decreased specificity. The data indicated that predictions of the preference of a NiCoT for either Co^{2+} or Ni^{2+} ion, solely based on the primary structure, are not possible (Degen and Eitinger 2002).

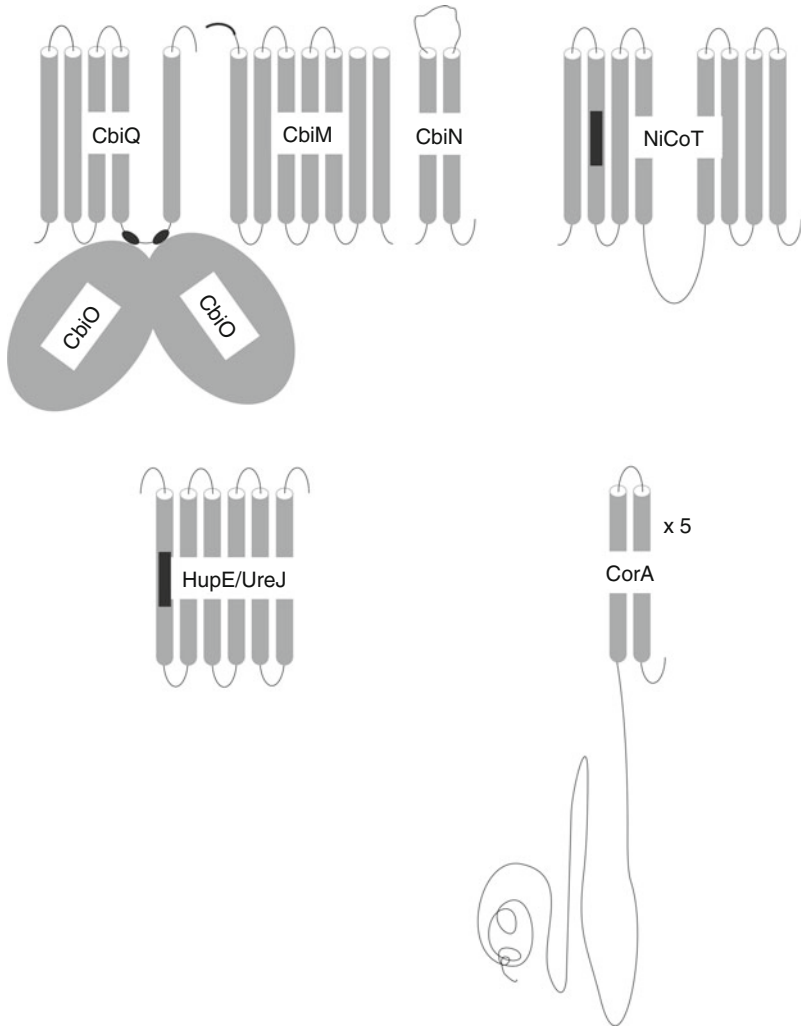
HupE/UreJ

As indicated by the designation HupE/UreJ, those proteins represent a family whose members – in many cases – are encoded within NiFe hydrogenase (*hup*, "hydrogen uptake") or urease (*ure*) gene clusters. Those proteins mediate the uptake of Ni^{2+} ions. HupE/UreJ are integral membrane proteins with six TMDs in the mature state. Many HupE/UreJ proteins are produced as precursors with a predicted N-terminal signal peptide which is cleaved off at a conserved site releasing an N-terminal histidine residue of the processed proteins. TMD I of mature HupE/UreJ proteins contain a HPXXGXDH motif which resembles the signature sequence of NiCoTs (Eitinger et al. 2005).

Another set of *hupE* genes, mainly found in cyanobacteria, is genomically unlinked to nickel metabolism. Bioinformatic analyses predicted a role of those HupE proteins as transporters for Co^{2+} ion in the metabolic context of biosynthesis of the cobalt-containing coenzyme B_{12} (Rodionov et al. 2006; Zhang et al. 2009).

CbiMNQO

CbiMNQO is the prototype of a novel type of micronutrient importers in prokaryotes, named energy-coupling factor (ECF) transporters (Rodionov et al. 2009; Eitinger et al. 2011). The first such system was mentioned upon sequence analysis of the coenzyme B_{12} biosynthesis gene cluster of *Salmonella enterica* serovar Typhimurium which contains a set of *cbiMNQO* genes. Since CbiO represents a typical nucleotide-binding protein of ATP-binding cassette (ABC)



Cobalt Transporters, Fig. 1 Characteristics of microbial cobalt-uptake systems. See the text for details. Transmembrane helices are indicated as cylinders. The contact sites in the T unit CbiQ with the ABC ATPases of ECF-type Co^{2+} transporters are depicted. The strongly conserved N-terminus of CbiM proteins is highlighted. *Black bars* indicate the signature sequence in TMD II of NiCoTs and related sequences in TMD I of HupE/UreJ. The secondary structure of a CorA monomer is illustrated. CorA has a homopentameric quaternary structure. The N-terminal regions of the CorA pentamer form a funnel-like structure in the cytoplasm, and the C-termini contain a total of 10 transmembrane domains. Outer-membrane cobalt transporters of Gram-negative bacteria are not shown

transporters, it was proposed that CbiMNQO acts as an ABC transporter for Co^{2+} ions. The original conclusion neglected the fact that canonical ABC-type importers in prokaryotes strictly depend on extracytoplasmic solute-binding proteins, but no such protein was encoded in the *cbi* cluster (summarized in Rodionov et al. 2006).

Energy-coupling factors of ECF transporters consist of a conserved transmembrane protein (T component, CbiQ in the case of Co^{2+} transporters) and pairs of typical ABC ATPases (A components, 2x CbiO). Substrate specificity is conveyed through an S component which is made up of a single integral membrane protein (in the case of most ECF transporters) or multiple membrane proteins, e.g., CbiMN in the case of the Co^{2+} transporters. In contrast to canonical ABC importers, all ECF systems are devoid of extracytoplasmic soluble solute-binding proteins. The list of ECF transporters includes uptake systems for vitamins, for intermediates of salvage pathways and for Ni^{2+} or Co^{2+} ions (Eitinger et al. 2011).

Many components of ECF transporters in prokaryotic or even plant genome sequences are misannotated as cobalt transporters because the presence of *cbiQO*-like genes or of a solitary *cbiQ*-like gene (the latter occurs in plant genomes) is considered as an indicator. These approaches ignore the fact that the highly diverse S units are responsible for substrate specificity, and thus, the S units rather than homologous T and homologous A units should be used for assigning

substrate specificities to ECF transporters (reviewed in Eitinger et al. 2011). Cobalt-specific ECF transporters can be identified by sequence alignments of the CbiM and CbiN proteins and by the fact that many *cbiMNQO* operons are colocalized and/or coregulated with genes for coenzyme B_{12} synthesis (Rodionov et al. 2006; Zhang et al. 2009; Eitinger et al. 2011).

Two bacterial ECF-type Co^{2+} transporters have been analyzed in some detail. Deletion analyses of the *cbiMNQO* operons of *S. Typhimurium* (Rodionov et al. 2006) and *Rhodobacter capsulatus* (Siche et al. 2010) revealed that in the absence of CbiQO, CbiMN has a basal Co^{2+} transport activity. The fact that the solitary CbiM and a tripartite CbiMQO system lacking CbiN are completely inactive underscores the essential role of the small transmembrane protein CbiN. Nevertheless, this component is only loosely bound to its partners and copurifies neither with CbiM nor with stable CbiMQO complexes. Construction of a Cbi(MN) fusion protein of the *R. capsulatus* system led to a functional S unit that interacted with CbiQO in vivo (Siche et al. 2010). The Cbi(MN) fusion was used to characterize the extremely conserved MHIMEGYLP N-terminal sequence of CbiM located on the extracytoplasmic side of the membrane (illustrated in Fig. 1). A total 16 Cbi(MN) variants was constructed in which individual N-terminal residues were replaced, deleted, or inserted. Among those, only the forms with the M_4A or M_4S replacement, which represent naturally occurring variations, were active. The position of the N-terminus of the peptide chain relative to the histidine residue at position 2 (in the natural situation) seems to be essential. Insertion of an additional N-terminal methionine residue or an alanine residue between M_1 and H_2 completely inactivated the core transporter.

As a distinctive feature between active and inactive variants, a significant percentage of active Cbi(MN) variants forms a recalcitrant structure that is not resolved in the presence of dodecyl sulfate. The molecular basis of this structure that obviously correlates with activity has not yet been unraveled (Siche et al. 2010).

CorA

CorA is the major transport system for Mg^{2+} uptake in prokaryotes, and functional homologs are known in eukaryotes (reviewed in Niegowski and Eshaghi 2007; Moomaw and Maguire 2008). As indicated by its name, CorA was originally identified during screens of cobalt-resistant clones of enterobacterial species. Enterobacterial CorA transports Mg^{2+} and Co^{2+} with affinities in the range of 20 μM, and Ni^{2+} with 10–20-fold lower affinity. Since micromolar concentrations of transition metal cations are toxic and considered to be unphysiological, the primary role of CorA is presumed to be the transport of Mg^{2+}.

Crystal-structure analyses of CorA of the hyperthermophilic bacterium *Thermotoga maritima* revealed a very unusual organization as a homopentamer. Each monomer of the channel consists of a cytosolic N-terminal domain and a C-terminal domain with two transmembrane helices. In the pentameric state, the latter form the pore in the membrane and the former a funnel-like structure in the cytoplasm.

The universal role of CorA as a Mg^{2+} transporter has been questioned recently when *T. maritima* CorA was shown to function as a Co^{2+} transporter that strongly prefers Co^{2+} over Mg^{2+} (Xia et al. 2011). This study suggests that variants of CorA proteins (e.g., in hyperthermophilic prokaryotes) may have different functions including the role as a selective transporter for Co^{2+} ions.

Other Co^{2+} Importers in Prokaryotes

NikABCDE and UreH represent canonical ABC-type and secondary transporters for Ni^{2+} ions, respectively. In a few cases, *nikABCDE* and *ureH* genes are under control of coenzyme B_{12}-dependent riboswitch regulatory elements or are colocalized with coenzyme B_{12} biosynthesis genes. Those NikABCDE and UreH systems may function in Co^{2+} uptake.

Based on bioinformatics, a couple of additional transmembrane proteins (CbtAB, CbtC, CbtD, CbtE, CbtF, CbtX) have been implicated in Co^{2+} uptake (summarized by Zhang et al. 2009). Like in the cases of hypothetical Co^{2+} transporters within the UreH and NikABCDE families, experimental evidence in support of this role has not been reported. Very recently, a canonical ABC-type cobalt transporter was characterized in the root-nodulating bacterium *Sinorhizobium meliloti* (Cheng et al. 2011).

TonB-Dependent Outer-Membrane Transporters (TBDT)

Until recently, active transport of solutes across the outer membrane of Gram-negative bacteria was only known for Fe^{3+} ions in complex with organic siderophores and for coenzyme B_{12}-related cobalamins. Recently, however, functional genomics and biochemical analyses identified a large number of putative outer-membrane transporters for alternate solutes (Schauer et al. 2008). Outer-membrane transporters consist of a C-terminal β-barrel domain and an N-terminal plug domain, and they bind their substrates with high affinity. They depend on ExbB-ExbD-TonB, a complex of proteins located in the cytoplasmic membrane. TonB contains an extensive periplasmic segment that interacts with the outer-membrane receptors.

Genes for outer-membrane transporters and *exbBD-tonB* clusters implicated in cobalt and/or nickel metabolism were identified by functional genomics in proteobacteria (Rodionov et al. 2006). Experimental analyses of methylotrophic bacteria correlated Co^{2+} deficiency and the resulting cobalamin deficiency with lowered expression of a TBDT gene located adjacent to a coenzyme B_{12} biosynthetic gene (Kiefer et al. 2009). These data corroborate the bioinformatic findings and support the hypothesis that Co^{2+} ions may cross the outer membrane of Gram-negative bacteria by a TonB-dependent active transport mechanism.

Cobalt, Physical and Chemical Properties

Fathi Habashi
Department of Mining, Metallurgical, and Materials Engineering, Laval University, Quebec City, Canada

Physical Properties

Pure metallic cobalt has few applications, but its use as an alloying element and as a source of chemicals makes it a strategically important metal. End uses of cobalt-containing alloys include superalloys for aircraft engines, magnetic alloys for powerful permanent magnets, hard metal alloys for cutting-tool materials,

cemented carbides, wear-resistant alloys, corrosion-resistant alloys, and electrodeposited alloys to provide wear and corrosion-resistant metal coatings. Cobalt chemicals, among their many applications, are used as pigments in the glass, ceramics, and paint industries; as catalysts in the petroleum industry; as paint driers; and as trace metal additives for agricultural and medical use. About 36% of the worldwide annual production of cobalt is converted to chemicals, whereas high temperature and magnetic alloys account for 41% and 14% of the consumption, respectively.

The γ-rays emitted in the decay of ^{60}Co have energies of 1.17 and 1.33 MeV, and these taken with the 5.3 years half-life of the isotope, provide a widely used source of radioactivity for use in food sterilization, radiography, and radiotherapy as an external source. The isotope is also used in chemical and metallurgical analysis and in biological studies as a radioactive tracer.

Cobalt exists in two allotropic modifications, a close-packed hexagonal ε-form stable below ca. 400°C and a face-centered cubic α-form stable at high temperature. The transformation temperature is 421.5°C.

Chemical Properties

Cobalt is much less reactive than iron. It is stable to atmospheric oxygen unless heated. When heated, it is first oxidized to Co_3O_4 and then, above 900°C, to CoO. The metal does not combine directly with hydrogen or nitrogen, but it combines with carbon, phosphorus, and sulfur on heating. The reaction with sulfur is influenced by the formation of a low melting eutectic (877°C) between the metal and the Co_4S_3 phase; the reaction between cobalt and sulfur is rapid above this temperature. Below 877°C, a protective layer of sulfide scale is formed. In an atmosphere of hydrogen sulfide, cobalt also forms a scale of sulfide, but in air containing sulfur dioxide, a mixed oxide sulfide scale is formed.

The main oxidation states of cobalt are Co^{2+} and Co^{3+}. In acid solution and in the absence of complexing agents, Co^{2+} is the stable oxidation state. Cobalt is often removed from solution as its sulfide.

Cobalt is a transition metal having the electronic configuration 2, 8, 15, 2. It dissolves in ammoniacal solutions in presence of oxygen forming ammine complex:

$$Co + {}^1/_2O_2 + 2NH_3 + H_2O \rightarrow \left[Co(NH_3)_2\right]^{2+} + 2OH^-$$

Cobalt powder is precipitated from cobalt sulfate solution by hydrogen at high temperature and pressure:

$$Co^{2+} + H_2 \rightarrow Co + 2H^+$$

Cobalt sulfide undergoes oxidation in neutral medium at ambient conditions to $CoSO_4$:

$$CoS + 2O_{2(aq)} \rightarrow CoSO_4$$

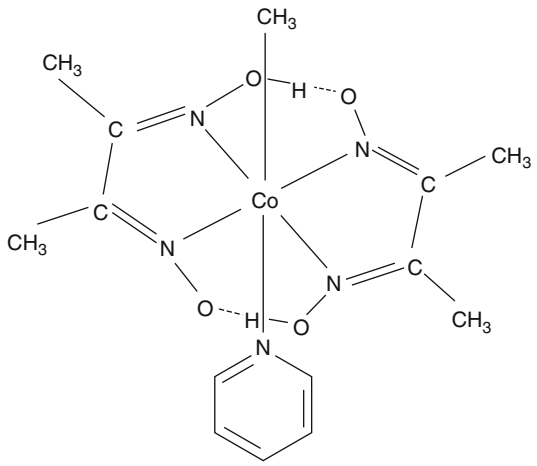
In acidic medium, however, elemental sulfur forms:

$$CoS + {}^1/_2O_{2(aq)} + 2H^+ \rightarrow Co^{2+} + S + H_2O$$

Cobalt sulfide is oxidized at high temperature to CoO and sulfur dioxide:

$$CoS + 1{}^1/_2O_2 \rightarrow CoO + SO_2$$

Cobalt chemicals are used to correct cobalt deficiencies in soils and in animals. Soil treatments usually involve top dressings containing cobalt sulfates, whereas treatment of ruminant animals involves the use of either salt licks containing ca. 0.1% of cobalt as



Cobalt, Physical and Chemical Properties, Fig. 1 Cobalt in vitamin B12

sulfate, or concentrated feeds, or pellets of cobalt oxide bound in an inert material such as china clay. The medicinal uses of cobalt are dominated by the use of vitamin B_{12} (Fig. 1).

Introduction

Among the metals of the first transition series, ▶ cobalt (Co) is next to iron (Fe) and exhibits three oxidation states (+1, +2, and +3) much like its congener iron (+2, +3, and +4). However, unlike iron, it is present in a relatively small number of enzymes and cofactors (Kobayashi and Shimizu 1999). In addition, it does not participate in oxygen activation, a process that iron frequently takes part in. In the +3 oxidation state, ▶ cobalt enjoys high crystal field stabilization energy (CFSE) in several coordination geometries. Significantly, high stability arises when Co^{3+} exists in spin-paired (low-spin) electronic configuration within an octahedral coordination environment of strong ligands. Such stability often makes the Co^{3+} center resistant to substitution processes such as exchange of a bound water molecule for the substrate. Such a center however can serve as a strong Lewis acid and promote activation of free water molecule(s) and subsequent nucleophilic attack of OH^- on substrate both present in the active site pocket (as in the enzyme nitrile hydratase). Although Co^{2+} is susceptible to oxidation, especially in aqueous environment, in many enzymes, Co^{2+} centers participate in catalytic processes without any tendency toward oxidation (as in various isomerases described below). Ligand fields arising from biological ligands around Co^{2+} centers in such proteins raise the oxidation potential and protect the metal centers from oxidation with dioxygen. Finally, cobalt-carbon bonds are readily formed and broken with concomitant formation of carbon-based radicals in certain biological pathways. This organometallic chemistry in an aqueous environment is quite unusual and is a unique aspect of vitamin B_{12} chemistry.

In biomolecules (proteins and cofactors), Co centers are bound to (a) amino acid side-chain residues such as carboxylato-O and imidazole-N, (b) carboxamido-N from the peptide frame, and/or (c) substituted corrin macrocycles. For example, in coenzyme B_{12}, an important cofactor, cobalt is bound to a corrin macrocycle and a carbon atom of a 5′-deoxyadenosyl moiety (or a CH_3 group), while in methionine aminopeptidase from *E. coli*, two Co^{2+} ions are bound to His-N, Glu-O, and Asp-O centers (Fig. 2). In general, Co^{2+} centers show preference for imidazole-N and carboxylato-O donors (methionine aminopeptidase is an example) while strongly

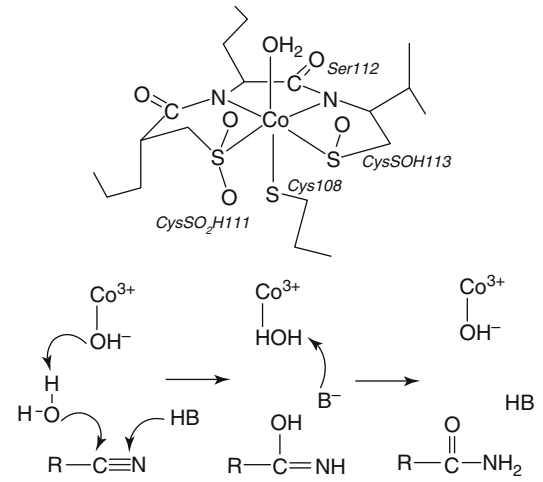
σ-donating ligands like carboxamido-N and thiolato-S donors prefer Co^{3+} centers (as in nitrile hydratase, Fig. 1). In this chapter, the cobalt enzymes have been classified into two groups depending on whether cobalt is bonded to a corrin moiety (corrin-containing proteins) or not (non-corrin cobalt proteins). Since the corrin-containing enzymes include cobalt in the cobalamine cofactor, the non-corrin enzymes with cobalt bound directly to the peptide framework are discussed first.

Non-corrin Cobalt Enzymes

Nitrile hydratase (NHase). Among the non-corrin cobalt proteins, ▶ nitrile hydratase (NHase) has recently drawn special attention for its successful use in the industrial scale production of acrylamide, used in plastic and paper pulp industry (Kobayashi and Shimizu 1998). This soluble metalloenzyme is involved in the microbial degradation/assimilation of organic nitriles in nature. The heterotetrameric $(\alpha\beta)_2$ protein contains either a Fe^{3+} or a Co^{3+} ion at the active site depending on the organism and catalyzes the conversion of nitriles into amides (Fig. 1). Structural studies have revealed quite a few unusual features

$$R{-}C{\equiv}N \xrightarrow{\text{NHase}} R{-}\overset{\overset{O}{\|}}{C}{-}NH_2 \qquad (1)$$

in the coordination sphere around the M^{3+} center in the functional αβ unit of both Fe- and Co-NHase. In Co-NHase from *Pseudonocardia thermophila* JCM 3095, the Co^{3+} center is ligated to four amino acid residues of the α subunit (αCys108, αCys111, αSer112, and αCys113) and strongly interacts with at least two arginine residues of the β unit (βArg52 and βArg157) (Miyanaga et al. 2001). The most unusual feature is the coordination of two carboxamido-N donors of the αCys111-αSer112-αCys113 portion of the peptide frame (Fig. 1). In addition to these two carboxamido-N donors, two S donors of αCys111 and αCys113 are also bound to the Co^{3+} center in the equatorial plane. Interestingly, these two S centers are posttranslationally oxygenated further to cysteine sulfinic ($-SO_2H$) and cysteine sulfenic (-SOH) acid, respectively (Fig. 1). The axial coordination is completed by the αCys108-S and a water molecule.



Cobalt-containing Enzymes, Fig. 1 *Top panel*: schematic structure of the cobalt-containing active site of Co-NHase from *Pseudonocardia thermophila* JCM 3095. *Bottom panel*: proposed mechanism of nitrile hydrolysis at the Co^{3+} site in Co-NHase

Although the α and β subunits of NHases do not show homology in amino acid sequence, in all known NHases, each subunit has highly homologous amino acid sequences. In particular, the Cys cluster sequence of the α subunit that binds the Fe^{3+} or Co^{3+} is highly conserved in addition to the two Arg residues of the β subunit. Strong interactions between the two subunits appear necessary for the function of the enzyme. The role of the unusual coordination of the carboxamido-N donors has been elucidated by modeling studies (Harrop and Mascharak 2004; Mascharak 2002). Coordination of the strongly σ-donating carboxamido-N centers stabilizes the +3 oxidation state of the Fe center in Fe-NHase, and as a consequence, the Fe^{3+} center exhibits no tendency to bind and/or activate dioxygen. Rather, it acts as a Lewis acid and promotes hydrolysis of nitriles into amide. In case of Co-NHase, the highly stabilized Co^{3+} center also behaves similarly. The posttranslational oxygenation of the equatorial Cys-S centers is essential for the enzymatic activity. Such modification most possibly alters the pK_a of the bound water at the active site.

The mechanism of nitrile hydrolysis has yet to be firmly established. Since low-spin Co^{3+} centers are substitutionally inert, direct binding of nitriles at the metal site and subsequent release of the amides

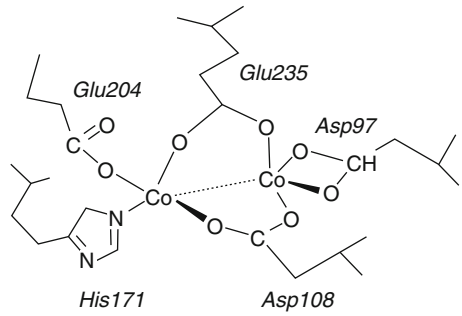
following hydrolysis at a fast rate appear quite unlikely. It is therefore believed that a metal-bound hydroxide activates a free water molecule at the active site (via deprotonation), and nucleophilic attack by the resultant OH^- on the C atom of RCN (nested at the active site pocket) leads to the formation of amide (Fig. 1).

Thiocyanate hydrolase (THase). Closely related to Co-NHase is the protein thiocyanate hydrolase (THase) which catalyzes thiocyanate (SCN^-) hydrolysis to carbonyl sulfide (COS), ammonia, and hydroxide ion (2). Interest in this enzyme stems from its role in

$$SCN^- + 2H_2O \rightarrow COS + NH_3 + OH^- \qquad (2)$$

remediation of industrial wastewater. THase isolated and purified from *Thiobacillus thiocapsa*, an obligate chemolithotrophic eubacterium, has been structurally characterized (Arakawa et al. 2006, 2009). The heterododecameric structure $(\alpha\beta\gamma)_4$ is composed of four αβγ heterotrimers, each containing one low-spin Co^{3+} ion within the γ subunit. The close evolutionary relationship between THases and NHases is readily recognized by the conserved amino acid sequence and overall structure of the core domain of the αβγ trimer which resembles those of Co-NHase very closely. For example, the γCys128-γCys133 locus of the γ subunit of THase resembles that of the α subunit of NHase. In the equatorial plane of Co^{3+}, two carboxamido-N donors from the peptide backbone (of γSer132 and γCys133) and two sulfur atoms of γCys131 and γCys133 are coordinated. Also, the γCys131 and γCys133 are posttranslationally oxygenated to $\gamma CysSO_2H$ and γCysSOH, respectively; a modification once again is necessary for enzymatic activity. The only difference in the active site structure of these two proteins is the fact that in the THase active site no tightly bound water is present, i.e., the Co^{3+} is 5-coordinate. It is quite possible that the catalytic mechanism involves direct binding of SCN^- to the cobalt site.

Methionine aminopeptidase (MA). Methionine aminopeptidase (MA) is a ubiquitous enzyme that cleaves the N-terminal methionine from newly translated polypeptide chains in both prokaryotes and eukaryotes and plays important roles in both protein turnover and functional regulation. Although MAs examined so far contain variable amounts of metals and can be



Cobalt-containing Enzymes, Fig. 2 Schematic structure of the cobalt-containing active site of methionine aminopeptidase from *E. coli*

activated by metal ions such as Mn^{2+}, Co^{2+}, and Zn^{2+}, careful purification and structural characterization of MA from *E. coli* have been shown to be a true cobalt protein. *E. coli* MA is a monomeric protein (29 kDa, 263 residues) that binds two Co^{2+} ions at its active site. The dimeric site is situated between two double β-antiparallel sheets, and the two Co^{2+} ions are ligated to the highly conserved amino acid residues Asp97, Asp108, His171, Glu204, and Glu235. As shown in Fig. 2, the dicobalt site (Co–Co distance = 2.9 Å) is held by two bridging carboxylates (Asp 108 and Glu 235), and the metal centers have open site(s) for further binding. It is interesting to note that the active site structure of MA shares common features with other metalloproteases such as bovine leucine aminopeptidase with two zinc (Zn) ions. Although the catalytic mechanism of MA has not been firmly established, it is believed that activation of a Co^{2+}-bound water (either at one Co^{2+} site or in the bridge) and its subsequent attack on the substrate bound at the other Co^{2+} site leads to the peptidase action.

Prolidase. Prolidases are dipeptidases that selectively cleave pro-containing peptides and are widely distributed in nature (from bacteria to human). They are involved in degradation of intracellular proteins and recycling of proline. The enzyme from the hyperthermophilic archaebacterium *Pyrococcus furiosus* is a homodimer (39.4 kDa per subunit) that contains two Co^{2+} ions per subunit. One of the Co^{2+} ions is tightly bound, while the second Co^{2+} could be replaced by Mn^{2+} (resulting in a decrease in activity), but not by other divalent metal ions such as Ni^{2+}, Cu^{2+}, or Zn^{2+}. It is therefore evident that prolidases belong to the general class of metallohydrolases with two metal ions at

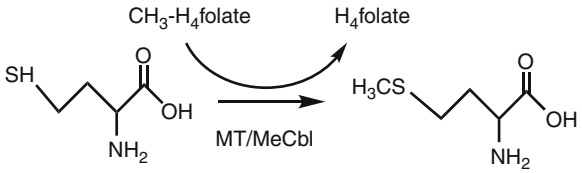
the active site. Although the amino acid sequence of *P. furiosus* prolidase exhibits no significant homology to that of methionine aminopeptidases (MAs), all five cobalt-binding residues are conserved in the former enzyme (Asp209, Asp220, His280, Glu313, and Glu327). In addition, the two-domain polypeptide fold of *P. furiosus* prolidase is similar to that noted in MAs.

Corrin-Containing Cobalt Enzymes

B_{12}-Dependent enzymes. ▶ Vitamin B_{12}, first identified as the antipernicious anemia factor in 1925, is a cobalt-containing cofactor in biology. The cobalt is coordinated to a corrin ring and a 5,6-dimethylbenzimidazole ligand that is covalently linked to the corrin frame (Fig. 3). The sixth ligand in ▶ Vitamin B_{12} is cyanide (CN^-). In coenzyme B_{12}, the sixth ligand is 5′-deoxyadenosine (Fig. 3), while in alkyl cobalamine, a methyl group (CH_3) occupies this position. These two different forms of the B_{12} (cobalamine) cofactor, with cobalt bonded to a methyl group or to a 5′-deoxyadenosine (Fig. 3), are utilized by the various B_{12}-dependent enzymes.

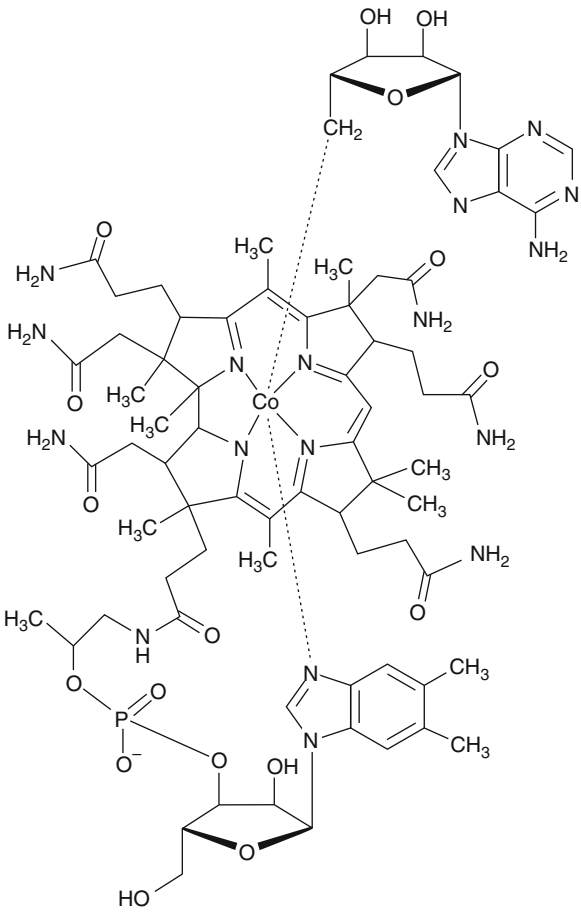
Methyl Transferase (MT)

B_{12}-dependent methyltranferases catalyze transfer of a methyl group from different methyl donors (such as methyltetrahydrofolate) to acceptor molecules (Mathews 2001). For example, the enzyme methionine synthase transfers a methyl group from methyltetrahydrofolate to homocysteine to form methionine and tetrahydrofolate (3).



(3)

In such reactions, the Co(III)–CH_3 bond of methylcobalamine (MeCbl) is cleaved *heterolytically*, leaving both bonding electrons (i.e., a reductive elimination) on the cobalt (forming a Co(I)alamin), and formally, CH_3^+, a carbocation, is transferred to the substrate. These enzymes play important roles in amino acid metabolism in many organisms including humans. The catalytic process involves three protein components, each of which is localized on different polypeptide domains. The first protein component, MT1, binds the methyl donor and transfers it to the B_{12}-containing protein, leading to the formation of the organometallic intermediate with the Co(III)–CH_3 moiety. The third component (MT2) catalyzes the transfer of CH_3^+ cation to the substrate Y^- to form CH_3–Y. The MT2 protein components in general are all zinc proteins that bind and activate the thiolate methyl acceptor (Y^-). Methionine synthase from *E. coli* is the best-characterized protein in this class.



Cobalt-containing Enzymes, Fig. 3 Structure of coenzyme B_{12} (5′-deoxyadenosylcobalamine, dAdoCbl) an organic cofactor (axial ligation is shown as slanted to avoid cluttering). In methylcobalamin (MeCbl), the 5′-deoxyadenosine group in the axial position is replaced with a methyl (–CH_3) group

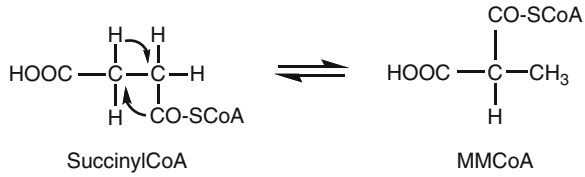
During the catalytic cycle, B_{12} cycles between Co(III)–CH_3 and Co(I). In case of oxidative inactivation of the Co(I) center to Co(II), other ancillary reductases (methionine synthase reductase in human) prime the site back to Co(III)–CH_3 via CH_3 transfer from the methyl donor S-adenosyl methionine (AdoMet) which in turn binds at a different location on the peptide frame.

B_{12}-Dependent Isomerases

The B_{12}-dependent isomerases (mostly found in bacteria) employ 5′-deoxyadenosylcobalamin (Fig. 3) as the cofactor (Banerjee and Ragsdale 2003). The primary function of this unit is to act as a stable entity in the storage and generation of free radicals catalyzing rearrangement and isomerization reactions (e.g., glutamate mutase, methylmalonyl-CoA mutase, diol dehydratase, ethanolamine ammonia lyase), methyl group transfer (e.g., methionine synthase), and deoxyribonucleotide biosynthesis (class II ribonucleotide reductase). In these proteins, the first step is *homolytic cleavage* of the Co(III)–CH_2dAdo bond to form Cob(II)alamine and the 5′-deoxyadenosyl radical (dAdo-CH_2•). Specific amino acid residues around the cofactor at the B_{12}-binding domain of these enzymes initiate this *different mode* of cleavage of the cobalt-carbon bond (Ludwig and Mathews 1997). Although the cobalt-carbon bond in the Co(III)–CH_2dAdo unit is stable in water, it is inherently labile with a bond dissociation energy of ~30–35 kcal mol^{-1}. The B_{12}-dependent isomerases utilize the 5′-adenosyl radical (dAdo-CH_2•) to effect radical-based rearrangements (Fig. 4, Banerjee 2003). The high-energy dAdo-CH_2• radical abstracts an H atom from the substrate to generate a substrate-centered radical intermediate (step 2 in Fig. 4). Following the 1,2 rearrangement (step 3), this intermediate captures the H atom back from dAdo-CH_3 and affords the final rearranged product (step 4).

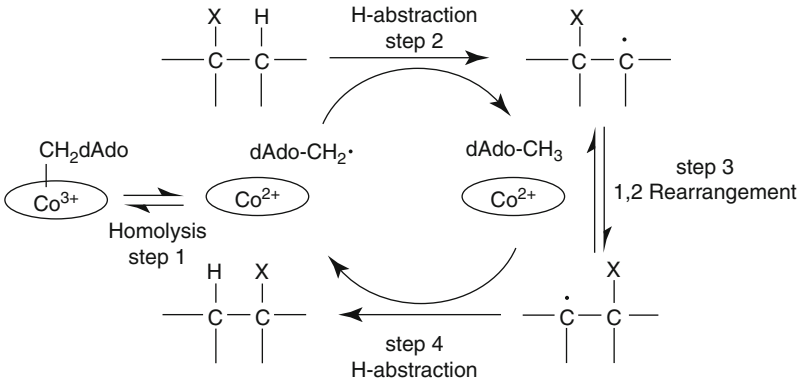
The corrin ring of 5′-deoxyadenosylcobalamin provides some support to the facile Co(III)-C bond homolysis (step 1, Fig. 4) in the enzyme-bound cofactor, a key feature of the B_{12}-dependent isomerases. This macrocycle is analogous to the porphyrin ring found in hemes with some notable exceptions. For example, the corrin ring is sufficiently reduced with predominantly sp^3-hybridized carbons along the outer ring that are all chiral in nature and carries a total 1 charge (versus 2- in porphyrin). These features along with the strained C–C link between rings A and D of the corrin result in a more distorted basal plane coordination unit. The structural distortion could further worsen upon binding of the substrates and could weaken the Co(III)–C bond promoting bond homolysis.

Methylmalonyl-CoA mutase. Methylmalonyl-CoA mutase (MMCM) is the only dAdoCbl-dependent enzyme present in both mammals and bacteria where it catalyzes the reversible rearrangement of (2R)-methylmalonyl-CoA (MMCoA) to succinyl-CoA (4) through hydrogen atom exchange with the methyl group for the carbonyl-CoA group on the adjacent carbon of MMCoA (Banerjee 2003). The most frequently studied enzyme was isolated from *P. shermanii* and consists of a heterodimer with subunits of 69.5 and 80.1 kDa. The catalyzed reaction is a crucially important step in the metabolism of odd-



(4)

chain fatty acids, and the absence of a functional protein is the basis for the human metabolic disease methylmalonic acidemia. As is the case with many B_{12}-dependent enzymes, the mechanism of the rearrangement involves the conversion of substrate radical (S•) to a product radical (P•). Many polar residues such as arginine and tyrosine line the active site pocket to neutralize the carboxylic acid group of the MMCoA substrate. Additionally, the thioester-O of the MMCoA is within H-bonding distance of a crucial histidine-N that when mutated results in a 10^2–10^3-fold decrease in k_{cat}. It has been proposed that this residue promotes rearrangement chemistry by serving as a general base to facilitate proton transfer in the transition state of this enzyme (Thomä et al. 2000). The detailed mechanism of this reaction remains inconclusive, but two proposals involve the formation of a cyclopropyl oxy radical intermediate or



Cobalt-containing Enzymes, Fig. 4 General mechanism for 5′-deoxyadenosylcobalamine-dependent isomerases

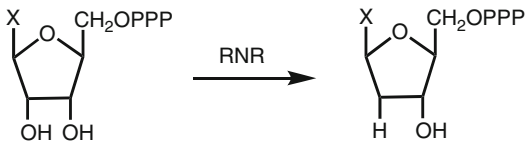
acrylate intermediate via a fragmentation-recombination mechanism.

Ethanolamine ammonia-lyase. Another dAdoCbl-dependent bacterial enzyme that utilizes radical-initiated isomerization reaction is ethanolamine ammonia-lyase (EAL) which converts ethanolamine to acetaldehyde and ammonia (5). In EAL from *E. coli*, dAdoCbl binds at the interface of the α and β subunits of the $\alpha_6\beta_6$ enzyme (Shibata et al. 2010), and formation of the dAdo-CH_2• radical (and Cob(II) alamine) occurs upon substrate binding. Rotation of the ribosyl moiety around the glycosidic linkage brings the radical center close to the substrate C1, forming the substrate-based radical.

$$H_2NCH_2CH_2OH \xrightarrow{EAL} CH_3CHO + NH_3 \qquad (5)$$

Following amino group migration via a cyclic transition state, the radical is transferred to C2 which then captures the hydrogen back from dAdoCH_3. Finally, the rearranged product 1-amino-1-ethanol undergoes elimination of ammonia to form the final product acetaldehyde.

Adenosylcobalamin in DNA biosynthesis. ▶ Ribonucleotide reductases (RNRs) are allosterically regulated enzymes responsible for the conversion of nucleotides to deoxyribonucleotides (6) in all organisms and represent the central players in DNA replication and repair by providing the four basic monomeric deoxynucleotide precursors (Nordlund and Reichard 2006). In all organisms, the RNR-catalyzed synthesis is achieved by the reduction of the corresponding ribonucleotide via radical-based chemistry mediated by a neighboring cysteine thiyl radical formed at a transition metal site (Stubbe and van der Donk 1998). RNR enzymes have been further classified based on the metal cofactor required for the radical initiation process, and these comprise the three distinct RNR classes I, II, and III.



(6)

The Co-dependent RNRs are found in bacteria, algae, and archaea and make up the class II RNRs, which require dAdoCbl for enzyme activity. The function of the Co center in class II RNR is slightly different than other B_{12}-dependent enzymes. In such RNR, the overall radical product responsible for catalysis is not dAdo-CH_2• but a cysteine thiyl radical originating from the peptide backbone; the enzyme in essence utilizes dAdo-CH_2• to generate the thiyl radical required for ribonucleotide reduction. The structure of a class II RNR from *L. leichmannii* reveals some similarities with other RNRs (Sintchak et al. 2002). In contrast to class I and III RNRs, the Co-dependent RNR is a monomeric protein (76 kDa) but contains a similar effector protein interface structure as class I RNRs. Despite its structural simplicity, class II RNRs contain a very similar site for catalysis, namely, the conserved 10-stranded αβ barrel with a finger loop that houses the active Cys-S at the tip. The enzyme accelerates the homolytic Co–C bond cleavage rate

$\sim 10^{11}$-fold faster than the uncatalyzed reaction corresponding to a transition state stabilization of 15 kcal/mol. The radical character of the intermediate dAdo-CH_2• radical is then transferred to the active cysteine residue forming the thiyl radical which finally abstracts the H atom at the 3′ position of the ribose substrate moiety to form the deoxyribose product. Transfer of radical character from dAdo-CH_2• to cysteine is supported by epimerization of (5′R)-[5′-^{2}H] adenosylcobalamin observed when the critical cysteine was mutated to serine or alanine. The distance between the Co(II) center and the thiyl radical has been estimated to be in the 5–8 Å range.

Conclusion

Taken together, the role of Co centers in biology, while not quite as profound as Fe or copper (Cu), is multifaceted in nature. Cobalt either takes on a primary role in the catalytic process effecting direct chemical transformation or indirectly as a cofactor that initiates a reaction but remains a spectator after the reaction begins. In particular, Co(III), although generally thought of as kinetically inert, directly participates in the hydrolytic cleavage of relatively high-energy RC ≡ N bonds (where R = aliphatic or aromatic-C). Indeed, the high Lewis acidity of Co(III) provides an ideal platform to generate such a potent Co(III)–OH nucleophile analogous to Zn(II)–OH at the active sites of hydrolytic zinc enzymes. Since these centers are inert to oxygen, they are perfect choices to perform hydrolytic chemistry without the possibility of undesirable oxidation reactions that would occur at both Fe and Cu centers. As a cofactor, the Co center facilitates isomerization/methylation/redox processes through the formation of carbon-based free radicals to initiate chemical transformations. In this case, the overall facile nature of the Co(III)–C bond toward homolytic cleavage initiates and propagates the free radical chemistry performed at these unique active sites. Collectively, Co-containing proteins, though limited in number with respect to other first-row transition metals like Fe, partake in diverse roles in biology that impact many metabolic processes. ▶ The overview of Co-binding proteins supports this fact in a succinct way.

CO-Dehydrogenase/Acetyl-CoA Synthase

Stephen W. Ragsdale, Elizabeth Pierce and Gunes Bender
Department of Biological Chemistry, University of Michigan Medical School, Ann Arbor, MI, USA

Synonyms

Carbon monoxide dehydrogenase/acetyl-CoA synthase; CODH/ACS

Definition

Carbon monoxide dehydrogenase (CODH) is a Ni–Fe_4S_4-dependent enzyme that catalyzes the interconversion of CO and CO_2. Acetyl-CoA synthase (ACS) is a Ni–Ni–Fe_4S_4 dependent enzyme that synthesizes the central metabolite, acetyl-CoA, from CO, a methyl group from CFeSP, and CoA. CODH and ACS form a tightly bound bifunctional enzyme in *Moorella thermoacetica*.

Background

Carbon monoxide dehydrogenase (CODH) allows microbes to extract CO from the air at the low levels present in the environment and use it as a sole source of carbon and energy (Fig. 1). Besides being a toxic gas, CO is a remarkably potent source of reducing equivalents; thus, the CODHs can couple CO oxidation to the reduction of various cellular redox systems (ferredoxin, hydrogenase, pyruvate synthase, etc.). Two types of CODH have been described: one harbors a molybdopterin/copper active site and the other contains a nickel–iron–sulfur cluster catalytic core. Given the focus on nickel of this volume, we will focus on the Ni–CODH, which uses a bimetallic mechanism to catalyze the oxidation of CO to CO_2 (Fig. 1 and (1)) In some anaerobic microbes, the Ni–CODH couples to another Ni-enzyme called acetyl-CoA synthase (ACS). In this situation, they function as the major players in a microbial pathway of CO and CO_2 fixation called the Wood-Ljungdahl (or reductive acetyl-CoA) pathway (Ragsdale and Pierce 2008). When CODH and ACS are coupled, CODH catalyzes the reduction of CO_2 to CO, and CO is then channeled to ACS to catalyze the reaction of CO with two other substrates (CoA and a methyl group bound to a corrinoid iron-sulfur protein, CFeSP, CH_3–Co as shown in Fig. 1) to generate the central metabolite, acetyl-CoA (2). The Wood-Ljungdahl pathway is unusual in that it generates CO as a metabolic intermediate, channels it as a gaseous substrate and uses complex metal clusters and organometallic intermediates to fix CO and CO_2 into cellular carbon. This review is aimed at covering the contemporary literature related to the Ni-containing CODH and ACS and placing recent research results in perspective. The review is geared for advanced undergraduate and graduate students, researchers, instructors, and professors in the areas of biochemistry, cell biology, and genetics and for whom this may not be their primary area of expertise.

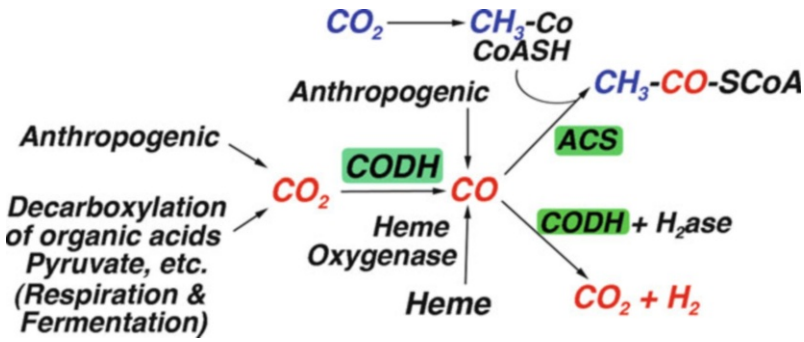
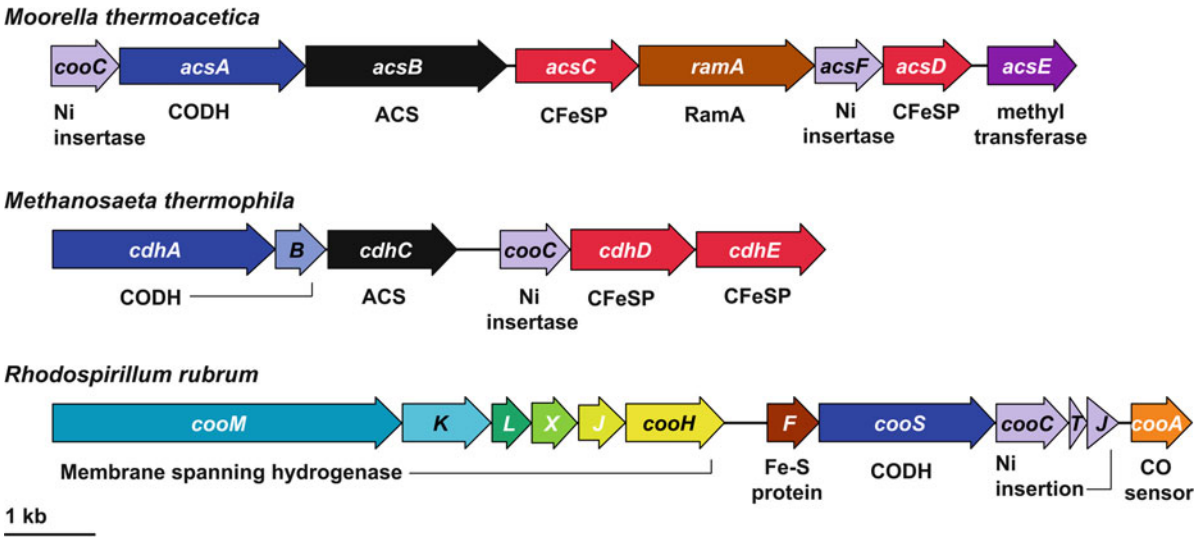
CODH

General Characteristics of Ni–CODH

Early studies on CODH (reviewed in Ragsdale and Pierce 2008) showed that Ni is necessary for CO oxidation by acetogenic bacteria and methanogenic archaea. CODHs catalyze reaction (1), which allows organisms to interconvert CO and CO_2 (Ragsdale and Pierce 2008). In the forward direction, this reaction allows microbes to grow on CO as the sole source of carbon and energy. The fate of the electrons determines the metabolic substrates utilized or end products produced; for example, CO oxidation can be coupled to the reduction of protons, metals, sulfate, etc. (Techtmann et al. 2009). The microbial coupling of CO oxidation to H_2 formation is linked to proton translocation. Similarly, purified CODH and hydrogenase have been adsorbed onto conducting graphite platelets to generate a device that can produce either



CO-Dehydrogenase/Acetyl-CoA Synthase, Fig. 1 Role of CODH and ACS in catalyzing reactions involving CO and CO_2. H_2ase designates hydrogenase



CO-Dehydrogenase/Acetyl-CoA Synthase, Fig. 2 Gene clusters encoding the Type III CODH/ACS from an acetogen, a methanogen the uses the Wood-Ljungdahl pathway in reverse, and a Type I CODH from *R. rubrum* that is coupled to a membrane bound hydrogenase

current or H_2 (Lazarus et al. 2009). Equation 1 also can be run in reverse, enabling organisms to grow on CO_2 as an electron acceptor coupled to the utilization of reducing equivalents produced by various fermentative reactions, e.g., H_2 oxidation and oxidative decarboxylation of pyruvate and aromatic acids. In the Wood-Ljungdahl pathway, CO_2 is reduced to CO, which reacts with CoA and the methylated CFeSP to generate acetyl-CoA, as shown in Fig. 1 (Ragsdale and Pierce 2008).

The genes encoding Ni-CODHs (*acsA*, *cdhA*, and *cooS*) are highly homologous and are found in different contexts, depending on the physiological function of that particular CODH (Fig. 2). For example, *acsA* encodes a CODH that forms a tight complex with ACS (*acsB*). *AcsA* and *acsB* are in the same cluster as the genes encoding the two subunits of the corrinoid iron-sulfur protein (CFeSP) and methyltransferase (MeTr), which are the component enzymes of the Wood-Ljungdahl pathway (Ragsdale and Pierce 2008). In methanogens, an analogous gene cluster (called *cdh* in *M. thermophila*) encodes the proteins involved in utilization of acetyl-CoA as an energy and carbon source. Indicating the function of the protein that it codes for, *cooS* is often found in a gene cluster that includes a membrane-bound hydrogenase.

There are several Ni–CODH subfamilies, with sequence identity as low as 30% between the most distantly related pairs of sequences across these subfamilies. In fact, *Carboxydothermus hydrogenoformans*

encodes five CODHs (Techtmann et al. 2009), named CODH I–V. CODH I and CODH II are loosely associated with the inner side of the cytoplasmic membrane. The proposed physiological role of CODH I, encoded by a gene in a cluster like the one from *Rhodospirillum rubrum* in Fig. 2, is to couple CO oxidation to proton uptake by a membrane-associated hydrogenase, thus generating a transmembrane H^+ gradient for ATP synthesis. CODH II appears to be involved in coupling CO oxidation to reduction of cellular electron carriers.

CODH III shares ~50% sequence identity with CODH I and II; however, its sequence is most similar to that of the AcsA enzyme from *M. thermoacetica*, which catalyzes both CO_2 reduction to CO for acetyl-CoA synthesis and oxidation of CO to provide reducing equivalents for cellular redox carriers (Ragsdale and Pierce 2008). In *M. thermoacetica* the AcsA CODH is isolated in a complex with ACS. In some methanogens, a much larger protein complex called acetyl-CoA decarbonylase/synthase (ACDS) is assembled, which includes CODH, ACS, and both subunits of the CFeSP. This complex functions to catalyze the Wood-Ljungdahl pathway in reverse, with CODH oxidizing the CO that is generated during acetyl-CoA utilization (Ragsdale and Pierce 2008).

CODH IV appears to be involved in protecting against oxidative stress, while the sequence of CODH V differs most from the other CODH sequences and its gene neighborhood does not indicate a physiological role. Neither CODH IV nor CODH V have been purified.

The Involvement of a CO Sensor in Induction of CODH

A heme-containing transcriptional regulator called CooA, which is part of the *cooS* gene cluster, induces expression of CODH and the other proteins in the *coo* gene cluster (Techtmann et al. 2009). CooA is closely related to the cAMP receptor protein, containing a domain that binds ligand (heme instead of cAMP) and a DNA-binding domain that recognizes a promoter sequence similar to that targeted by CRP. Binding of CO to the heme elicits a conformational change that promotes association of CooA with DNA. Another CO-responsive transcriptional regulatory protein called RcoM has been identified that binds heme within a PAS domain (Techtmann et al. 2009).

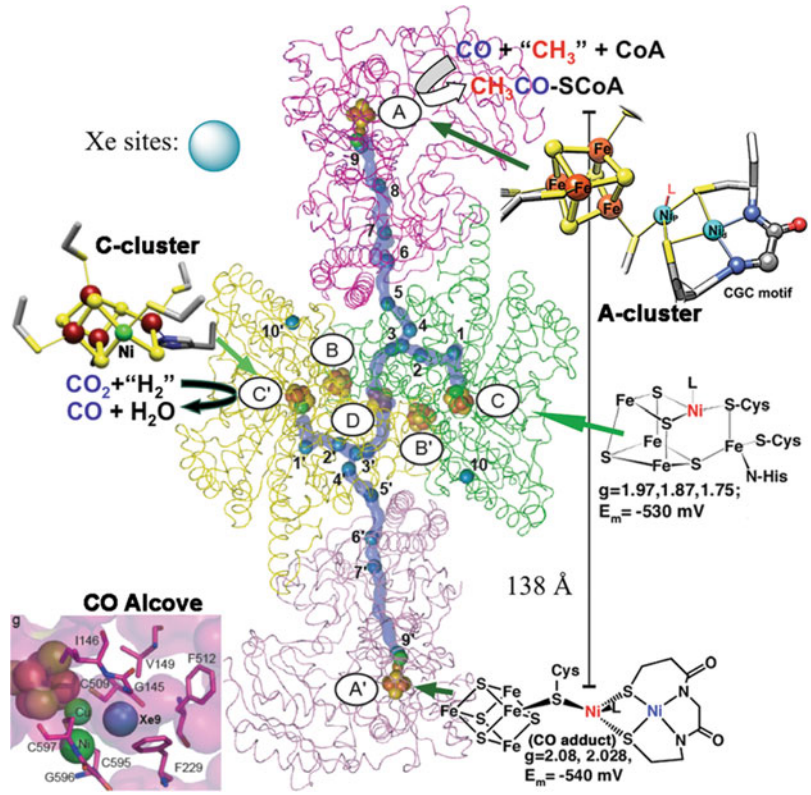
Maturation of the Ni–CODH

While the various proteins involved in assembly of the active site of hydrogenase and urease are rather well defined, comparatively little is known about maturation of the Ni–CODH (Lindahl 2002). Many of the CODH gene clusters in bacteria contain two small genes, *cooC* and *acsF*, that appear to play a role in active site maturation. In *R. rubrum*, *cooC* is found in a *cooCTJ* gene cluster and deletion of portions of this gene cluster increases the concentration of Ni needed for CO-dependent growth of *R. rubrum*. Enzymatic experiments also indicate a role for CooC in the ATP-dependent insertion of Ni into CODH. It is not known if chaperones are involved in metal incorporation or maturation of the A-cluster of ACS. There is some evidence that the product of the *acsF* gene (Fig. 2) facilitates insertion of Ni into the A-cluster.

Metal-Centered Cofactors of the Ni–CODH

Crystal structures have been determined for the *R. rubrum* CO-induced type I CODH, CODH II from *C. hydrogenoformans*, the CODH/ACS complex from *M. thermoacetica* (Fig. 3) and the CODH component of the ACDS complex of *Methanosarcina barkeri*, as described in a recent structural paper (Kung and Drennan 2010). The bacterial CODH structures are very similar and overlay with root mean square deviations of <1.0 Å, while the methanogenic (*M. barkeri*) CODH contains an additional domain that harbors two additional Fe_4S_4 clusters and tightly associates with a small subunit whose function is unknown. All of the CODHs crystallize as a homodimer and each monomer contains a unique Ni–Fe_4S_4 cluster (the C-cluster) at its active site and another Fe_4S_4 cluster (the B-cluster). A third Fe_4S_4 cluster (D-cluster) bridges the two subunits by binding to cysteines from separate monomers in a manner similar to that in the Iron Protein, which transfers electrons to nitrogenase. The B- and D-clusters associate with the N-terminal helical domain and form a redox wire that transfers electrons to the C-cluster, which binds to two Rossmann domains.

The C-cluster is where CO oxidation is catalyzed (Fig. 3). It is conserved in all Ni CODHs and contains a Fe_3S_4 cluster that is ligated by three cysteine residues and is connected to a binuclear Ni–Fe site. The Fe of the Ni-Fe site, called ferrous component II (FC II), is ligated by a histidine and a fifth cysteine ligand that



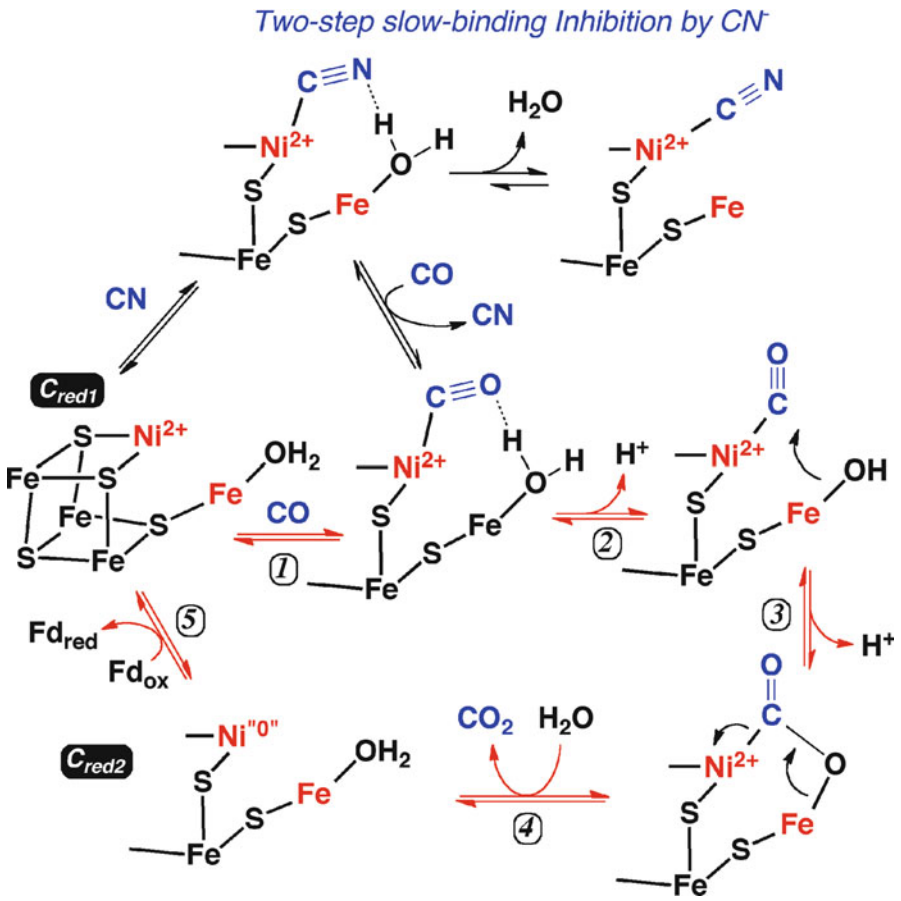
CO-Dehydrogenase/Acetyl-CoA Synthase, Fig. 3 Structures of CODH/ACS and the metallocenter active sites, the C-cluster and A-cluster. The CO channel is shown in *blue*, with the *blue spheres* representing the Xe sites located by crystallographic studies. A site near the A-cluster, termed the CO alcove, is shown in the *lower left hand corner*. EPR *g*-values and midpoint redox potentials (E_m) of the C- and A-clusters are also indicated. The homodimeric CODH component of the complex is shown in *yellow* and *green* in the *middle*, while the two ACS subunits are located on opposite sides of the CODH dimer. The structures of the ACS-associated type III CODHs are very similar to those of the CooS-type I (or II) CODHs

forms a μ_3-S coordination at one corner of the cubane center, while the Ni, which is approximately planar, is bridged to two sulfurs of the Fe_3S_4 moiety and coordinated by a fourth cysteine. There has been some discussion about whether there is an additional bridge between Ni and FC II (Kung and Drennan 2010). In the first structure of the *C. hydrogenoformans* CODH II, an additional inorganic S was modeled at this bridging position, while in the *R. rubrum* CODH structure, the sulfur of a Cys residue appeared as the bridge. In the *M. thermoacetica* CODH/ACS structure, this cysteine could be modeled in different positions, one in which it coordinates Ni and another in which it coordinates FC II. In the most recent structures of CODH containing CO_2, water, and cyanide bound to the C-cluster, the bridging sulfur is absent and is replaced by one of the different ligands used.

Bimetallic Ni–CODH Mechanism

Determination of the enzymatic activity of CODH is straightforward and involves adding enzyme to a buffer solution containing CO and an electron acceptor. A low-potential one-electron acceptor, methyl viologen, is often used; however, the Ni–CODH is rather promiscuous, so most redox dyes can be employed. Methyl viologen is colorless in the oxidized state and is converted to a deep violet color with a high extinction coefficient in the one-electron reduced state. The natural electron acceptor is considered to be ferredoxin.

As described in Fig. 4, CODH uses a ping–pong mechanism (Ragsdale and Pierce 2008). In the first half-reaction, CO reduces CODH, thus forming CO_2 and, in the second half-reaction, an electron acceptor binds and reoxidizes CODH. Spectroscopic and crystallographic studies indicate that Ni and FC II are both involved in binding ligands during catalysis (Ragsdale and Pierce 2008; Lindahl 2002). The C-cluster can equilibrate among at least three different oxidation states: C_{ox}, which is EPR-silent, C_{red1} (with *g* values of 2.01, 1.81, and 1.65) and C_{red2} (with *g* values of 1.97, 1.87, and 1.75). One-electron reduction of C_{ox} generates C_{red1} (following a midpoint potential of −220 mV) and lowering the redox potential to around −530 mV leads to the formation of C_{red2}. As studied by rapid freeze-quench EPR experiments, when CODH is



CO-Dehydrogenase/ Acetyl-CoA Synthase, Fig. 4 CODH mechanism. The individual steps 1–5 of the catalytic mechanism and the slow binding cyanide inhibition are described (Based on Kung and Drennan 2010)

treated with CO, C_{red1} is rapidly converted into C_{red2} at a diffusion-controlled rate. Next, the B-cluster undergoes reduction at a rate constant (60 s^{-1} at 5°C) that is similar to the k_{cat} for CO oxidation (47 s^{-1} at 5°C).

Step 1 of the CODH mechanism involves CO binding to the Ni site of the C-cluster, as suggested by X-ray crystallographic and spectroscopic studies of the complexes of CODH with CO and with CN, a competitive inhibitor with respect to CO (Ragsdale and Pierce 2008; Kung and Drennan 2010). Apparently there are two modes of CO and CN binding to the enzyme: one with an acute Ni-C-N/O angle and another that is linear. The existence of two Ni–CN conformations is consistent with kinetic studies of CN^- inhibition, which demonstrate that CN is a slow binding inhibitor, indicating that CODH forms a complex with CN that is rapidly reversible followed by a separate complex that releases very slowly (Ragsdale and Pierce 2008). *Step* 2 involves the deprotonation of bound water, which apparently involves base catalysis by Lys or His residues near the C-cluster. In *Step* 3, OH^- from the Fe-hydroxide attacks Ni–CO to form a carboxylate that bridges the Ni and Fe atoms. In *Step* 4, elimination of CO_2 is coupled to two-electron reduction of the C-cluster ($Ni^{"0"}$) and the binding of water. The two-electron reduction could generate a true Ni^0 state (Lindahl 2002) or, more likely, the electrons delocalize into the Fe and S components of the C-cluster. In *Step* 5, electrons are transferred from the reduced B- and D-clusters to an external redox mediator, e.g., ferredoxin. Each of the steps above can occur in reverse to catalyze the reduction of CO_2.

Electrochemical and Photochemical Studies of the Ni–CODH

Electrochemical methods have been used to help understand the redox chemistry associated with CO oxidation and CO_2 reduction. For example,

spectroelectrochemical studies (monitoring changes in the spectra as a function of potential) of the interconversion between the different states of CODH defined the midpoint potentials for the C_{red1} and C_{red2} states, which are linked to catalysis (Ragsdale and Pierce 2008; Lindahl 2002). Several direct electrochemistry experiments have also been described in which cyclic voltammetry was performed with CODH directly attached to a pyrolytic graphite edge or glassy carbon working electrode (Lazarus et al. 2009). The direct reduction of CO_2 to CO in the presence of the mediator, methyl viologen, occurs at a rate that is half maximal at a redox potential near the midpoint potential for the CO_2/CO couple. The enzyme was active in both directions with the electrocatalytic reaction being dependent on the pH and CO/CO_2 concentrations. At low pH values, the rate of CO_2 reduction surprisingly exceeds that of CO oxidation. The high catalytic efficiency of CO_2 reduction at the thermodynamic potential for the CO_2/CO couple appears to be due to its ability to undergo rapid successive two-electron transfers coupled to proton transfer, unlike nonenzymatic catalysts that reduce CO_2 through a high-energy $\bullet^{-}CO_2$ anion radical. Electrochemical studies also revealed a one-electron oxidative inactivation of CODH at −50 mV and reductive reactivation at −250 mV.

Electrochemistry is also a valuable tool to drive the direct reduction of CO_2 and to produce electricity and H_2 from CO (a major component of syngas). For example, when CODH was adsorbed on graphite platelets with the *Escherichia coli* hydrogenase, H_2 was produced, thus, coupling CO oxidation to proton reduction to H_2 (essentially by (2)) (Lazarus et al. 2009). CODH could also be co-adsorbed with an inorganic ruthenium complex onto TiO_2 nanoparticles, allowing the photoreduction of CO_2 to CO using very mild reductants (Woolerton et al. 2010).

Energy Conservation Linked to CO Oxidation

Physiological data clearly show that microbial CO oxidation and CO_2 reduction are linked to energy conservation and ATP synthesis by formation of ion gradients. For example, acetogenic bacteria can grow autotrophically on H_2/CO_2 or CO using the Wood-Ljungdahl pathway (Ragsdale and Pierce 2008; Drake et al. 2008). Through this pathway, *M. thermoacetica* generates acetyl-CoA, which is converted to acetate and ATP through the actions of phosphotransacetylase and acetate kinase. However, because one ATP is required for the conversion of formate to formyltetrahydrofolate in the methyl branch of the Wood-Ljungdahl pathway, there is no net ATP synthesis by substrate-level phosphorylation. Therefore, for autotrophic growth by this pathway, ATP synthesis must occur through some type of chemiosmotic mechanism.

It has been proposed that CO oxidation in *Moorella thermoautotrophica* is coupled to reduction of membrane-bound *b*-type cytochromes in a process that is linked to the reduction of methylenetetrahydrofolate to methyltetrahydrofolate by methylenetetrahydrofolate reductase (Muller 2003). The following electron transport chain has been proposed: oxidation of CO coupled to reduction of cytochrome b_{559}, which then reduces methylenetetrahydrofolate or menaquinone and cytochrome $b_{554,}$ which would finally reduce rubredoxin. A proton-pumping F_1F_0 ATP synthase from *M. thermoacetica* has been characterized and, when *M. thermoacetica* membrane vesicles are exposed to CO, they generate a proton motive force.

While formation of a proton gradient through a cytochrome-based pathway can be linked to CO oxidation, some acetogens like *Acetobacterium woodii* lack cytochromes. Such organisms have been suggested, by analogy to the corrinoid-containing, Na^+-pumping methyltetrahydromethanopterin: coenzyme M methyltransferases of methanogenic archaea, to use a sodium gradient involving a sodium-requiring methylenetetrahydrofolate reductase for energy conservation (Muller 2003). Furthermore, acetogenesis in *A. woodii* is coupled to Na^+ import and the *A. woodii* Na^+-dependent ATP synthase has been purified and characterized.

Mechanisms that are being considered for coupling CODH to generation of a transmembrane ion gradient include the Rnf-type NADH dehydrogenase complex, which has been recently shown to couple H_2 oxidation or caffeate reduction to ATP synthesis in *A. woodii* (Biegel et al. 2009). This complex translocates Na^+ while coupling the oxidation of ferredoxin to NAD^+ reduction. The NADH dehydrogenase genes are homologous to *E. coli* NADH dehydrogenase and to components of *R. rubrum* and *C. hydrogenoformans* hydrogenases that are coupled to CO oxidation.

ACS: Acetyl-CoA Synthase

Coupling CO_2 Reduction by CODH to Acetyl-CoA Formation by ACS

During growth of various substrates via the Wood-Ljungdahl pathway, CO is generated by CODH as a metabolic intermediate. For example, when acetogens grow on pyruvate, PFOR catalyzes the oxidative decarboxylation of pyruvate to acetyl-CoA and CO_2, CODH catalyzes the reduction of CO_2 to CO and ACS utilizes the CO (in its reaction with the methyl donor and CoA) to generate a second molecule of acetyl-CoA (Ragsdale and Pierce 2008). Given the very low midpoint potential for the CO_2/CO couple, the generation of CO is a significant investment by the organism. For example, there is over a 200 mV difference in redox potential between the NAD^+/NADH and CO_2/CO couples, which allows for the CO-coupled reduction of NAD^+ to yield about 40 kJ/mol of free energy, which is sufficient for synthesis of one mol of ATP.

Enzymatic and X-ray crystallographic studies revealed the existence of a gas channel connecting the active site of CODH, which produces CO, to the active site of ACS, which utilizes it (Ragsdale and Pierce 2008). When CODH/ACS crystals were subjected to high pressures of Xenon gas, Xe atoms were found at 19 discrete sites in the protein, showing the path of the CO tunnel between the active sites. Mutations of residues to block the movement of CO in the channel led to enzyme variants with much lower CODH and ACS activities. A similar gas channel was observed in the crystal structure of the acetyl-CoA decarbonylase/synthase complex of aceticlastic methanogens. The CO channel could confer several selective advantages. After the large energetic investment represented in CO synthesis, it would be important to sequester the produced CO, thus maintaining a relatively high local concentration and not having it diffuse away from the enzyme. It has been shown that CO_2 is a better donor of CO for acetyl-CoA synthesis than CO in solution, which is in relatively low concentration in the environment. In addition, CO is a potent inhibitor of various metalloenzymes like hydrogenase. Finally, the channel may help coordinate activity of the C- and A-clusters.

The Synthesis of Acetyl-CoA by ACS

The Structure of ACS and its Active Site A-Cluster

ACS catalyzes a remarkable reaction that is key to the Wood-Ljungdahl pathway (Ragsdale and Pierce 2008). The enzyme binds its three substrates, CO (generated by CODH and arriving from the channel just described), a methyl group (donated by the CFeSP) and CoA. Then, the enzyme connects together the methyl and CO groups to make an acetyl intermediate. Finally, it attaches the acetyl group to the thiol group of CoA to generate the high-energy and ubiquitous cellular feedstock, acetyl-CoA. This series of reactions involves the formation of methyl-Ni or Ni–CO and acetyl-Ni organometallic intermediates. ACS consists of three domains that exhibit large conformational changes to accommodate the three very differently sized substrates (a 15 Da methyl group on an 88 kDa CFeSP, a 28 Da CO molecule, and 770 Da Coenzyme A) and to coordinate the reaction steps. For example, to transfer the methyl group to the A-cluster, the C-terminal domain of ACS must open to bring the A-cluster and Co(III)-CH_3 moiety within bonding distance; however, it must coordinate this opening with closure of the CO channel to prevent the release of CO into solution. Thus, ACS must precisely accomplish a series of intriguing reactions to allow organisms to utilize the Wood-Ljungdahl pathway.

A-Cluster: Structure and Formation of the A-Cluster

As shown in Fig. 3 and reviewed recently (Ragsdale and Pierce 2008), the A-cluster consists of a Fe_4S_4 cluster that is bridged by a cysteinyl sulfur to a dinuclear Ni center. As in most Fe_4S_4 clusters, four Cys residues (Cys506, Cys509, Cys518, and Cys528, numbering based on the *M. thermoacetica* sequence) coordinate the iron sites in this component of the A-cluster. Cys 509 also bridges the Fe_4S_4 unit to the proximal Ni (Ni_p), nearest to the cluster. Two other Cys residues (Cys595 and Cys597) bridge Ni_p to the distal Ni (Ni_d), which is additionally coordinated by the backbone amide groups of Cys595 and Gly596, forming a square planar coordination environment for Ni_d.

One complicating feature of Ni_p is its lability and susceptibility to substitution by Cu and Zn (Ragsdale and Pierce 2008). In fact, Cu was present at high occupancy in the first crystal structure (with Ni in the

distal site) and activity appeared to correlate with the Cu content, suggesting that the active form of ACS might contain a binuclear Cu–Ni center. However, various experiments, including activity measurements over a very wide range of metal concentrations, finally provided conclusive evidence that the Ni–Ni form of the A-cluster is active and the Cu–Ni form is not.

ACS exhibits conformational flexibility, as exhibited by large differences between the structures of the "open" Ni–Ni form of ACS versus the closed state of the Zn–Ni and Cu–Ni enzyme (Ragsdale and Pierce 2008). This plasticity may allow for alternative coordination and oxidation ($Ni^{1+,\ 2+,\ 3+}$) states during the catalytic cycle, e.g., adopting a closed conformation to react with CO as it exits from the channel and an open conformation to allow reaction with the much larger substrate, methylated CFeSP.

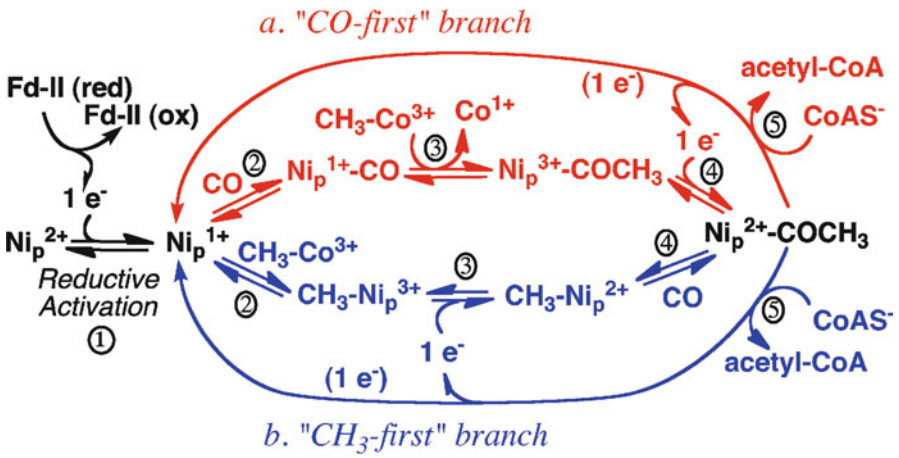
Assays and Mechanism of Acetyl-CoA Synthesis

The most convenient assay for ACS is an isotopic exchange reaction between the ^{14}C labeled carbonyl group of acetyl-CoA and unlabeled CO in solution (Ragsdale and Pierce 2008). This assay does not require any of the other Wood-Ljungdahl pathway proteins. In this assay, one incubates ACS or CODH/ACS with commercially available [1-^{14}C]-acetyl-CoA in a CO atmosphere and follows the decrease in radioactivity of the acetyl-CoA over time. Another relatively convenient assay is an isotopic exchange between radioactively labeled CoA or dephospho-CoA and acetyl-CoA. All activities have been shown to exhibit redox dependence and most of the data indicate an $n = 1$ (one-electron) process with an activation potential between −520 and −540 mV. One can also determine the activity of ACS by quantifying the relative (spins/mol enzyme) amount of an EPR signal that develops when ACS is treated with CO. The CO-treated reduced enzyme exhibits a characteristic EPR spectrum with g-values at 2.074 and 2.028. Studies of this EPR signal provided the first indication that ACS contains a heterometallic Ni–Fe–S cluster. When ^{13}CO was used and when the enzyme was labeled with ^{61}Ni and ^{57}Fe, hyperfine splittings were observed, indicating CO binds to a Ni-iron-sulfur cluster containing more than two iron atoms and that there is extensive delocalization of the unpaired electron spin among these components of the cluster; therefore, this signal was named the NiFeC signal.

It appears that the labile Ni_p in the A-cluster is the site to which substrates directly bind. Pulse-chase experiments indicate that CO and the methyl group bind randomly to ACS to form the acetyl-ACS intermediate that reacts with CoA to form acetyl-CoA. This is consistent with experiments indicating that methylated and carbonylated forms of ACS can both be intermediates during the catalytic cycle. Thus, as shown in Fig. 5, productive binary complexes can form between ACS and either CO or the methylated CFeSP to form viable ACS-CO or methyl-ACS intermediates in the overall synthesis of acetyl-CoA.

The active state of the A-cluster has been alternatively described as a Ni_p^{0}, a Ni_p^{1+}, or a Ni_p^{2+} species, as well as a spin-coupled center in which Ni_p^{1+} is coupled to a $[Fe_4S_4]^{1+}$ cluster. Based on the results of electrochemical, isotope chase, and transient kinetic experiments, the authors favor Ni_p^{1+} as the active starting state. Stopped flow IR and freeze quench EPR studies indicate that the only ACS-CO species that forms at catalytically relevant rates is the paramagnetic Ni_p^{1+}-CO species. Because either CO or the methyl group can bind to ACS in the first step in acetyl-CoA synthesis, the Ni_p^{1+}-CO intermediate must be a viable intermediate in the pathway. Transient kinetic studies following formation and decay of the EPR-active Ni^{1+}-CO species also have established its catalytic competence as an intermediate in acetyl-CoA synthesis. Furthermore, the midpoint potential for formation of the NiFeC species (−540 mV) is consistent with the values for reductive activation of ACS in the CO/acetyl-CoA and CoA/acetyl-CoA exchange reactions.

According to the "paramagnetic" mechanism (Fig. 5), *Step* 1 of acetyl-CoA synthesis involves reductive activation of Ni_p^{2+} to the active Ni^{1+} state, which can bind CO ("a" branch in red) or the methyl group ("b" branch in blue). In *step* 2*a*, Ni_p^{1+} binds CO to form a paramagnetic Ni_p^{1+}-CO intermediate. This step can be reversed by photolysis of Ni_p^{1+}-CO, generating Ni_p^{1+}; however this is a highly labile species that must be maintained at very low temperatures, otherwise, it quickly recombines with CO. The CO used in this step is generated in situ by CODH and channeled to the active site of ACS. In *step* 3*a*, ACS binds the methyl group to form acetyl-Ni^{3+}, which is rapidly reduced (*step* 4*a*) by a proposed internal redox shuttle to form acetyl-Ni^{2+}. Finally, in *step* 5*a*, CoA reacts with acetyl-ACS to release acetyl-CoA in a reaction that leads to transfer of one electron to the



CO-Dehydrogenase/Acetyl-CoA Synthase, Fig. 5 Random paramagnetic mechanism. This mechanism indicates that ACS can first bind either the methyl group or CO (see the text for details). CH_3–Co represents the methylated CFeSP. When $CoAS^-$ reacts, two electrons are introduced, one of which is proposed to go to an internal electron shuttle to reduce Ni^{3+} to Ni^{2+} in the next catalytic cycle and the other is proposed to be retained at the Ni center (depicted by the 1 e^- in parenthesis) to generate a transient unstable Ni(I) state

A-cluster to regenerate the Ni^{1+} starting species and the other to the electron shuttle, which can reduce acetyl-Ni^{3+} in the next catalytic cycle. In the lower "b" branch, reductive activation is coupled to methylation (*step* 2*b*). Transfer of the methyl group to ACS occurs by an S_N2 pathway and the methyl-ACS product appears to not be a species with an S = ½ EPR signal i.e., methyl-Ni(III). Thus, in *step* 3*b*, it is proposed that one-electron is transferred to methyl-Ni^{3+} to generate methyl-Ni^{2+}. Then, in *step* 4*b*, CO binds to form the acetyl-ACS intermediate, which reacts with CoA (5*b*), as in the "a" branch. Chemical modification studies implicate the involvement of arginine and tryptophan residues in binding CoA. Chemical modification and CoA protection experiments indicate that Trp418, which is in the middle domain of ACS, is involved in interacting with CoA.

The diamagnetic mechanism (Lindahl 2002) can be related to the lower path (b) except that it includes a two-electron reductive activation to generate Ni^0 or a spin-coupled species with Ni and the cluster in the 1+ states, methylation to generate methyl-Ni^{2+}, subsequent carbonylation to generate acetyl-Ni^{2+}, and nucleophilic attack by CoA to regenerate the active Ni"0" state. The diamagnetic mechanism considers Ni^{1+}-CO to be an off-pathway state and, due to the two-electron reduction, does not require an internal electron shuttle.

The methyl group of chiral isotopomers of CH_3–H_4folate is converted to acetyl-CoA with retention of configuration. Both the paramagnetic and diamagnetic mechanisms satisfy the stereochemical requirements because they involve two successive nucleophilic attacks, i.e., by Co(I) on methyl-H_4folate and by Ni(I) on the methylated CFeSP, which would lead to net retention of configuration.

Synthetic Analogs of the Anaerobic Ni–CODH and Ni–ACS Active Sites

Model complexes have been synthesized that mimic different aspects of the structure of CODH C-cluster and/or catalyze either CO oxidation or its reverse. Most of these are covered in a review by Evans (Evans 2005). Significant effort has been devoted to development of catalysts that can catalyze CO_2 reduction. The ultimate CO_2 reduction catalyst would be relatively inexpensive and have the ability to capture CO_2 from the atmosphere and reduce it to a useful fuel. Ideally, the catalyst would also mimic photosynthesis in coupling solar energy to convert a mild reductant to a powerful electron donor. Similarly, various models of the ACS active site have been synthesized. The ACS reaction is essentially the Monsanto or Reppe process.

The review by Evans also gives a succinct survey of model compounds related to the ACS active site.

Final Perspective

Over the past decade, many significant findings have been revealed related to the metabolism of CO_2 and CO by CODH and ACS. The structures of these enzymes have been determined and with these structures, surprising atomic level descriptions of novel metal-centered redox cofactors, including unusual nickel–iron–sulfur clusters, have been revealed. These structures provide an architectural framework for mechanistic studies, which are revealing novel ways that metals function in biology. Perhaps, further research on these processes will return important practical benefits, such as development of processes to more efficiently utilize CO_2 as a chemical feedstock and generate energy-rich compounds. While current nonbiological catalysts are relatively unselective and require significant overpotentials to drive CO_2 reduction, the enzymatic reactions are fast and operate at the thermodynamic redox equilibrium. These studies are expected to provide insights into the Wood-Ljungdahl pathway, which has been proposed to have been key to the emergence of life on earth. Studies of this pathway also have revealed novel mechanisms involving metallocenters that act as nucleophiles to form organometallic intermediates and catalyze C–C and C–S bond formation, the latter generating the high-energy thioester bond of acetyl-CoA.

Definition

Purposely modified silver nanoparticles (AgNPs) using bovine serum albumin (BSA) is a biofunctionalization technique to obtain biocompatibility in metals where the surface of the metal nanoparticle is altered for various biomedical applications. Among the serum albumins, the most abundant proteins in plasma and with a wide range of physiological functions, BSA has made it a model protein for biofunctionalization. BSA-coated AgNPs are being increasingly used in the recent past as sensors for environmental pollutants, targeted drug delivery, diagnostics, biosensors owing to exceptional biocompatibility, and optoelectronic properties. Besides functionalizing the nanoparticles for such uses, it highly stabilizes the nanoparticle, thereby preventing from aggregation and agglomeration, which is a major limitation for the application of nanoparticle in biological systems.

Principles and Role of BSA Interaction with AgNPs

Nanoparticles and proteins, in the formation of biocompatible defensive conjugates, have promising uses in targeted delivery (Di Marco et al. 2010). Serum albumins are the most abundant proteins in plasma (Carter 1994). BSA has exceptional property to bind reversibly a huge number of compounds. As the major soluble protein constituent of the circulatory system, albumin has a wide range of physiological functions involving binding, transport, and delivery of fatty acids, porphyrins, bilirubin, steroids, etc. (Olson and Christ 1996). The sulfhydryl groups present in BSA are scavengers of reactive oxygen and nitrogen species which plays an important role in oxidative stress (Valanciunaite et al. 2006 and Hansen 1981). BSA has been selected as a protein model due to its water-soluble nature which is important for interaction studies (Valanciunaite et al. 2006). It contains 582 amino acid residues with a molecular weight of 69,000 Da and two tryptophan moieties at positions 134 and 212 as well as tyrosine (Tyr) and phenylalanine (Phe) (Sklar et al. 1977 and Hansen 1981). BSA serves well as a bio-receptor since the molecule is known to the human antigen recognition system. The interaction of nanoparticles with the proteins present in plasma is of vital importance in biomedical applications of nanoparticles and also in the biosafety concern of nanomaterials. Moreover, biocompatibility of the nanoparticles is one of the prerequisites to biosensing applications. Over a decade, AgNPs have been recognized for its excellent optoelectronic properties (Mariam et al. 2011). As one of most popular surface enhancement Raman scattering (SERS) active substrates, AgNPs have been used to obtain millionfold enhancement in Raman scattering, which provides a highly sensitive tool for trace analysis and even for probing single molecules (Nie and Emory 1997). Coating of BSA or any other protein molecule reduces the toxicity levels of the nanoparticles to a larger extent.

Methods Adopted

UV–Vis Spectral Study

Depending on the shape, size, and size distribution of the nanoparticles, metal AgNPs are known to exhibit their unique surface plasmon resonance (SPR) upon excitation thorough light. UV–Vis spectra of AgNPs (50 μg/ml) and varying concentrations of BSA were recorded in the UV–Vis spectrophotometer (Shimadzu UV-1700, Japan). The recorded spectral range was between 200 and 600 nm.

Adsorption Isotherm Studies

For adsorption studies, concentrations of BSA ranging between 0.05% and 0.85% were interacted with AgNPs (50 μg/ml) for 4 h in a rotary shaker at 300 rpm. The interacted sample was centrifuged and the supernatant was carefully collected and the absorbance was recorded at 280 nm to measure unreacted BSA concentrations. Different graphs were plotted to find the mode of adsorption of BSA over the Ag nanoparticles. In our case, BSA and AgNPs were the adsorbate and adsorbent, respectively.

$$\text{Linear form of Langmuir isotherm is: } C_e/q_e = C_e/q_m + 1/K_a q_m \quad (1)$$

$$\text{Linear form of Freundlich isotherm is: } log\, q_e = 1/nf \log C_e + \log KF \quad (2)$$

where C_e (mg/l) is the amount of adsorbate in solution at equilibrium; q_e (mg/mg) is the amount of adsorbate adsorbed per gm of adsorbent; nF, KF, K_a, q_m are constants.

FTIR Studies

AgNP dispersion was centrifuged at 10,000 rpm, and the pellet was interacted with 0.85% BSA at pH 7, 10, and 12 to study the interaction of colloidal Ag nanoparticles with BSA. These measurements were carried out on a PerkinElmer Spectrum One instrument in diffuse reflectance mode at a resolution of 4 cm^{-1} in KBr pellets.

X-Ray Diffraction Studies

The colloidal Ag nanoparticles were lyophilized and subjected to interaction with BSA (0.85%) for 4 h and then subjected to XRD analysis.

Atomic Force Microscopic Analysis

Atomic force microscopy (Nanosurf Easy Scan 2, Nanosurf Inc; USA) was carried out to study the 3-D structures of nanoparticles in order to analyze the topography and size of engineered nanoparticles. The z dimension of individual particles was used for the histogram analysis and the average particle diameter calculation. Ag nanoparticles of 10 μg ml^{-1} were dispersed in Milli-Q water by sonicating for 15 min using a 750-W (20 kHz) ultrasonic processor (Sonics Corp., USA). A drop of nanoparticles dispersion was placed on to the cover slip and spread evenly in order to get a thin film and dried in hot air oven at 60°C for 30 min, and then the slides were subjected to microscopic analysis.

Results

Preliminary Characterization by the Atomic Force Microscopic Analysis

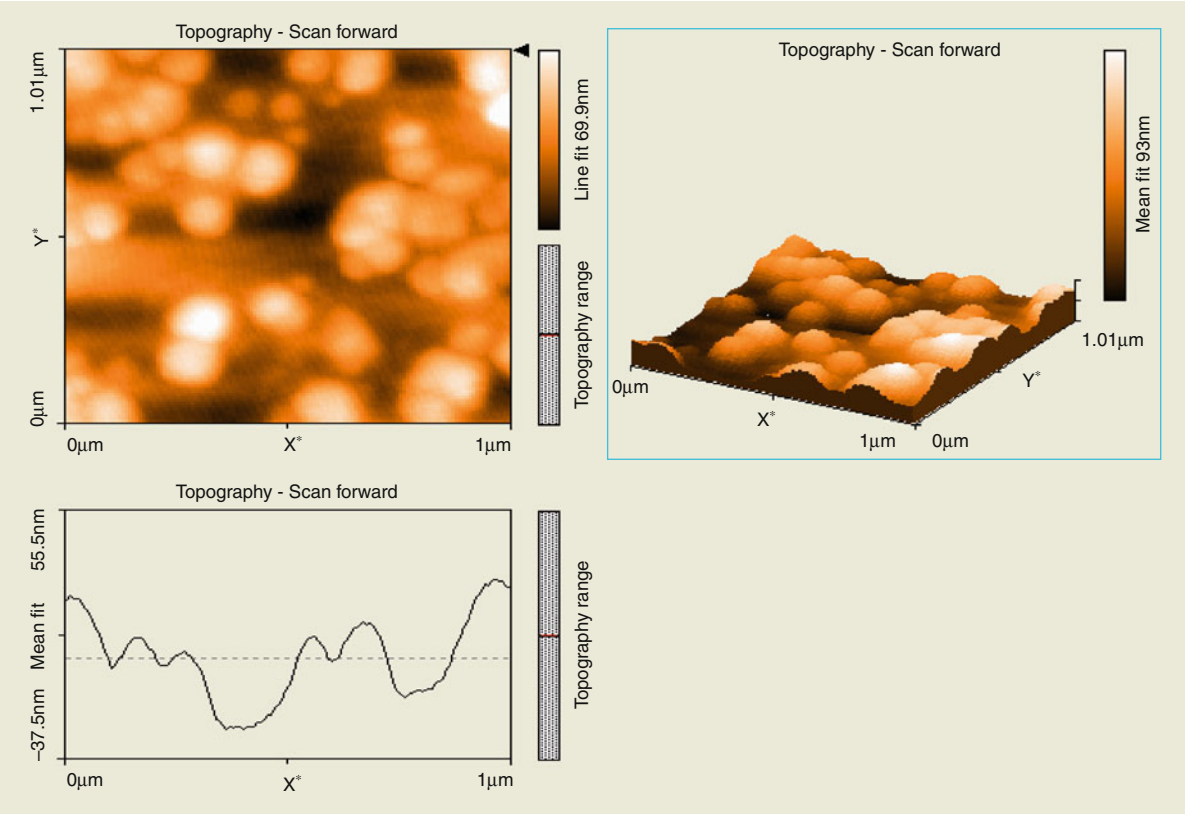
AFM measurements had been carried out for procured Ag nanoparticles to find out the surface topography and the 3-D structure of nanoparticles. Figure 1 below shows a characteristic AFM image of nano Ag. Nanoparticles were observed to be polydisperse condition; topography and shape of the particles were shown in the image with particles, ranging from 100 to 120 nm in diameter. The particles were nearly spherical to oval in shape.

UV–Vis Spectral Study

The λ_{max} value for colloidal Ag nanoparticles (50 μg/ml) was at 425 nm. A decrease in intensity at 425 nm was observed for lower concentrations of BSA, and after a certain concentration (i.e., 0.45%), the blue shift toward the lower wavelength is known to possess better stability. The colloidal AgNPs were stabilized by the negatively charged BSA at higher concentrations, which prevents aggregation. The lowest λ_{max} value was noted at 410 nm. Thus, the colloidal Ag nanoparticles have been capped by BSA as a function of protein concentration.

Surface Changes Recorded by FTIR over pH

The amide A band was obtained at 3,500 cm^{-1}, and amide I band obtained between 1,600 and 1,700 cm^{-1} represented carboxyl group. These peaks were found in all the three interacted mixtures studied at different pH (7, 10, and 12) which potentially proves the interaction of BSA on the AgNPs irrespective of pH. At pH 7, since the FTIR studies revealed only the bands corresponding to the protein (i.e., BSA), it is a proof that the AgNPs are completely coated by BSA (Ravindran et al. 2010). The similar bands



Colloidal Silver Nanoparticles and Bovine Serum Albumin, Fig. 1 Atomic force microscopic image of procured Ag nanoparticles

representing protein adsorbed were observed for elevated pH values (at pH 7 and 10) also as shown in Fig. 2a and b.

Adsorption Isotherm Studies

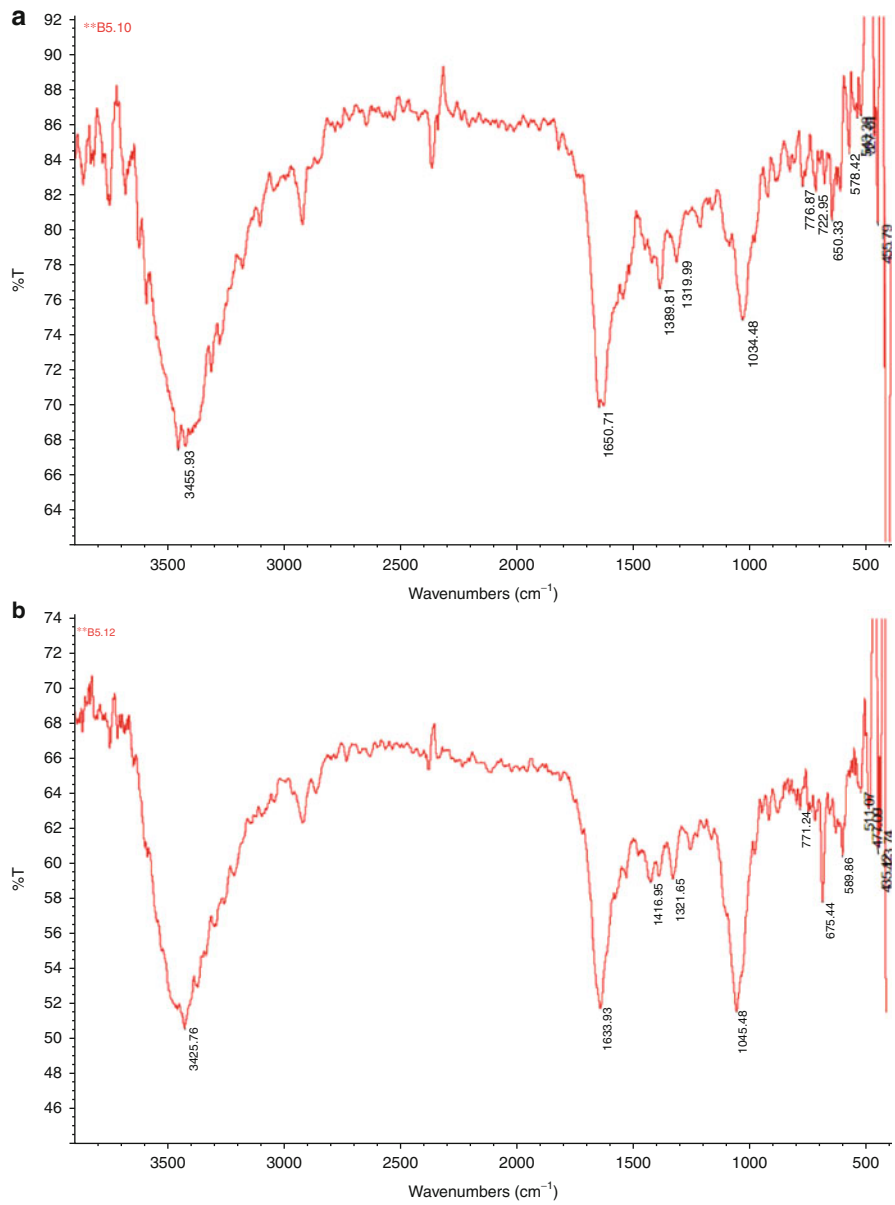
The adsorption data was fitted to the linearized forms of both Langmuir and Freudlisch isotherms to find the optimum isotherm relationship. The isotherms are plotted as a function of BSA/Ag and equilibrium concentration of BSA. Linear regression analysis was used to determine the best-fit isotherm, and the method of least squares was used in finding the parameters of the isotherm. From the R^2 values of both the isotherm equations, it is calculated that the Freudlisch isotherm was more appropriate for the interaction. Moreover, Freudlisch isotherm is based on multilayer adsorption with interaction between adsorbed molecules. The calculated regression values revealed that BSA formed multiple layers on the nanoparticle surface, thereby stabilizing the surface of the particles.

X-Ray Diffraction Studies

The X-ray diffraction image also proved the adsorption of BSA on the surface of Ag nanoparticles. The characteristic crystallite facets of AgNPs were not revealed. The absence of AgNP facets in the XRD spectra upon interaction with BSA confirmed the complete coverage of BSA on the surface of AgNPs (Fig. 3).

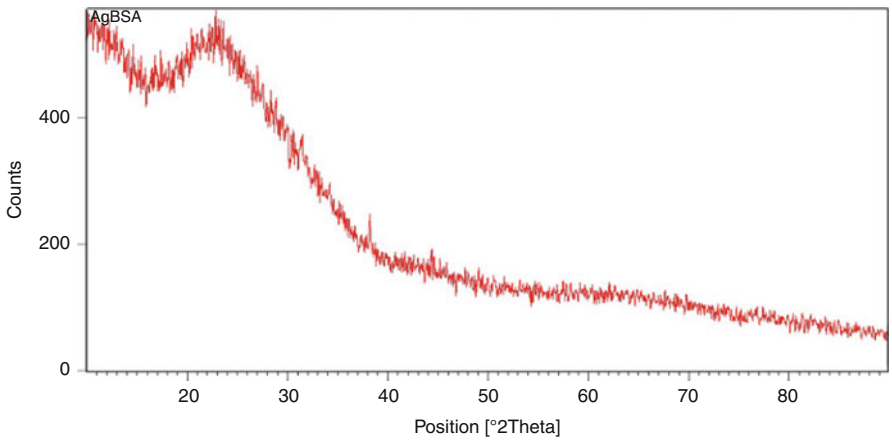
Concluding Remarks

In conclusion, the UV–Vis absorption properties of colloidal Ag nanoparticles coated with BSA were observed to behave different from the uncoated



Colloidal Silver Nanoparticles and Bovine Serum Albumin, Fig. 2 (**a**) FT-IR spectra of BSA-coated silver nanoparticles (0.85% BSA with 50 ppm Ag nanoparticles) at pH 10 (**b**) FT-IR spectra of BSA-coated silver nanoparticles (0.85% BSA with 50 ppm Ag nanoparticles) at pH 12

particles. The BSA adsorption on the Ag nanoparticle surface prevented them from aggregating in solutions of pH > 5. With increasing concentrations of BSA, initially, a decrease in intensity of the absorption spectra was noticed without change in plasmon peak. The decrease in absorbance was corresponding to a stepped adsorption layer behavior. Beyond 0.45% of BSA concentration, a blue shift from 425 to 410 nm in the spectrum was noticed. The results of FT-IR spectroscopy also revealed the prominent peaks of proteins, thereby proving the complete coating of Ag nanoparticles by BSA. The equilibrium adsorption data was fitted better to the Freudlisch isotherm plot than the Langmuir curve. A strong hydrophobic interaction is between the colloidal AgNPs and BSA. Tailoring the concentration of BSA and pH of the medium, it is possible to reduce. The biomolecules conjugated with nanoparticles have received the most attention in the field of clinical diagnosis and drug delivery because of their high stability, good



Colloidal Silver Nanoparticles and Bovine Serum Albumin, Fig. 3 XRD pattern of BSA (0.85%) coated over colloidal Ag nanoparticles where the characteristic facets for silver are not pronounced

biocompatibility, and high affinity for biomolecule. The colloidal Ag nanoparticles and BSA interact at the surface level and lead to the formation of protein "corona" around nanoparticles which highly characterize their biological identity as well as their potential usage for various applications. Lynch and Dawson suggested the importance of the "protein corona" as the vehicle and the biological identity of a nanoparticle for its transport through cell membranes (Di Marco et al. 2010). Hence, functionalizing the surface of the nanoparticles with biomolecules would pave a way for the use of these particles in various biomedical applications.

Advantages of Functionalization Approach

1. A major drawback of using the procured or synthesized nanomaterials due to their very responsive agglomeration and aggregation behavior has been overcome by functionalizing the surface with bioreceptive protein molecules or recognizable molecules such as antibodies, enzymes, starch, dextrin, polymers that are an added advantage for the usage of nanoparticles.
2. Toxicity levels of the BSA-coated Ag nanoparticles have also been considerably reduced with the proven seed germination and phytotoxicity tests.

Potential Applications

Biosensing is performed using BSA as a stabilizer on Ag nanoparticles for protein detection. Upon binding of proteins to the silver nanoparticles, the changes in both the intensity and the wavelength of the particle make an easy way for sensing the presence of a particular protein of interest from a heterogeneous sample. They are widely used in for imaging applications due to the easy recognition of the biomolecules such as BSA inside human system. They are also used as effective antimicrobial agents in the form of hydrogels and silver colloids which are safe on skin.

Research in the field of interaction of nanomaterials to biological conditions especially to human system is of a potential use in the development of nano-drugs and nano-sensors for the diagnostics and pharmacotherapy. Ag nanomaterials are widely synthesized with BSA as a bioreceptor for various biomedical applications such as piezoelectric sensors and antibody-mediated drug delivery systems.

Amine oxidase (copper-containing); Primary amine oxidase; Primary amine:oxygen oxidoreductase (deaminating)

Definition

Copper amine oxidase refers to a ubiquitous family of enzymes that catalyze the oxidative deamination of primary amines, concomitant with the two-electron reduction of molecular oxygen to hydrogen peroxide. To accomplish this reaction, these enzymes utilize the redox-active cofactor 2,4,5-trihydroxyphenylalanine quinone (TOPA quinone or TPQ).

Classification

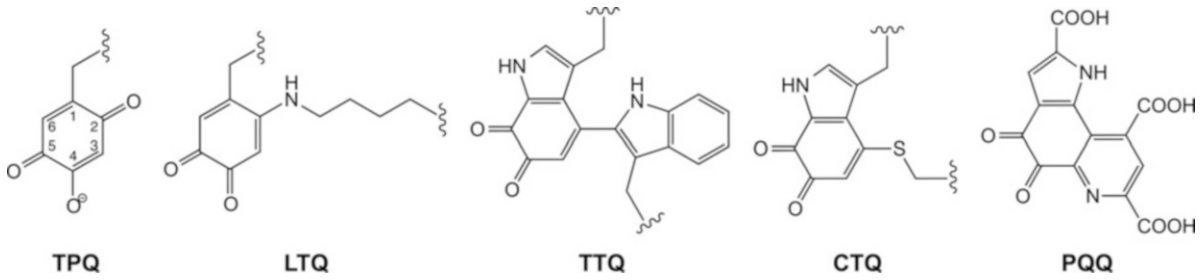
Up until recently, copper amine oxidases (CAOs) were classified within the Enzyme Commission classification EC 1.4.3.6, distinct from the flavin-containing amine oxidases (monoamine oxidase, EC 1.4.3.4) (Boyce et al. 2009). This distinction was based on cofactor content rather than reaction catalyzed, however, leading to some confusion in the literature. For clarification, EC 1.4.3.6 has now been deleted and replaced with two distinct entries: EC 1.4.3.21 and EC 1.4.3.22 (Boyce et al. 2009). EC 1.4.3.21 (accepted name primary amine oxidase) refers to enzymes that oxidize primary monoamines but have little or no activity toward diamines, such as histamine, or toward secondary or tertiary amines (Boyce et al. 2009). EC 1.4.3.22 (accepted name diamine oxidase), on the other hand, refers to a group of enzymes that oxidize diamines such as histamine and also some primary monoamines but have little or no activity toward secondary and tertiary amines (Boyce et al. 2009). This entry will deal with the primary amine oxidases from EC 1.4.3.21.

Mechanism of TPQ Biogenesis

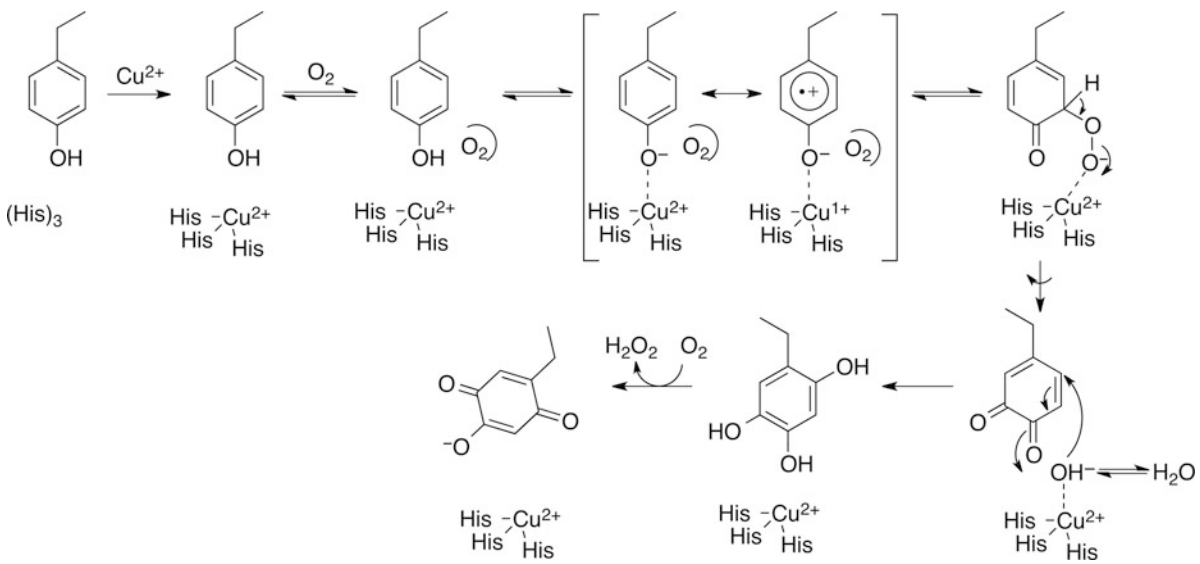
Historically, it had been thought that CAOs contained either a pyridoxyl phosphate cofactor or pyrroloquinoline quinone (PQQ), a bacterial vitamin (DuBois and Klinman 2005). It was later discovered that CAOs instead contained the novel quinocofactor TPQ, derived from a precursor tyrosine in the protein backbone (Janes et al. 1990). The discovery of TPQ led to the identification of a series of new quinone cofactors, including lysine tyrosylquinone (LTQ) in lysyl oxidase, cysteine tryptophylquinone (CTQ) in quinohemoprotein amine dehydrogenase, and tryptophan tryptophylquinone (TTQ) in bacterial methylamine dehydrogenase (Scheme 1) (reviewed in Davidson 2007).

The biogenesis of TPQ, formally a monooxygenation, hydroxylation, and two-electron oxidation of tyrosine, occurs without the aid of any auxiliary enzymes or external reducing equivalents (DuBois and Klinman 2005) (Scheme 2). This autocatalytic processing depends solely on the presence of molecular oxygen and a functional copper center (DuBois and Klinman 2005). Thus, CAOs are able to catalyze both cofactor formation and, subsequently, the oxidation of amines within a single active site. The active site Tyr that leads to TPQ (Y405 in the CAO from *H. polymorpha*, HPAO) is absolutely conserved among CAO family members and is contained within the consensus sequence T-X-X-N-**Y**-D/E (Guss et al. 2009). Other strictly conserved residues include three histidine residues (H456, H458, and H624 in HPAO) that form the three protein ligands of the copper ion and a second Tyr (Y305 in HPAO) that is located at the active site near the O-4 position of the TPQ cofactor (Fig. 1) (DuBois and Klinman 2005).

Prior spectroscopic and structural studies have led to a working mechanism for TPQ biogenesis, summarized in Scheme 2 (DuBois and Klinman 2005). When Cu(II) is added to apo-enzyme anaerobically, an absorbance at 380 nm forms immediately and then decays to



Copper Amine Oxidase, Scheme 1 Structures for protein-derived (TPQ, LTQ, TTQ, CTQ) and peptide-derived (PQQ) cofactors



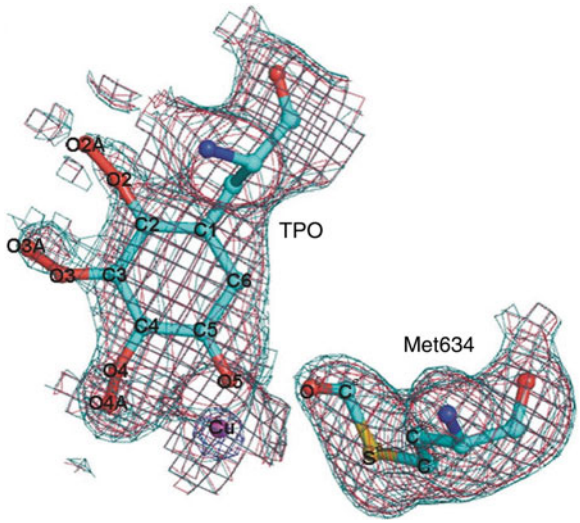
Copper Amine Oxidase, Scheme 2 Proposed mechanism for TPQ biogenesis (DuBois and Klinman 2005)

baseline. This absorbance has been attributed to a transient ligand-to-metal charge transfer between the Cu(II) and a residue en route to the active site. It is then proposed that binding of O_2 at the active site near the precursor tyrosine causes a conformational change that promotes the deprotonation of the tyrosine and ligation of the resulting tyrosinate to Cu(II) (DuBois and Klinman 2005). Next, dioxygen reacts with the "activated" precursor tyrosine in the form of a tyrosinate-Cu(II) ligand-to-metal charge transfer (LMCT) complex (bracketed species in Scheme 2) (DuBois and Klinman 2005). Due to the nature of the oxygen-copper bond in this complex, partial radical character is expected to be imparted onto the tyrosyl ring, thus circumventing the spin-forbidden nature of direct reaction between singlet tyrosine and triplet dioxygen. Experimental evidence for the LMCT complex comes from the observation of a spectral intermediate (λ_{max} = 350 nm) that forms rapidly upon aeration of HPAO prebound with Cu(II) and decays rapidly concomitantly with the appearance of TPQ (DuBois and Klinman 2005). The 350-nm intermediate represents the species that reacts with the first mole of oxygen, the rate-limiting step in Cu(II)-catalyzed TPQ biogenesis (DuBois and Klinman 2005). It should be noted that this 350-nm intermediate has only been seen in HPAO and not other well-studied CAOs from *E. coli* (ECAO) and *Arthrobacter globiformis* (AGAO). This is most likely due to the considerably slower rate of TPQ biogenesis in HPAO, which allows for the detection of the intermediate using a conventional UV-vis spectrophotometer. In the other two enzymes, stopped-flow techniques would likely be necessary to detect any intermediates.

Acidic chains are in *red*, basic in *cyan*, aromatic in *purple*, neutral hydrophilic in *lime*, TPQ cofactor in *red*, and Cu(II) in *crimson*. A network of six active site water molecules (W1–W6) and one axial copper-coordinating water (Wa) that forms hydrogen bonds to TPQ and side chain atoms are shown in *blue*. Hydrogen and metal coordination bonds are shown as *black* and *red dashed lines*, respectively (Reprinted with permission from DuBois JL and Klinman JP 2006. Copyright 2006 American Chemical Society)

A second strictly conserved Tyr in the active site distinct from the TPQ precursor residue also plays an important role in TPQ biogenesis. This residue is Y305 in HPAO and hydrogen bonds to the O-4 of TPQ in the mature enzyme (Fig. 1). The role of Y305 in cofactor biogenesis has been studied by analyzing the properties of Y305A and Y305F mutant proteins (DuBois and Klinman 2006). It was found that the Y305F mutant gave rates for TPQ production that were close to that of WT (reduced ~3-fold), while the Y305A mutant was significantly more hindered, with a rate ~30-fold slower than WT (DuBois and Klinman 2006). In biogenesis, the fairly high rate for Y305F in relation to Y305A implicates a role for steric bulk and hydrophobicity at this position in steering the position of Y405 and its oxygenated intermediates that form en route to TPQ. It is also possible that this Tyr residue acts as a general acid to help facilitate breakdown of the arylperoxide intermediate (Scheme 2) or as a general base to abstract a proton from C-3 of the cofactor ring to drive breakdown of this intermediate (DuBois and Klinman 2006).

Furthermore, an additional product was detected that absorbed at ~400 nm in the case of Y305A and at ~420 nm for Y305F when Cu(II) was added to apo-enzyme (DuBois and Klinman 2006). The formation of this product, in relation to the amount of TPQ (λ_{max} ~480 nm), increased with pH (DuBois and Klinman 2006). The two peaks form independently without an isosbestic point, indicating that the alternate product is not a direct intermediate leading to TPQ. This has implicated two parallel pathways during cofactor biogenesis in the case of Y305 mutants, with one pathway leading to the expected TPQ product and the other producing a new, uncharacterized species. In the case of Y305F, the alternate species forms fourfold more quickly than TPQ at pH 7, facilitating its preferential crystallization and characterization by X-ray crystallography (Chen et al. 2010). In this crystal structure, a novel 2,3,4-trihydroperoxo, 5-hydroxo derivative was detected (Fig. 2) (Chen et al. 2010). The pathway for the formation of this new species is postulated to involve the partitioning of the normal, arylperoxy intermediate (E-I) between concomitant proton abstraction and O-O bond cleavage to generate dopaquinone and ultimately TPQ (top of Scheme 3a), and proton loss and ring aromatization to yield the first, off-path hydroperoxo-product (bottom of Scheme 3a). During the normal biogenesis pathway, E-I is expected to undergo a 180° rotation, placing the O-O bond



Copper Amine Oxidase, Fig. 2 Simulated annealing omit maps of the Y305F mutants of HPAO computed using coefficients ($F_o - F_c$) where F_c were calculated from models in which the side chain of residue 405 was absent, and F_o were the structure factors observed from crystals of the *E. coli*–expressed mutant. The maps are contoured at σ levels of 2.5 (*cyan*), 3.0 (*crimson*), and 10.0 (*purple*). Atoms are colored *blue* for nitrogen, *red* for oxygen, and *magenta* for copper; for the residue 405 cofactor, the carbon atoms are in *cyan* (Reprinted with permission from Chen et al. 2010. Copyright 2010 American Chemical Society)

undergoing cleavage in close proximity to the hydroxyl group of Y305. Insertion of Phe in place of Tyr at position 305 creates, instead, a hydrophobic patch, precluding the normal 180° rotation and leading to the energetically more favorable deprotonation coupled to ring aromatization.

Proceeding further, it can be seen from the electron density map that the oxygen chemistry has not stopped at a single hydroperoxide insertion, indicating instead three such side chains (Fig. 2). A proposed pathway for the production of the 3,4-dihydroperoxo-product, designated TPO-3,4, is detailed in Scheme 3b. An analogous scheme can be written in which a 2,4-dihydroperoxo-product (TPO-2,4) is obtained (Scheme 3c). These results implicate a runaway oxidative process following the replacement of a single, absolutely conserved side chain.

Catalytic Mechanism

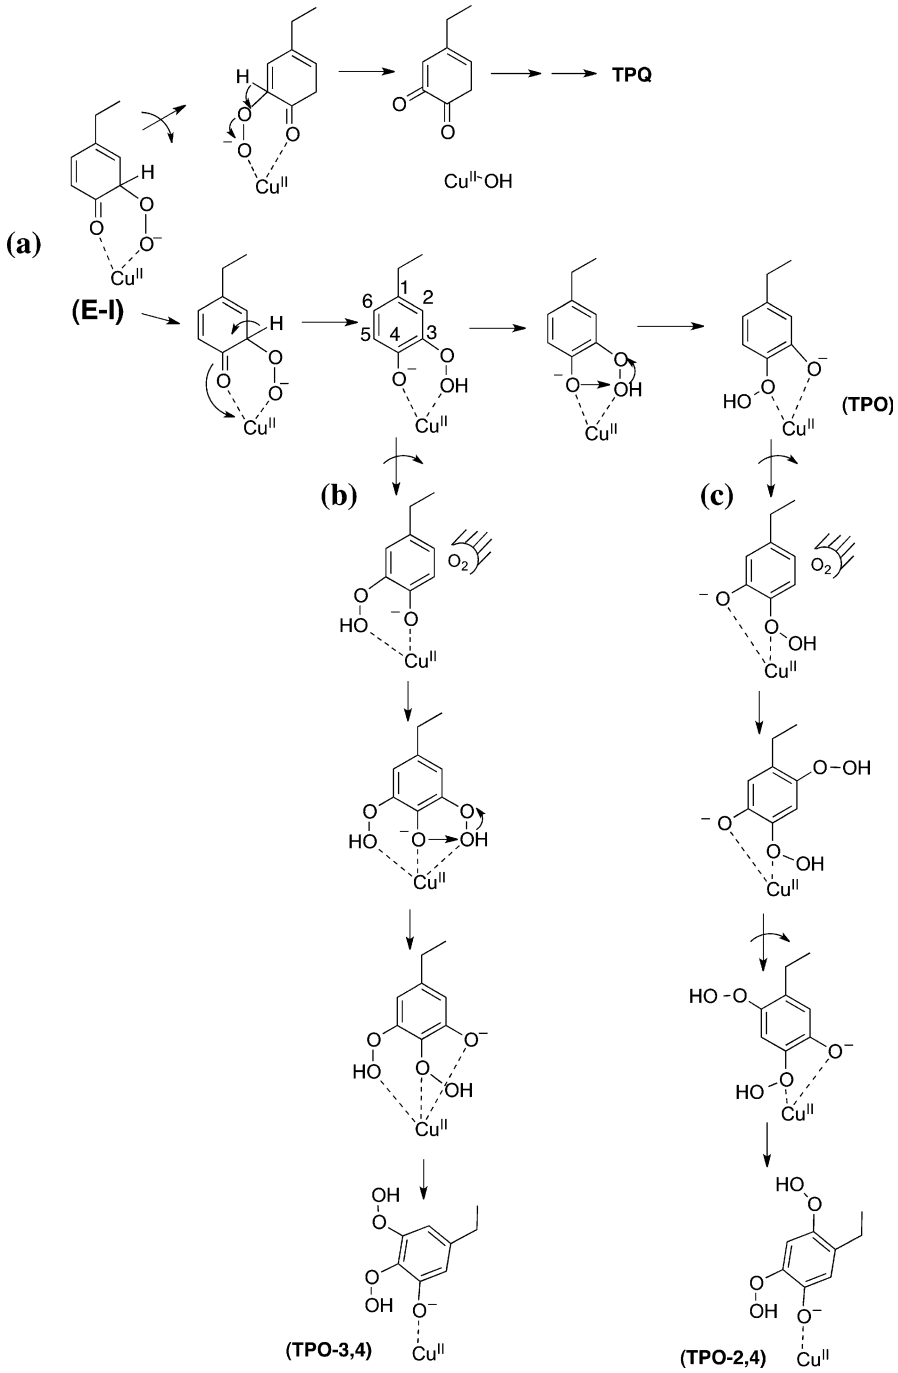
The reaction catalyzed by CAOs proceeds via a ping-pong mechanism involving a covalently bound redox cofactor, TPQ, and a copper ion, Cu(II) (Mure et al. 2002). The catalytic cycle consists of two half-reactions: (1) a reductive half reaction, in which the substrate is oxidized to an aldehyde product via a Schiff base intermediate and the cofactor is converted to a reduced, aminoquinol form; and (2) an oxidative half reaction in which dioxygen is reduced to hydrogen peroxide and the oxidized TPQ is regenerated following release of an ammonium ion (Mure et al. 2002) (Scheme 4).

Reductive Half Reaction

In the first half reaction, TPQ initially undergoes a two-electron reduction, serving as a "storage site" for reducing equivalents that are eventually transferred to O_2 to form hydrogen peroxide in the oxidative half reaction. The starting oxidized form of TPQ gives CAOs their characteristic absorbance around 480 nm and distinct pink color (Mure et al. 2002). TPQ exists in the oxidized state due to the acidity of the 4-hydroxyl group ($pK_a = 4.1$ in model compound) (Mure et al. 2002). Charge is delocalized between oxygens on C-2 and C-4, which decreases the electrophilicity at these sites and directs nucleophilic attack of amine substrates exclusively to the C-5 position. This nucleophilic attack is aided by an active site base that deprotonates the substrate (Asp319 in HPAO) (Mure et al. 2002). Addition of the substrate amine to TPQ leads to the formation of the first stable intermediate, the substrate Schiff base (Mure et al. 2002). This intermediate is proposed to form through a carbinolamine intermediate that has not been observed directly. The next step is the formation of the product Schiff base, proceeding through base-catalyzed proton abstraction at C-1 of the substrate (Mure et al. 2002). This involves the transfer of two electrons from the substrate amine to the TPQ cofactor and is driven by the gain of aromaticity in the cofactor (Mure et al. 2002). The final step in the reductive half reaction involves hydrolysis of the product Schiff base, releasing aldehyde product and generating the aminoquinol form of the cofactor (Mure et al. 2002).

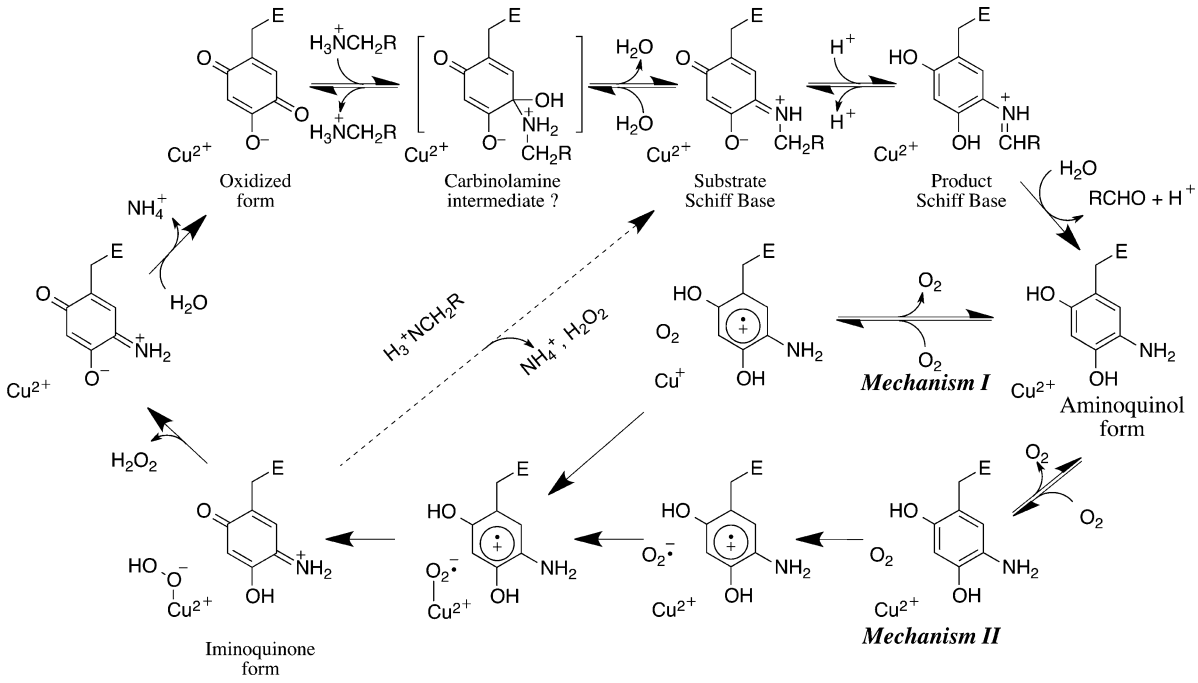
Oxidative Half Reaction

In the oxidative half reaction, molecular oxygen binds to a hydrophobic pocket in the active site. Then, an electron is transferred from the aminoquinol form of TPQ to O_2, generating the semiquinone form of



Copper Amine Oxidase, Scheme 3 (**a**) Postulated mechanism for the branching of a biogenesis intermediate to TPQ and TPO. (**b**) Model to explain 3,4-dihydroperoxo-product. (**c**) Model to explain 2,4-dihydroperoxo-product

TPQ and superoxide, respectively (Mechanism II, Scheme 4) (Mure et al. 2002). Superoxide then moves onto the Cu(II), allowing for transfer of a second electron and two protons from the semiquinone, resulting in the formation of hydrogen peroxide and an iminoquinone form of the cofactor (Mure et al. 2002). Finally, hydrolysis of the iminoquinone results in the release of ammonium ion and regeneration of the oxidized form of TPQ, ready for another round of catalysis (Mure et al. 2002). Alternatively, release of ammonium from the iminoquinone can proceed by a transamination



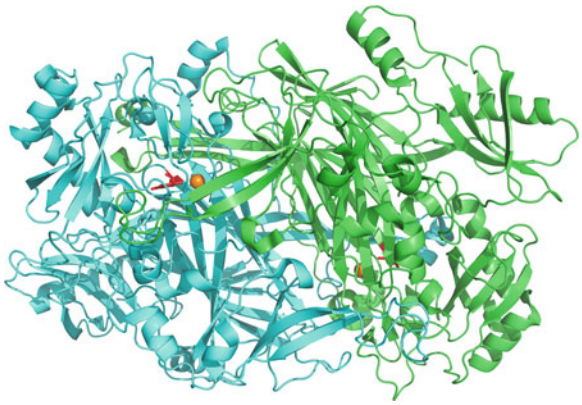
Copper Amine Oxidase, Scheme 4 Proposed catalytic mechanism of CAOs (Mure et al. 2002)

reaction with substrate amine to form the substrate Schiff base (dashed arrow, Scheme 4) (Mure et al. 2002).

An alternative mechanism has also been proposed for the oxidative half reaction. The chief difference is that the first electron is transferred from the aminoquinol TPQ to Cu(II), generating a semiquinone radical and Cu(I) (Mechanism I, Scheme 4) (Mure et al. 2002). Molecular oxygen then combines with Cu(I) to form Cu(II) superoxide (Mure et al. 2002). The transfer of, a second electron and two protons yields hydrogen peroxide and iminoquinone. Finally, the iminoquinone is hydrolyzed, releasing ammonium and regenerating the oxidized form of TPQ. Evidence for this pathway comes from the accumulation of TPQ semiquinone/Cu(I) when the enzyme is reacted with amine substrate in the absence of O_2 (Mure et al. 2002). The level for accumulation ranges from 0 % to 40 %, depending on the source of the enzyme (Mure et al. 2002). In the case of HPAO, however, substitution of the active site cupric ion by a cobaltous ion yields an enzyme form with k_{cat} similar to the native enzyme. Since the redox cycling of Co(II) to Co(I) is prohibited by a very low redox potential, the metal substitution reaction provides strong support for Mechanism II (Mure et al. 2002).

Structural Properties of Copper Amine Oxidases

Structural studies have contributed greatly to the interpretation of the wealth of kinetic and spectroscopic data in the literature on CAOs. As previously mentioned, CAOs are ubiquitous and found in bacteria, plants, fungi, and animals. Structures of CAOs have been solved from a variety of sources, including *Escherichia coli* (ECAO), pea seedling (PSAO), *Hansenula polymorpha* (HPAO), bovine serum (BSAO), *Arthrobacter globiformis* (AGAO), *Pichia pastoris* (PPLO), and human (human vascular adhesion protein-1) (reviewed in Guss et al. 2009). The overall three-dimensional structure for all solved CAO structures is similar (HPAO shown in Fig. 3) (Brazeau et al. 2004). In all cases, the CAOs are homodimers of ~70 kDa subunits that contain a carboxy-terminal domain that folds into a β-sandwich with twisted β-sheets (Brazeau et al. 2004). The overall shape of the dimer resembles a mushroom cap. The active site is buried deeply within each subunit and contains a TPQ cofactor, which is not directly liganded to the Cu but rather has hydrogen bonding between O-2 and a water molecule and between O-4 and another



Copper Amine Oxidase, Fig. 3 Ribbon diagram of HPAO (PDB entry; 2OOV). One monomer is colored *cyan*, the other *green*. Copper ions are shown as *orange spheres*. TPQ is colored *red*

conserved Tyr in the active site (Y305 in HPAO) (Fig. 1). In addition, O-5 of the cofactor is oriented close to the catalytic base (Asp319 in HPAO) in the amine substrate binding pocket (Brazeau et al. 2004). The Cu(II) is liganded in a distorted square pyramidal geometry with three histidine sidechains (H456, H458, and H624 in HPAO) providing N ligands ~2.0 Å away, an axial water at a distance of ~2.4 Å, and sometimes a labile equatorial water ligand ~2.0 Å away (Brazeau et al. 2004).

Biogenesis Intermediates

Biogenesis of TPQ can be studied structurally by preparing enzyme in the absence of copper, as TPQ formation is a self-processing event. What has been particularly insightful is the identification of intermediates along the pathway by freeze-trapping techniques (Kim et al. 2002, reviewed in Brazeau et al. 2004). In the first of these structures, that of apo-enzyme, the His metal ligands along with the TPQ precursor Tyr residue are arranged in a tetrahedral geometry, poised to bind copper (Kim et al. 2002). When Cu is added anaerobically, another structure can be trapped that is virtually identical to that of apo-enzyme, with Cu now coordinated by the three His residues and TPQ precursor Tyr residue (Kim et al. 2002). After exposing these anaerobic crystals to oxygen for a short period (10 min), the next intermediate that is trapped is that of 3,4-dihydroxyphenylalanine (or the oxidized quinone form) (Kim et al. 2002). In this structure, an oxygen atom of either water or hydroxide is located in an equatorial position to Cu. When anaerobic crystals were instead exposed to oxygen for a longer period (100 min), a different, later-stage intermediate is observed, which now has three oxygens and can be modeled as either the reduced or oxidized form of TPQ (Kim et al. 2002). This structure also shows that the structure has rotated 180° about the Cβ-Cγ bond. Evidence that this structure is the reduced cofactor comes from single crystal microspectrophotometry, which shows no evidence of a 480 nm absorbance characteristic of oxidized TPQ (Kim et al. 2002). To visualize the final step of TPQ biogenesis, anaerobic crystals were aerobically soaked in copper solutions for a week, which resulted in pink crystals indicative of oxidized TPQ formation (Kim et al. 2002). In the final structure, the TPQ is clearly in an "off-copper" conformation, with the O-4 pointed away from the Cu.

Structural Data and Catalysis

Structural studies have also been insightful in studying intermediates of both the reductive and oxidative half reactions. The structure of a substrate Schiff base with the inhibitor 2-hydrazinopyridine (2-HP) has been solved (Brazeau et al. 2004). Hydrazines irreversibly inhibit CAO activity and can be used to derivatize the TPQ cofactor for spectral analysis (e.g., phenylhydrazine generates a strongly absorbing hydrazone). In this structure, 2-HP is covalently bound to the C-5 that is also the site of nucleophilic attack by natural amine substrates (Brazeau et al. 2004). This structure also shows N-2 of 2-HP hydrogen bonded to the carboxylate side chain of the catalytic base (Asp383 in ECAO). This position is analogous to the methylene carbon of a primary amine substrate where a proton is abstracted by the active site base in the conversion of substrate Schiff base to product Schiff base. To examine the aminoquinol form of the enzyme, crystals were prepared anaerobically and subsequently reduced with substrate (2-phenethylamine). In this structure, the aminoquinol form of the cofactor is ordered in the same position as the oxidized form of TPQ.

In order to study the oxidative half reactions, studies were conducted in which crystals were reduced with substrate anaerobically, reduced with substrate in the presence of nitric oxide (NO), or aerobically trapped. In the substrate reduced structure, previously mentioned with respect to the reductive half reaction, there is clearly the presence of product phenylacetaldehyde in the active site (Brazeau et al. 2004).

This is consistent with the ping-pong kinetics of the enzyme in which irreversible formation of product occurs prior to oxygen binding. In the structure with NO, NO takes the place of the axial water, and is situated between the copper and the O_2 of the aminoquinol (Brazeau et al. 2004). Thus, the dioxygen mimic NO appears capable of interaction with both the copper ion and the aminoquinol, consistent with a mechanism of electron transfer from either Cu(I) or aminoquinol to O_2. In the aerobically trapped structure, oxygen occupies the same site as NO did, with an electron density compatible with the peroxide product (Brazeau et al. 2004). The fact that these crystals lacked any visible absorbance is consistent with the presence of a hydrogen-bonded iminoquinone (Brazeau et al. 2004).

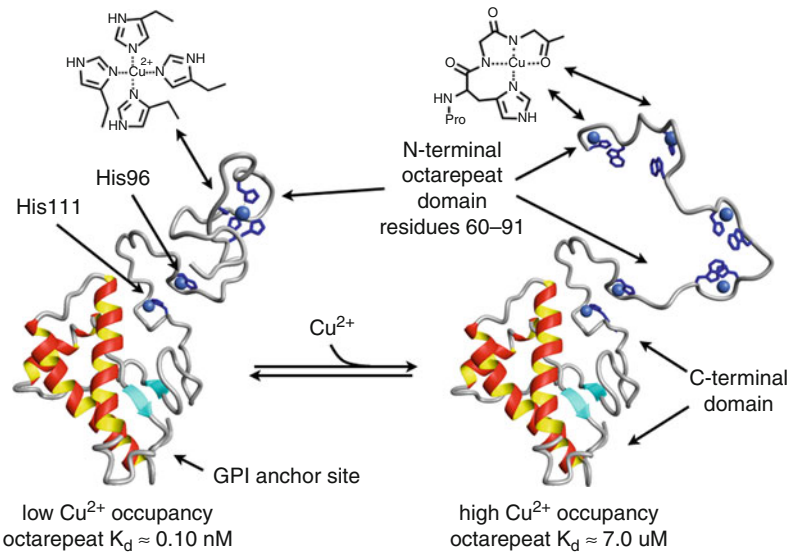
Definition

Prion diseases are infectious, neurological disorders that arise from accumulation of a misfolded form of the endogenous prion protein. These disorders affect a wide range of mammalian species and present an ongoing public health threat. The function of the normal prion protein is not well characterized, but recent research suggests that it is linked to the protein's ability to bind copper.

Prions, Copper Coordination, Function, and Disease

The prion protein, discovered by Stanley B. Prusiner and colleagues, is a ubiquitous component of tissues in



Copper and Prion Proteins, Fig. 1 Structural features of PrP^C showing copper coordination modes at different copper concentrations. The secondary structure of the folded C-terminal domain is primarily composed of three α-helices. Copper (Cu^{2+}) binds to two distinct regions. Coordination within the octarepeat (OR) domain depends on the ratio of copper to protein. At low copper levels, Cu^{2+} coordinates to imidazole side chains (*left*). At high levels, each OR segment takes up a single Cu^{2+} equivalent. Respective coordination features are shown at the *top* of the figure. In addition to OR binding, copper is also taken up at sites located to histidine 96 and histidine 111

both mammals and avian species that is found at high levels in the central nervous system (CNS). The normal form is referred to as cellular PrP and denoted PrP^C. PrP^C is a glycoprotein of approximately 210 amino acids, with an unstructured N-terminus and a folded C-terminus containing three α-helices (Fig. 1). The final amino acid links to a glycophosphatidylinositol (GPI) group that anchors the protein to extracellular membrane surfaces. The precise physiological function of the cellular prion protein remains unknown. It is thought to have a neuroprotective role, perhaps by suppressing apoptosis. PrP^C is also linked to transmembrane signaling.

The transmissible spongiform encephalopathies (TSEs), or "prion diseases," are infectious neurodegenerative disorders that include mad cow disease (bovine spongiform encephalopathy, BSE), chronic wasting disease (CWD) in deer and elk, scrapie in goats and sheep, and the four human disorders Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome (GSS), fatal familial insomnia (FFI), and Kuru. TSEs are marked by spongiform pathology and progressive loss of neuronal function. Within the affected tissues, the prion protein is found in a β-sheet-rich misfolded form, referred to as a prion or PrP^{Sc} (scrapie form). Most cases of prion disease are sporadic, with no known cause, while approximately 10% are inherited and arise from gene insertions, deletions, or single point mutations. A very small percentage of prion diseases are caused by transmission of infectious PrP^{Sc}. These infectious routes are responsible for the 1980s outbreak of BSE in the United Kingdom and the current spread of CWD in the Rocky Mountain regions of North America. Approximately 200 individuals in the UK, who consumed infected meat, developed variant CJD (vCJD). Through the middle part of the twentieth century, cannibalistic practices of the Fore people of Papua New Guinea led to widespread transmission of Kuru. In Western Society, prions have been spread through infected cadaver-derived tissues and hormones, and improper surgical operating room procedures.

As demonstrated in 1997, PrP^C binds copper (Cu) in vivo (Brown et al. 1997). The connection to copper was initially suggested by mass spectrometry studies showing a high affinity for binding to the flexible PrP

N-terminus. Copper, one of the most abundant metal species of the CNS, is found both within cells and in the extracellular spaces. It is essential for numerous enzymatic processes including cellular respiration and neurotransmitter synthesis. Although copper has two oxidation states, Cu^{+} and Cu^{2+}, most investigations into the interaction between copper and PrP examined Cu^{2+}, the dominant species in the extracellular space. There are two adjacent copper binding regions in PrP^{C} (Fig. 1) (Millhauser 2007). The first is in the N-terminal octarepeat (OR) domain, residues 60–91 in human PrP, comprised of tandem repeats of the fundamental sequence PHGGGWGQ (Pro-His-Gly-Gly-Gly-Trp-Gly-Gln). The precise way in which Cu^{2+} coordinates to this 32 amino segment depends on the ratio of copper to protein (Chattopadhyay et al. 2005). A single equivalent of Cu^{2+} coordinates to the imidazole side chain groups of the four OR histidine residues. The affinity is high, as reflected by a subnanomolar dissociation constant (K_d) of approximately 0.1 nM (Walter et al. 2006). This K_d is substantially lower than the estimated concentrations of extracellular copper, thus supporting an in vivo interaction between copper and PrP^{C}. The OR domain is also able to bind Zn^{2+} with a similar coordination mode, although with much lower affinity than that found for Cu^{2+} (Walter et al. 2007).

At higher Cu^{2+} concentrations, each HGGGW module within an individual repeat takes up a single copper equivalent. In this high occupancy state, a histidine imidazole, the backbone nitrogens from the two glycines immediately following the histidine and a backbone carbonyl oxygen, coordinate each Cu^{2+} (Burns et al. 2002). The K_d for this coordination mode is approximately 7.0 μM (Walter et al. 2006), comparable to the highest estimates of the Cu^{2+} levels in the synaptic space. Progressive copper uptake exhibits negative cooperativity, consistent with the increase in K_d from the low to the high occupancy state.

The second copper-binding region encompasses residues 94–111 (human sequence) with histidines at 96 and 111 (Fig. 1) (Burns et al. 2003). Although less studied than the OR domain, this segment is thought to take up two Cu^{2+} equivalents, each one localized to a histidine. Coordination at each site is from four nitrogens originating from the histidine imidazole and exocyclic nitrogen, and the backbone amide nitrogens from the two residues preceding each histidine. The dissociation constant is approximately 0.1 nM and does not vary significantly between the His96 and the His111 sites.

There are physiological connections between PrP^{C} and its ability to take up copper. In cell culture, Cu^{2+} levels in excess of 200 μM stimulate PrP internalization through endocytosis (Pauly and Harris 1998). Moreover, copper binding to the *PRNP* promoter region stimulates PrP expression, which then increases copper levels at extracellular membranes. Whole brain imaging finds that PrP expression correlates with copper levels in regions adjacent to the lateral ventricles (Pushie et al. 2011). The course of Wilson's disease, a genetic disorder associated with copper accumulation, is affected by PrP allele.

Many emerging functional studies consider the role of the copper binding domains. Early experiments suggested that PrP^{C} may function as a superoxide dismutase (SOD), converting superoxide to peroxide. This line of research has been controversial, and to date there is still no consensus. Another possibility is that copper complexation by PrP^{C} modulates copper's intrinsic redox activity thus protecting cellular components from radicals produced through Fenton-like reactions (Millhauser 2007). In this scenario, PrP^{C} functions as an antioxidant. Although this specific function remains unproven, it is noteworthy that the cerebral spinal fluid lacks many of the copper-binding proteins found in blood serum that serve a protective role outside of the CNS. Copper may also participate in PrP processing, releasing N-terminal fragments with downstream activities such as transmembrane signaling and caspase regulation.

Copper is also implicated in the development of prion disease. The histidine 96 and 111 sites are within a region thought to misfold in the formation of PrP^{Sc}. Kinetic studies demonstrate that synthetic prions form more slowly in the presence of high copper concentrations (Bocharova et al. 2005). A spectrum of rare genetic disorders also link copper binding to prion disease. Approximately 30 families and 110 individuals have been affected by prion diseases arising from expansions in the PrP OR domain, with modular inserts of one to nine PHGGGWGQ segments. Beyond a threshold of four to five inserts, prion disease switches from late to early onset, with some individuals diagnosed in their teen years. At the same

insert number threshold, the PrP OR domain loses its ability to respond to increasing copper loads and does not readily transition to high occupancy binding mode where each repeat takes up a single Cu^{2+} equivalent.

Although the initial connection between copper and PrP was established nearly 15 years ago, the precise biological role of the copper sites is unknown, as is the function of PrP itself. The vibrant research activity driving toward a defined function will enhance the understanding of metal ion homeostasis in the CNS and may also clarify the molecular details that contribute to neurodegenerative disease.

Copper, Biological Functions

Edward D. Harris
Department of Nutrition and Food Science, Texas A&M University, College Station, TX, USA

Synonyms

Copper enzymes; Micronutrient; Nutritionally essential metal; Trace metal

Definition

To understand the biological functions of copper is first to realize that the advent of copper (and iron) into the biosphere was timed with an enrichment of O_2 in the atmosphere. Consequently, many copper enzymes use O_2 as a substrate and in so doing have endowed living systems with the means to cope with a potentially toxic gas.

Background

In biological systems, copper is primarily a catalytic metal. The scarcity of copper in the system puts it in the category of a micronutrient, or more specifically a trace metal. Foremost in its actions is to allow the system to deal with iron. Other studies have linked copper in animals and humans with the synthesis of neurotransmitters, pituitary hormones, biopigments, and the establishment of a firm connective tissue network, functions that are manifested through copper-dependent enzymes. Copper in plants in confined mainly to the photosynthetic system of the plant. Through studies of copper deficiency, it is clear that ► Copper's physical and chemical properties allow the metal to serve as an enzyme cofactor, as an oxygen activator, and as an indispensible factor in ► iron homeostasis and transport in biological systems.

Historical Significance

By the mid-nineteenth century, copper was known only to be a constituent of blood, but of more importance to benefit people (mainly women) suffering from chlorosis, an anemic-like condition characterized by a grayish or yellow color of the skin, irregular menstruation, and breathlessness. A seminal discovery in 1928 showed that both copper and iron was required to fully restore blood hemoglobin in iron-deficient rats. An unexpected interdependence between the two metals was thus forecast. In time, dietary deficiencies in copper were shown to cause aneurysms and blood vessel ruptures in pigs and chicks, thus showing a need for copper for a sound cardiovasculature. Biochemically, copper was identified as cofactor for an enzyme that catalyzed the formation of cross-links in elastin and collagen in the blood vessels and in a connective tissue network in general. Further insights came with investigations of Wilson disease. First described in 1912 by an English physician, Wilson disease was characterized by copious amounts of copper accumulating in brain and liver. Sufferers had low levels of the blood copper protein ceruloplasmin and were unable to excrete copper through the bile. A second human disorder, Menkes disease, was more akin to a copper deficiency. Sufferers displayed arrested mental development, tortuous blood vessels, alterations in bone structure, and unusual hair texture referred to as "kinky." This X-linked disease, fatal to infants, was eventually traced to defective intestinal copper absorption. Both Wilson and Menkes diseases provided major insights into the pathologies that can occur if copper intake or metabolism is disrupted.

Copper Enzymes

In deciphering copper's necessity in biological systems, enzymes that require copper as a cofactor become a focal point. The catalytic function depends on copper; no other metal can substitute at the ► copper binding site. Many were discovered by identifying the biochemical factors underlying deficiency symptoms or genetic mutations. Some of the more notable ones are listed in Table 1. A brief description of their function and mechanism is listed below. A more complete understanding of their role in the system is described under "Functions of Copper in Organs and Tissues."

(a) ► Ascorbate Oxidase: Found in the cell walls of plants the enzyme catalyzes the oxidation of the

Copper, Biological Functions, Table 1 Biological functions of copper

Function	Copper factor
Ascorbate metabolism	Ascorbate oxidase
Antioxidant activity	Cu_2Zn_2 superoxide dismutase
Aerobic metabolism	Cytochrome c oxidase
Bone strength	Lysyl oxidase
Cardiovascular integrity	Lysyl oxidase
Iron metabolism	Ferroxidase, hephaestin
Lipid metabolism	Fatty acyl desaturase
Oxygen transport	Hemocyanin
Neurological functions	Dopamine β-monooxygenase
Neurohormone biosynthesis	Peptidyl-α-amidating monooxygenase
Pigmentation	Tyrosinase
Angiogenesis	Unknown

L-ascorbate to dehydroascorbate as shown in the reaction below. Although

$$2\text{L-ascorbate} + O_2 \rightarrow 2\,\text{dehydroascorbate} + 2H_2O$$

the function of ascorbate oxidase has not been clarified, as an oxidoreductase, the enzyme is considered to be a component in the interaction between redox signaling and light-modulated control of ascorbic acid in apoplasts of plants.

(b) ▶ Copper-Zinc Superoxide dismutase: The copper/zinc form of the enzyme protects cells from oxidative damage by destroying superoxide anion, an aqueous phase free radical by-product of dioxygen. Otherwise known as SOD-1 or CuZnSOD, the enzyme is present in high concentrations in erythrocytes and the cytosol of most cells. The reaction catalyzed is shown below:

$$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$$

Copper's role as an antioxidant is primarily through this enzyme.

(c) Cytochrome c oxidase: Arguably, the most important enzyme in aerobic metabolism, cytochrome c oxidase (CcO), is the terminal complex in the electron transport chain in the mitochondria. CcO catalyzes a four-electron transfer from cytochrome c to O_2. O_2 is tethered to the copper in the ▶ Cu-binding site in the protein. The reaction of CcO is shown below:

$$4\,\text{cytochrome c}\left(Fe^{2+}\right) + O_2 + 4H^+ \rightarrow 4\,\text{cytochrome c}\left(Fe^{3+}\right) + 2H_2O.$$

The transfer of electrons to O_2 occurs concomitantly with the establishment of a proton gradient whose energy is used to form ATP from ADP and inorganic phosphate.

(d) Ferroxidase: Ferroxidase is another name for *ceruloplasmin*, the major copper protein in plasma. The name recognizes the enzymes ability to oxidize ferrous iron to ferric, a reaction that occurs with the transfer of four electrons to dioxygen as shown below. Note the similarity between ferroxidase and the reaction catalyzed by cytochrome c oxidase. Ferroxidase, however, is believed to act on free ferrous ions, not a protein-bound form of the metal:

$$4Fe^{2+} + O_2 + 2H^+ \rightarrow 4Fe^{3+} + 2H_2O.$$

(e) Lysyl oxidase: The formation of the cross-links in collagen and elastin requires the oxidative deamination of select lysine residues in the soluble precursor proteins. Lysyl oxidase catalyzes the reaction shown below:

$$\text{Peptidyl-L-lysyl-peptide} + H_2O + O_2 \rightarrow \text{Peptidyl-allysly-peptide} + NH_3 + H_2O_2.$$

The protein-bound aldehydes become a nucleus for forming cross-links at defined intervals along the chain. These cross-links support the architecture of blood vessels and other soft connective tissue. Since collagen also makes up most of the organic matter of bone, a lysyl oxidase failure can weaken bone structure and make bone prone to fracture.

(f) Peptidyl-α-amidating monooxygenase (PAM)

Many peptides synthesized by the pituitary gland have a glycine residue at the C-terminus. The biochemical rationale behind such structural similarity became clear with the discovery of PAM. PAM converts the C-terminal glycine of the peptide to an amide group which effectively activates the peptide. L-ascorbate provides the electrons for the reaction:

$$\begin{aligned}&\text{Peptidylglycine} + \text{L-dihydroascorbate}\\ &+ O_2 \rightarrow \text{peptidyl(2 hydroxyglycine)}\\ &+ \text{L-dehydroascorbate} + H_2O\\ &+ \text{desglycine peptide amide} + \text{glyoxylate}.\end{aligned}$$

At least nine pituitary hormones undergo amidation as discussed under "Copper and Brain."

(g) Dopamine β-monooxygenase (DMO)

Dopamine is both a neurotransmitter and a precursor of norepinephrine. Dopamine β-monooxygenase (DMO) catalyzes the reaction of dopamine to norepinephrine. As with PAM, ascorbate supplies the electrons for the reaction:

$$3,4\text{-dihydroxyphenylethylamine(dopamine)} + \text{L-dihydroascorbate} + O_2 \rightarrow \text{norepinephrine} + H_2O + \text{dehydroascorbate}$$

(h) Tyrosinase

This enzyme present in melanocytes is responsible for the formation of melanin and other pigments (pheomelanin, eumelanin). The oxidation of tyrosine to L-dopa begins the cascade as shown below:

$$\text{Tyrosine} \rightarrow \text{L-dopa} \rightarrow \text{dopaquinone} \rightarrow \text{dopachome} \rightarrow 5,6\text{-dihydroxyindole} + 5,6\text{-dihydroxyindole-2-}\textit{carboxylate} \rightarrow\rightarrow \text{pheomelanin and eumelanin.}$$

Copper Deficiency

By far, the clearest insights into defining copper's role in biology have come through studies of copper deficiency. Feeding young pigs, chickens, and rat diets lacking copper produces pathological changes in animals. Correlating the symptoms with a specific biochemical factor has allowed workers to pinpoint a specific site that is affected. Such strategies lead to the discovery of biochemical factors that lose function when copper is missing or in slow supply. Other strategies have used animals with genetic mutations or young animals raised on forage grown in indigenous soil lacking copper. The symptoms that appear when an animal, human, or plant is deficient in copper or mismanages its metabolism are signs impinging directly on copper's role in the system. Some of the more important ones are shown in Table 2. Each disorder has a specific biochemical factor responsible for the symptom.

Copper, Biological Functions, Table 2 Symptoms of copper deficiency in animals and humans

1.	Stunted growth and arrested development
2.	Swayback (sheep and goats)
3.	Iron-resistant anemia
4.	Hypercholesterolemia
5.	Aortic rupture (falling disease in cattle)
6.	Loss of pigmentation
7.	Connective tissue weakness
8.	Inflammatory distress
9.	Neutropenia
10.	Neurological impairment

Functions of Copper in Organs and Tissues

Copper in Brain

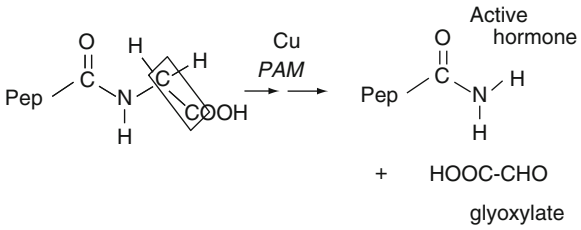
Two key enzymes in brain require copper: dopamine β-monooxygenase (DMO) and peptidyl-α − amidating monooxygenase (PAM). Together, the two play a major role in neurotransmitter biosynthesis and pituitary hormone activation, respectively. DMO has both a soluble and membrane-bound form, the latter in the chromaffin granules of the adrenal medulla, which is also a rich source of the ascorbate required in the reaction. Like DMO, PAM also shows wide distribution appearing in the adrenal medulla, pituitary, pancreas, and the atria of the heart. The reaction catalyzed by PAM occurs in two steps, the first step requiring two copper atoms. The product of the first step is converted to a peptide amide by a lyase enzyme as shown in Fig. 1.

In the reaction the, COOH group and alpha carbon are removed as glyoxylate. This reaction is necessary to give functional status to the hormones shown in Fig. 2.

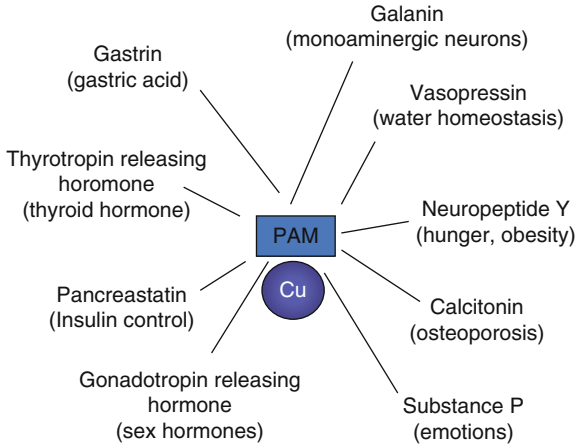
Whereas DBM and PAM catalyze distinctly different reactions, both enzymes appear to have structural similarity in their catalytic domain, which has led Southan and Kruse to suggest the two are homologous and may represent a family of copper type II ascorbate-dependent monooxygenases.

Copper in Connective Tissue

A lack of copper in the diet of new born chicks and pigs predisposes the animals to leg weakness, aneurysms, and death via aortic rupture. Rendering collagen and



Copper, Biological Functions, Fig. 1 Reactions of peptidyl-alpha-amidating monooxygenase



Copper, Biological Functions, Fig. 2 Pituitary hormones that depend on PAM for activation

elastin capable of withstanding the rigors placed on connective tissues such as tendon, ligaments, and bone requires a posttranslational modification of the tropocollagen and tropoelastin molecules to a highly cross-linked network of proteins. For elastin, cross-linking provides the anchors that allow the resilience property typical of expanding and contracting blood vessels to manifest. As a prelude to their formation, lysyl oxidase, a monocopper oxidase, catalyzes the oxidation of peptidyl lysyl residues in collage and elastin forming peptidyl aldehydes which then condense through Schiff base and aldol condensation reactions to form cross-link (Fig. 3). If cross-links do not form, the precursor proteins are soluble and can easily be extracted by neutral salt solutions. Thus, high salt solubility of collagen is a biomarker of lysyl oxidase dysfunction. The multitude of connective tissue functions that rely on the enzyme are shown in Table 3. It is of some interest to note that in laying hens, an elastin-like protein coats the ovalbumin in the inner core of an egg prior to the application of the eggshell. A copper deficiency will weaken the structure, allowing the core to expand and give rise to oversized eggs. These in turn will have week shells and in some cases no shell at all.

Copper in Lung

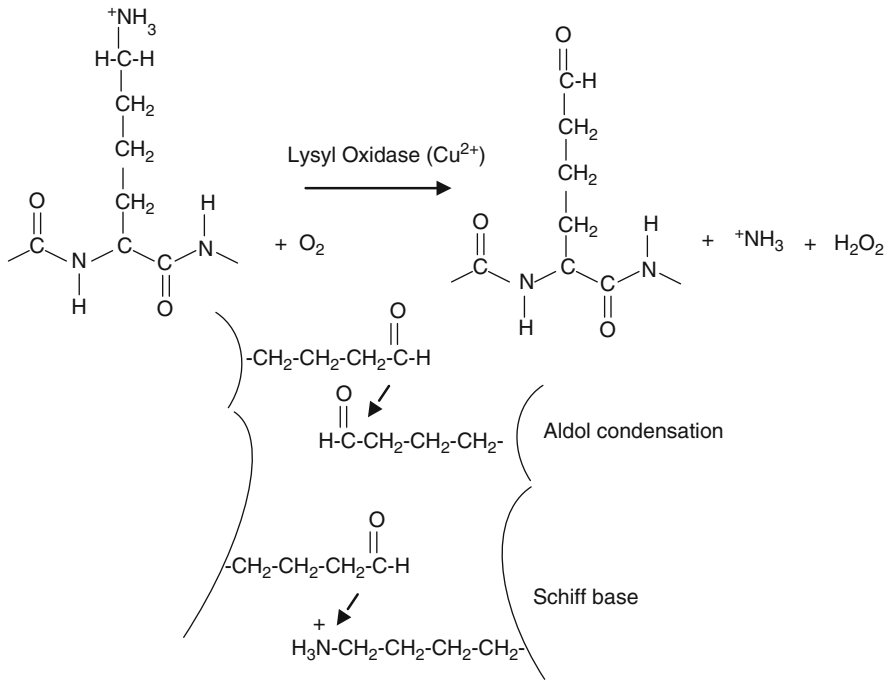
Normal functioning of lung aveoli provides another example of the need for copper in connective tissue. The outer surface of the aveoli (air sacs) is supported by an extensive network of elastin protein. The role of the elastin is to expel air from the expanded aveoli when exhaling. In the absence of copper, lysyl oxidase in lung is compromised which results in the erosion of the elastin in aveoli and an emphysema-like condition.

Copper-Iron Interactions

The hematopoietic system's dependence on copper was one of the earliest signs of a biological need for copper. The efforts to uncover the iron-copper link, i.e., where the two metals merge functionally have led to the discovery of two copper-dependent oxidase enzymes, ceruloplasmin and hephaestin. These two copper enzymes are designed to oxidize the ferrous iron to its ferric oxidation state. The simple reaction is critical for a number of reasons. Ferric iron (Fe^{3+}) is the only form that will bind to the iron transport protein transferrin for transport to the tissues. A copper deficiency or genetic mutation affecting ceruloplasmin will result in an iron overload in the liver and other tissues. Hephaestin, a second mammalian copper oxidase/ferroxidase, is responsible for transferring iron from the intestine into the system. A defect in the hephaestin gene gives rise to a sex-linked (x-chromosome involved) anemia in mice. In yeast, Fet3p is the copper oxidase/ferroxidase essential for iron to engage a ferric ion transporter in the membrane of yeast cell. These observations have helped understand why copper is critical to the safe utilization of iron by higher animals as well as microorganisms.

Copper as an Antioxidant

The enzyme ▶ copper-zinc superoxide dismutase (SOD-1) has both a copper and zinc site in each of its two subunits. As noted above, the primary function of SOD-1 is to rid the system of superoxide anion that form in the cells interior. This two-step reaction occurs first with the transfer of the unpaired electron of O_2^- to a type II Cu at the active site of the enzyme. In so



Copper, Biological Functions, Fig. 3 Reaction of lysyl oxidase leading to cross-linking of collagen and elastin

Copper, Biological Functions, Table 3 Connective tissue functions dependent on lysyl oxidase

1.	Lung elasticity
2.	Ligamentum nuchae elasticity
3.	Bone and cartilage strength and stability
4.	Blood vessel integrity
5.	Eggshell shape and size

doing, the copper is reduced to Cu I. A second O_2^- then becomes a recipient of the electron whose passing gives rise to hydrogen peroxide and restores the copper to its Cu II form. The Cu_2Zn_2 enzyme is present in all tissues as a 32-kDa homodimer. Four histidine residues make up the type II copper binding site. A deficiency in copper will suppress the activity of the enzyme, but not the enzyme protein which stays at a near constant level.

Copper and Respiration

Respiration is the act of taking up O_2. As a cofactor for the respiratory enzyme cytochrome c oxidase, copper plays a central role in this event. The enzyme exists as a complex situated on the distal end of the electron transport chain in inner membrane of the mitochondria. The ultimate goal of the chain is to transfer electrons from reduced cofactors at the proximal end to O_2. In the process, protons are pumped from the interior of the mitochondria to the intermembrane space, and their return to the interior drives ATP formation. Three of the enzyme's subunits are synthesized by mitochondrial genes. These subunits hold both copper and iron in distinct coordination spheres. The ▶ copper A in cytochrome oxidase has one coordinate open to bind the O_2. Through this enzyme, copper is linked to the major energy-generating system in the cell.

Copper and Genetic Regulation

A number of studies have supported the understanding that copper has the capacity to regulate genetic expression. The genes targeted code for ▶ metallothioneins that bind and store copper, proteins that regulate its metabolism or respond to oxidants. The discovery of metal-responsive elements (MRE) in the DNA in the promoter region of genes coding for these proteins is testament to this understanding. First observed for *CUP1*, a gene that codes for a copper storage protein in yeast, ACE1 (activation of CUP1 expression), a 11-kDa cysteine-rich protein, was the first eukaryote copper-dependent transcription factor identified. ACE1 is able to engage the MRE only when Cu^+(or Ag^+) is bound to the protein. The gene that codes for the antioxidant protein *SOD-1* likewise is regulated by

copper through the ACE1 transcription factor. A mammalian counterpart for ACE1 has not been found.

Summary and Conclusions

The multifaceted roles of copper in biological systems center around a need to handle O_2 and its by-products. Copper metalloenzymes are designed to use O_2 as a substrate. Such enzymes vary from the simplest monooxygenases to the more complex multisubunit multicopper oxidases (► Copper-Binding Proteins). Nearly all copper-dependent systems exploit the redox properties of the metal. The cardiovascular system, respiration, soft and hard connective tissues, central and peripheral nervous system, and hair and integument all rely on copper for normal function or appearance and all can be altered metabolically by a deficiency. Many copper-dependent biochemical factors have come to light and through these factors one has gained an understanding of the molecular basis for copper's necessity. One must consider that the safe handling of iron and oxygen were early needs for copper in biology. A deficiency in copper has a serious impact on iron absorption, transport, and metabolism. As pointed out in this chapter, however, the role of copper in biology extends beyond a cofactor function for copper-dependent enzymes, although this is perhaps the most visible role for the metal. Traditionally, copper has been regarded as a passive element, i.e., available when needed. In the last 20 years, however, considerable interest has been directed at learning an active role for copper at the genetic level; functions that casts copper in the role of a regulator of genetic expression. Copper-dependent transcription factors have been identified in microorganisms such as yeast; however, the expected crossover to higher animals has not been fully realized. Thus, there is still much to be discovered with regard to the functions copper and to uncover all of the biological properties unique to this metal.

Synonyms

Copper-containing hydroxylase; Copper-containing monooxygenase

Definition

Copper mononuclear monooxygenase is a unique class of metalloenzymes present in eukaryotes where they catalyze very important biosynthetic reactions in neurotransmitter and hormone pathways. Composed by dopamine β-monooxygenase (DβM), also named dopamine β-hydroxylase (DβH), tyramine β-monooxygenase (TβM), peptidylglycine

α-hydroxylating monooxygenase (PHM), and monooxygenase X (MOX), this class of metalloenzymes is characterized by the presence of two independent T2 ▶ Cu-Binding Sites where only one copper atom is involved in the hydroxylation reaction.

General Background

Mononuclear copper monooxygenases catalyze the stereospecific oxygen atom insertion in organic substrates and are ascorbate (reducer) and dioxygen-dependents (Klinman 1996).

Dopamine β-monooxygenase (DβM, EC 1.14.17.1) is a mammalian enzyme involved in the catecholamine biosynthetic pathway where it transforms dopamine into norepinephrine (Scheme 1a) (Stewart and Klinman 1988). Tyramine β-monooxygenase (TβM), the insect homolog of DβM, transforms tyramine into octopamine in a similar way (Scheme 1a) (Hess et al. 2008).

Peptidylglycine α-hydroxylating monooxygenase (PHM) functions in vivo toward the biosynthesis of α-amidated peptide hormones in mammals and insects. PHM is a catalytic domain of peptidylglycine α-amidating monooxygenase (PAM, EC 1.14.17.3), a bifunctional enzyme involved in the posttranslational amidation of C-terminal glycine-extended peptides (Kulathila et al. 1999). This posttranslational modification is a key step in the activation of several neuropeptides and peptide hormones (substance P, oxytocin, neuropeptide Y, adrenomedullin. . .). PAM is encoded by a complex single-copy gene that is subject to tissue-specific and developmentally regulated alternative splicing. The isolated domains, separated either through endoproteolytic cleavage or through independent expression, retain their enzymatic activities. The NH_2-terminal domain of PAM, the PHM domain, catalyzes the stereospecific hydroxylation of the C-terminal glycine residue into hydroxyglycine, which in turn is transformed into amidopeptide and glyoxylic acid by the peptidyl-α-hydroxylglycine α-amidating lyase domain (PAL) of PAM (1b). Both enzymatic activities have broad substrate specificity since peptides with all 20 amino acid amides have been isolated.

Analysis of the sequence of the monooxygenase X (MOX) allows to group this mammalian enzyme in the mononuclear copper monooxygenase family. However, its catalytic activity has not yet been characterized and its function is unknown (Xin et al. 2004).

Structural and Functional Features

Dopamine β-Monooxygenase (DβM) and Peptidylglycine α-Hydroxylating Monooxygenase (PHM)

Despite a large difference in macroscopic features (DβM is a tetrameric glycoprotein of 75 kDa/monomer; PHM is active as a 35 kDa monomer), DβM and PHM exhibit strong similarities. First of all, (1) both enzymes catalyze the cleavage of dioxygen to form hydroxylated products and water, (2) both enzymes require two copper ions per subunit for full activity, and (3) both enzymes are believed to use ascorbate as the in vivo two-electron donor. In addition, DβM and PHM share a 28% sequence identity extending through a common catalytic domain of 270 residues, which includes the conserved copper ligands. Although there is no crystal structure yet, structural data exist for DβM. Extended X-ray absorption fine structure has been used to characterize the ligand environment of the two copper atoms in both oxidized and reduced forms. Without any evidence for backscattering between the two copper sites confirmed in the electron paramagnetic resonance (EPR) spectrum by the absence of any spin coupling, the distance between the two coppers has been estimated to exceed 4 Å. These findings have provided early evidence against a reactive binuclear center and, instead, have suggested separate functions for the two copper centers. The Cu_A (Cu_H in PHM), surrounded by three histidine residues and a water molecule, has been assigned as the electron transfer site where ascorbate binds and delivers two electrons, whereas Cu_B (Cu_M in PHM), liganded by two nitrogen atoms from histidine residues and a water molecule together with an elongated bond to the sulfur atom from a methionine residue, has been assigned as the substrate binding and hydroxylation site. The crystal structures of oxidized and reduced PHM forms with or without a bound peptide substrate N-α-acetyl-*3*,*5*-diiodo-L-tyrosylglycine (IYG) (Fig. 1) have confirmed the conclusions of many of the earlier spectroscopic data (Prigge et al. 1997, 1999). The important features determined from the crystal structures of the oxidized or reduced forms of the PHM catalytic core (PHMcc) are (1) a two-domain

Copper, Mononuclear Monooxygenases, Fig. 1 Structure of the catalytic core of PHM (PHMcc) from Protein Data Bank (code 1OMP) showing the PHMcc fold with the binuclear active site and the bound substrate N-α-acetyl-3,5-diiodotyrosyl-glycine (IYG)

structure in which each domain binds a single copper atom, (2) a distance of 10.59 Å between the two copper sites, (3) the absence of closure in the copper binding domains in either enzyme form studied, and (4) the identification of a water-filled cavity that is located at the solvent interface and "links" the two copper binding domains. Several structures of oxidized and reduced forms of PHMcc with bound carbon monoxide, azide, and nitrite are now available on the Protein Data Bank and confirm a differential reactivity between the two copper sites (Chufán et al. 2010).

Comparison of the kinetic parameters for DβM and PHM with substrates of comparable reactivity indicates the same intrinsic H/D isotope effect for the

C–H activation step. Additionally, similar ^{18}O isotope effects decreasing with substrate deuteration observed for these two enzymes imply a chemical mechanism for substrate oxidation that is likely to be identical for both enzymes. Studies on kinetics indicate that both DβM (in the presence of the fumarate dianion activator) and PHM proceed in a preferred ordered mechanism with substrate binding to the enzyme before dioxygen interaction. Thus, all available data infer that DβM and PHM can be regarded as interchangeable with respect to mechanism and active site structure.

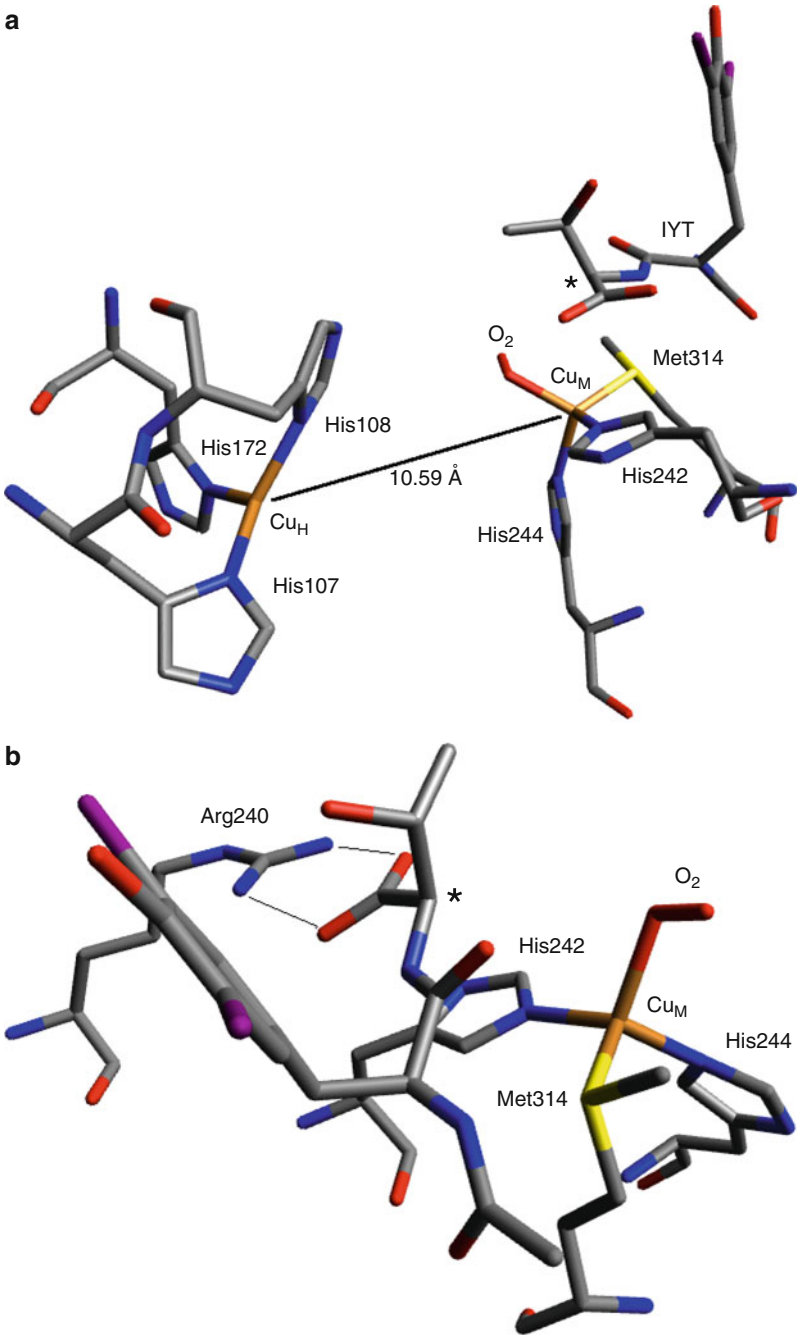
Regarding the pathway for the long-distance electron transfer between the copper sites and the nature of the various copper-oxygen species involved in dioxygen activation, an extensive and open debate has taken place in the recent literature. In early studies on DβM with either substrates or substrate analogs, it has been concluded that functionalization of the substrate involved hydrogen atom abstraction to yield a free radical intermediate. Identification of the oxygen species catalyzing hydrogen atom abstraction has proven to be far more elusive (Blain et al. 2002). The observation of pH-dependent isotope effects for DβM provided evidence for the involvement of a single proton in the chemical conversion process. This led to the hypothesis of a copper hydroperoxide (Cu(II)–OOH) as the reactive oxygen-centered intermediate. However, a detailed analysis of the effects of substrate structure and deuterium on ^{18}O isotope effects was found to be inconsistent with this hypothesis. Instead, a reductive cleavage of this intermediate to generate the copper-oxo (Cu(II)–$O^{\bullet}$ ↔ Cu(III)–O^{-}) as the species responsible for the hydrogen atom abstraction was suggested. In this proposal, the oxidation of both copper centers occurs before substrate activation and leads to the accumulation of a partially reduced form of dioxygen.

Recently, it was reported on two experimental probes of the activated oxygen species in DβM (Evans et al. 2003). First, the capacity of a substrate analog that cannot be functionalized (β,β-difluorophenethylamine) to induce reoxidation of the prereduced copper sites of DβM upon mixing with dioxygen under rapid freeze-quench conditions was examined. This experiment failed to give rise to an EPR-detectable copper species, in contrast to a substrate with an active C–H bond. This indicates either that the reoxidation of the enzyme-bound copper sites in the presence of dioxygen is tightly associated with the C–H activation or that a diamagnetic species Cu(II)–$O_2^{\bullet}$ has been formed. In the event of an active site that is open and fully solvent-accessible, as seen for the homologous peptidylglycine α-hydroxylating monooxygenase, the accumulation of a reduced and activated oxygen species in DβM prior to C–H cleavage would be expected to produce an uncoupling of dioxygen and substrate consumption by analogy to cytochrome P-450. For this reason, the degree to which dioxygen and substrate consumption are related in DβM was examined using both end point and initial rate experimental protocols. With substrates that differ by more than three orders of magnitude in rate, there was a strong correlation between dioxygen uptake and product formation. This has led to the conclusion that there is no accumulation of an activated form of dioxygen before C–H abstraction in the DβM and the formation a copper-superoxo species (Cu(II)–$O_2^{\bullet}$) was proposed to be responsible for the abstraction of the hydrogen atom of the dopamine substrate (Evans et al. 2003).

At the same time, a copper–dioxygen complex was trapped in PHM by freezing protein crystals that had been soaked in the presence of dioxygen with ascorbate and slow substrate N-α-acetyl-3,5-diiodo-tyrosyl-D-threonine (IYT). The X-ray crystal structure of this precatalytic complex, determined to 1.85 Å resolution (PDB code 1SDW), showed that dioxygen binds to one of the copper atoms in the enzyme with an end-on geometry (Fig. 2a, b). Given this structure, it is likely that dioxygen is directly involved in the electron transfer and hydrogen abstraction steps of the PHM reaction (Prigge et al. 2004). These findings suggested a mechanism in which a diamagnetic Cu(II)–$O_2^{\bullet}$ complex formed initially at very low levels, abstracts a hydrogen atom from the substrate to generate Cu(II)–OOH and a substrate-free radical as intermediates. Subsequent participation of the second copper site (Cu_H) per subunit completes the reaction cycle, generating hydroxylated products and water (Scheme 2).

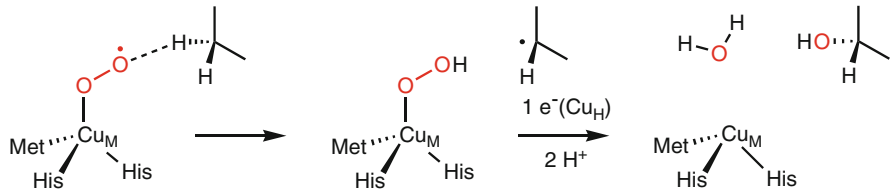
Tyramine β-Monooxygenase (TβM)

Tyramine β-monooxygenase (TβM) catalyzes the synthesis of the neurotransmitter, octopamine, in insects (Scheme 1). TβM shares 39% identity and 55% similarity with the mammalian DβM. In addition, as indicated by kinetic isotope effect, the TBM oxidation seems to proceed in agreement with the mechanisms proposed for the mammalian enzymes



Copper, Mononuclear Monooxygenases, Fig. 2 (**a**) Structure of the active site of the PHMcc from Protein Data Bank (code 1SDW) showing the two Cu_H and Cu_M centers with the bound slow substrate N-α-acetyl-3,5-diiodotyrosyl-D-threonine (IYT) and end-on coordinated dioxygen, (**b**) focus on the Cu_M center showing the interaction of the carboxylate group of the substrate IYT with Arg240 and in *asterisk* the D-threonine Cα which is the subject of hydroxylation

(PHM and DβM). However, a distinctive feature of TβM is the very strong substrate inhibition that is dependent on the level of the cosubstrate, dioxygen, and ascorbate as well as substrate deuteration (Hess et al. 2008). This feature has led to a model in which the substrate tyramine can bind to either the Cu(I) or Cu(II) forms of TβM, with substrate inhibition increased at very high ascorbate levels. The rate of ascorbate reduction of the Cu(II) form of TβM is also reduced at high tyramine level, leading to propose the existence of a binding site for ascorbate to this class of enzymes and that it was never observed with DβM or PHM (Hess et al. 2010). These findings may be relevant to the control of octopamine production



Copper, Mononuclear Monooxygenases, Scheme 2 Proposed mechanism for hydroxylation reaction catalyzed by mononuclear copper monooxygenases involving the formation of a copper-superoxo species Cu(II)–$O_2^{\bullet}$

in insect cells. Recent studies have demonstrated that tyramine and octopamine have antagonistic effects and suggest that behavioral regulation may depend on the balance of these two hormones. Thus, TβM is exquisitely sensitive to small shifts in cellular conditions. Overall, the TβM kinetics data imply tighter regulation of neurotransmitter levels by the insect enzyme than in the mammalian homologue.

Physiological Roles

The monoamine and amidopeptides neurotransmitters are involved in the control of a wide variety of neuronal functions (psychomotor function, reward-driven learning, arousal, processing of sensory input, memory, appetite, emotional stability, sleep, mood, vomiting, sexual behavior, and secretion of anterior pituitary and other hormones). Since DβM and PHM play an important role in controlling the levels of the neurotransmitters/hormones, the literature on the physiological role of DβM and PHM is abundant.

Mammalian genomes encode only a small number of copper-containing enzymes. The many genes involved in coordinating copper uptake, distribution, storage and efflux make gene/nutrient interactions especially important for these copper-containing enzymes. Copper deficiency and copper excess both disrupt neural function. Using mice heterozygous for PAM, it was identified alterations in anxiety-like behavior, thermoregulation, and seizure sensitivity. Dietary copper supplementation reversed a subset of these deficits. Wild-type mice maintained on a marginally copper-deficient diet exhibited some of the same deficits observed in $PAM^{+/-}$ mice and displayed alterations in PAM metabolism. Altered copper homeostasis in $PAM^{+/-}$ mice suggested a role for PAM in the cell-type-specific regulation of copper metabolism. Physiological functions sensitive to genetic limitations of PAM that are reversed by supplemental copper and mimicked by copper deficiency may serve as indicators of marginal copper deficiency (Bousquet-Moore et al. 2010).

DβM deficiency is a very rare form of primary autonomic failure characterized by a complete absence of noradrenaline and adrenaline in plasma together with increased dopamine plasma levels. DβM deficiency is mainly characterized by cardiovascular disorders and severe orthostatic hypotension (Senard and Rouet 2006).

Copper, Physical and Chemical Properties

Fathi Habashi
Department of Mining, Metallurgical, and Materials Engineering, Laval University, Quebec City, Canada

Copper is an ancient metal has a characteristic red color, was used to make statues and coins, later mixed with tin to make bronze and with zinc to make brass. Bronze was cast in statues, bells, cannons, and other objects. Brass was an alloy that looked like gold. Copper occurs in nature in the metallic state in certain locations such as in Lake Superior region but mostly as sulfide and to a minor extent as oxide and silicate. Some of its minerals when pure have beautiful blue color and are used as gem stones.

Physical Properties

Atomic number	29
Atomic weight	63.55
Density, g/cm^3	8.89
Melting point, °C	1,083
Boiling point, °C	2,595
Heat of fusion, J/g	210
Heat of vaporization, J/g	4,810
Vapor pressure at m.p., Pa	0.073
Specific heat capacity, J g^{-1} K^{-1}	
At 20°C and 100 kPa	0.385
At 957°C and 100 kPa	0.494
Average specific heat, J g^{-1} K^{-1}	
0–300°C at 100 kPa	0.411
0–1,000°C at 100 kPa	0.437
Coefficient of linear thermal expansion, K^{-1}	
0–100°C	16.9×10^{-6}
0–400°C	17.9×10^{-6}
0–900°C	19.8×10^{-6}
Thermal conductivity at 20°C, W m^{-1} K^{-1}	394

The most important property of copper is its high electrical conductivity; among all metals, only silver is the better conductor. Both electrical conductivity and thermal conductivity are connected with the Wiedemann–Franz relation and show strong dependence on temperature.

Chemical Properties

Copper has the electronic configuration: 2, 8, 18, 1. It is considered a less-typical metal because when the outermost electron is lost, then an 18-electron shell will be exposed and not an inert gas structure. Copper in dry air at room temperature slowly develops a thin protective film of copper(I) oxide. On heating to a high temperature in the presence of oxygen, copper forms first copper(I) oxide and then copper(II) oxide, both of which cover the metal as a loose scale. In the atmosphere, the surface of copper oxidizes in the course of years to a mixture of green basic salts, which consists chiefly of the basic sulfate, with some basic carbonate. Such covering layers protect the metal.

Copper has a high affinity for free halogens, molten sulfur, or hydrogen sulfide. It is not attacked by nonoxidizing acids, such as dilute sulfuric, hydrochloric, phosphoric, or acetic, and other organic acids. Copper is not attacked by alkali-metal hydroxide solutions. Dissolution of copper is possible either by oxidation or by formation of complexed copper ions. Thus, copper is soluble in oxidizing acids,

such as nitric acid, hot concentrated sulfuric acid, and chromic acid, or in nonoxidizing acids containing an oxidizing agent such as oxygen or hydrogen peroxide. The other method of dissolving copper is through formation of complex ions. The best reagents for this purpose are aqueous solutions of ammonia (Fig. 1) and ammonium salts or alkali-metal cyanides.

Copper dissolves in alkaline cyanide solution in presence of oxygen:

$$2Cu + {}^1/_2O_2 + 4CN^- + H_2O \rightarrow 2Cu(CN)_2{}^- + 2OH^-$$

Copper(I) ion precipitates from acid medium by HCN to form CuCN a white powder. Copper(II) ion precipitates from acid medium by H_2S to form CuS. Metallic copper is precipitated from $CuSO_4$ solution by hydrogen at high temperature and pressure:

$$Cu^{2+} + H_2 \rightarrow Cu + 2H^+$$

Copper sulfide undergoes oxidation in neutral medium at ambient conditions to $CuSO_4$:

$$CuS + 2O_{2(aq)} \rightarrow CuSO_4$$

In acidic medium, however, elemental sulfur forms

$$CuS + {}^1/_2O_{2(aq)} + 2H^+ \rightarrow Cu^{2+} + S + H_2O$$

Copper(I) and copper(II) can coexist in a single compound known as Chevreul salt: $Cu_2SO_3.CuSO_3.2H_2O$.

Molten copper sulfide undergoes a conversion reaction when oxygen is blown through

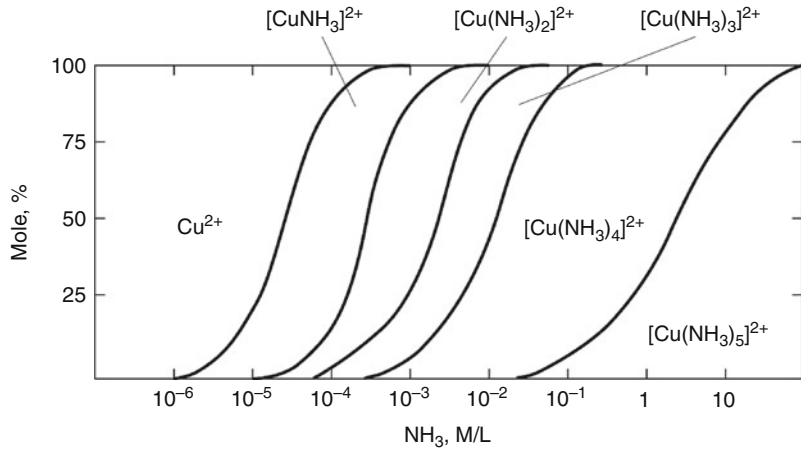
$$Cu_2S + O_2 \rightarrow 2Cu + SO_2$$

This is the basis of copper metallurgy. The solubility of gases in molten copper follows Henry's law: the solubility is proportional to the partial pressure. Oxygen dissolves in molten copper as copper(I) oxide up to a concentration of 12.65% Cu_2O (corresponding to 1.4% O). Sulfur dioxide dissolves in molten copper and reacts:

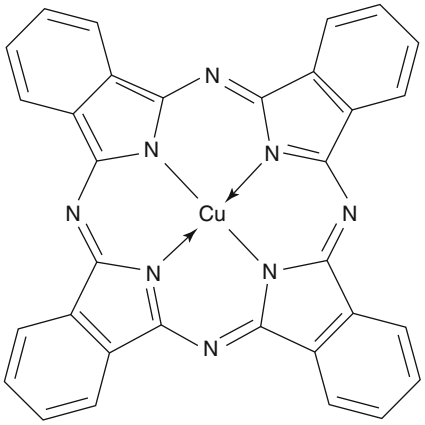
$$6Cu + SO_2 \rightarrow Cu_2S + 2Cu_2O$$

Hydrogen is considerably soluble in liquid copper, and after solidification some remains dissolved in the solid metal, although copper does not form a hydride. The solubility follows Sievert's law, being proportional to the square root of the partial pressure because the H_2 molecules dissociate into H atoms on dissolution. Nitrogen, carbon monoxide, and carbon dioxide are practically insoluble in liquid or solid copper. Hydrocarbons generally do not react with copper. An exception is acetylene which reacts at room temperature to form the highly explosive copper acetylides Cu_2C_2 and CuC_2; therefore, acetylene gas cylinders must not be equipped with copper fittings.

Although copper is toxic in exceedingly low concentrations to certain lower life forms, notably



Copper, Physical and Chemical Properties, Fig. 1 Copper ammine complexes



Copper, Physical and Chemical Properties, Fig. 2 Copper phthalocyanine

fungi and algae, it is a necessary constituent of higher plants and animals. It plays a necessary role as an oxidation catalyst and aids plants in photosynthesis and other oxidative processes. In higher animals, it is responsible for oxidative processes and is present in many proteins such as phenolase, hemocyanin, and galactose oxidase.

Copper Phthalocyanine

Copper phthalocyanine (Fig. 2) is analog of two natural porphyrins: chlorophyll and hemoglobin. It is a blue pigment.

Copper-Binding Proteins

Charles T. Dameron
Chemistry Department, Saint Francis University, Loretto, PA, USA

Synonyms

Copper metalloproteins; Cuproproteins

Definition

Copper-binding proteins specifically incorporate the metal into their structure for catalytic and structural purposes. Noncatalytic, structural sites are found in copper sensing proteins involved in the regulation of copper metabolism and in copper sequestering peptides and proteins involved in protection against copper intoxication. The sensing proteins regulate all aspects of copper metabolism, including the uptake, intracellular use, detoxification, and export of copper. Commonly, the regulation is affected at the transcriptional level, and the binding of copper by the protein is the switch that modulates the sensor protein's structure and function. The binding in these sites takes place through cysteinyl thiolates.

Noncatalytic Roles of Copper in Proteins

In noncatalytic proteins, copper serves a structural-regulatory role, a role mediated by its specific binding to sensory proteins where a change is elicited in the activity of the protein. Generally, copper's role in proteins is catalytic and is circumscribed by the metal's redox properties. In these copper enzymes, the metal repetitively cycles from a cupro (Cu^{+1}) to a cupric (Cu^{+2}) state as part of the catalytic cycle. It is, however, those same properties that dictate the need to control its availability in cells. Copper and other redox active metals can participate in the catalytic production of oxygen and other radical species capable of damaging biomolecules (Ercal et al. 2001). Copper bound to inappropriate binding sites in proteins has been postulated to play a role in many diseases through the production of radicals (Ercal et al. 2001).

When copper is specifically incorporated into enzyme and sensory protein structure, the redox capability of the ion is controlled.

Limiting the intracellular concentration is the principle function of copper sensing proteins as opposed to increasing the concentration. There are multiple ways by which copper can be brought into cells, both specific and nonspecific. Exportation and sequestration mechanisms are used to decrease the intracellular concentrations of the element. Exportation mechanisms, the most frequently used method in bacteria, utilize copper ATPases to translocate the ion out of the cell (Lu et al. 1999). Sequestration methods are varied and include methods in which the metal is imported into vacuoles, in some case as peptide complexes, or chelated by peptides and proteins. Regardless of which mechanism is utilized to relieve or prevent intoxication, the copper ion itself or a chelate of it becomes specifically bound to the sensor protein that controls the exportation or sequestration method. Acting at a DNA-binding level, the sensor proteins function as either negative repressors or positive-type transcription factors. For example, in the repressor case, copper binding lessens its affinity for DNA and, thereby, enables the transcription of the exporting ATPases when the protein-DNA complex dissociates (Cobine et al. 1999, 2002b). In the transcription factor case, copper binding increases the affinity of the protein for DNA and the active recruitment of the transcription complex (Dameron et al. 1993; Dobi et al. 1995).

Sensory Proteins Repressors

CopY, a Zn(II)-requiring but Cu(I)-regulated repressor from *Enterococcus hirae*, a gram-positive bacterium, is the archetype copper-regulated repressor (Strausak and Solioz 1997). CopY and the *Lactococcus lactis* homologue CopR are in the penicillinase repressor BlaI/MecI/CopY family of winged-helix repressors that bind DNA as dimers (Cantini et al. 2009; Portmann et al. 2006). Each of these members has a characteristic helix-turn-helix DNA-binding motif that is responsible for binding to DNA. Monomers in this family have a limited affinity for DNA (Gregory et al. 1997). CopY is the key regulatory component of the *E. hirae cop* operon and all related operons. The *E. hirae* operon contains CopY, a repressor; CopZ, a copper chaperone; CopA, a copper ATPase (import); and CopB, a copper ATPase (export) (Lu and Solioz 2001; Wunderli-Ye and Solioz 1999). The minimum requirement for a *cop* type operon is a CopY homologue and a CPX copper ATPase (Solioz and Vulpe 1996). Some *cop*-type operons do not contain CopZ and may also not have one of the ATPases. Analogous copper importing ATPases that use methionine sequences to bind copper are found in Ctr1 of ▶ *Saccharomyces cerevisiae* (Rubino et al. 2010) and hCtr1 of humans (Sharp 2003).

When in excess of the cell's needs, copper, as Cu(I), displaces the Zn(II) in CopY, leading to a decrease in the affinity for the promoter (Cobine et al. 1999, 2002a). CopY isolates with a Zn(II) to protein stoichiometry of 1:1 (Cobine et al. 2002b). The metal binding site at the C-terminus of the protein contains a single –CxCxxxxCxC-site. Zn(II) binding is essential for the formation of the DNA-binding active dimers (Cobine et al. 2002b). The dimerization takes place through the interaction of the two metal binding sites, but adjacent sequences containing regularly spaced hydrophobic residue repeats also contribute to the overall affinity (Pazehoski et al. 2008, 2011). Only the C-terminal 38 residues that contain the 10-residue metal-binding motif and the aliphatic repeats are needed for dimerization of CopY or other proteins to which it is fused (Pazehoski et al. 2011). The aliphatic repeats do not take the form of a leucine zipper. The formal stoichiometry is $Zn(II)_2(CopY)_2$. Similarly, when copper(I) displaces the Zn(II) from CopY, the final copper to protein stoichiometry is 2:1, but since the protein is still a dimer, the formal stoichiometry is $Cu(I)_4(CopY)_2$. The displaced Zn(II) does not copurify with the protein. In *E. hirae*, Cu(I)CopZ transfers Cu(I) to the Zn(II)CopY dimer (Cobine et al. 1999, 2002b). Cu(I)CopZ will also interact with and transfer Cu(I) to a homologous metal-binding domain of CopA (Banci et al. 2003). The displacement of one 4-coordinate Zn(II) by two 3-coordinate Cu(I) ions is postulated to promote the change in CopY's structure and, thereby, decrease its affinity for DNA. Derepression leads to the increased synthesis of the exporting copper ATPases and elevated export of copper (Lu et al. 1999, 2003; Solioz and Stoyanov 2003). As the intracellular copper concentration drops, newly synthesized Zn(II)CopY binds to the promoter and the synthesis of the ATPase is decreased and export slows. There is also evidence that high intracellular copper increases the turnover of Cop proteins through the increased synthesis of proteases (Solioz 2002).

Transcription Factors

The ▶ *Saccharomyces cerevisiae* transcription factor Ace1 is the archetype copper-regulated transcription factor. Copper(I) binding by Ace1, and close homologs such as Amt1, increases its affinity for the promoter. The distinct differences between CopY and Ace1 is that the copper binding to CopY causes it to lose affinity for DNA while copper binding to Ace1 causes it to have an increased affinity for DNA. In both situations, there is an increased synthesis of proteins involved in the copper detoxification process. Once bound to the DNA, the acidic N-terminal domain of Ace1 supports the recruitment of other transcription factors leading to an increase the synthesis of the yeast CUP1 (▶ Metallothioneins and Mercury, ScMT) which can ameliorate copper intoxication (Dameron et al. 1991; Winge et al. 1994). ▶ Metallothioneins (MT) are small cysteine-rich proteins that bind copper, and other transition metals, very tightly, making the metal less accessible (Coyle et al. 2002). Aside from their sequestration function, the MTs are proposed to be involved in a number of other metal homeostatic processes including serving as ▶ metallochaperones (Coyle et al. 2002). There are analogous proteins and pathways by which mammalian (human) MT production is increased, but the mechanism is more complex and not fully delineated (Samson and Gedamu 1998). The increased synthesis of the MT is only one of several ways that the yeast protects itself from copper intoxication. Export of copper is the primary protective mechanism. Ace1 and Amt1 are also involved in responses to oxidative stress, such as could be caused by adventitiously bound copper or organic oxidizers (Thorvaldsen et al. 1993; Zhou and Thiele 1993). The Ctr family of ATPases is transcriptionally regulated by an analogous protein called Mac1 (Xiao et al. 2004).

Copper-Binding Motifs

Cysteine-rich sequences are the hallmark of the metal-binding motifs in regulatory proteins such as CopY, Ace1, and Mac1, as well as the sequestration peptides and proteins such as the phytochelatins and ▶ metallothioneins. Ligation of the metals in these proteins is accomplished entirely through the cysteine residues. The cysteine content of the sequences within the metal-binding domains of these proteins is frequently between 20% and 30% and can be higher (Winge et al. 1994). The metals are bound in polythiolate clusters with a mixture of terminal and bridging cysteinyl thiolate ligands (Brown et al. 2002; Dameron et al. 1993; George et al. 1986; Zhang et al. 2008). X-ray absorption spectroscopy (XAS), crystallography, and NMR studies have been used to characterize these sites with a variety of metal ions in them. Zn(II), as expected, is bound in a 4-coordinate manner in sites with tetrahedral geometry (Cobine et al. 2002b). EXAFS indicates the average Zn-S distance in CopY to be 2.349 ± 0.005 Å, a typical value for complexes of this type. In biological systems, copper can be cuprous, Cu(I), a d^{10} electronic configuration, or cupric, Cu(II), a d^9 configuration. The proportion of Cu(I) versus Cu(II) is very dependent on ligands and anions present and solvent interactions (Cotton et al. 1999). In catalytic sites, the ligand structures are arranged to facilitate the redox changes between the Cu(I) and the Cu(II) which are typically part of the enzyme's catalytic cycle. In the sensor proteins copper is bound in the cuprous (Cu(I)) form, which has a preference for softer ligands like S. The distinction between Cu(I) and Cu(II) is significant because it profoundly affects the spectral properties; Cu(I) is diamagnetic so EPR spectroscopy cannot be applied to its complexes to determine the ligand structure around the metal. Also absent are the d-d transitions that lead to the blue color of Cu(II) complexes and are useful in characterizing the structure and electronic properties of the metal binding site. Cu(I)-thiolates do have weak-charge transfer bonds, and if the clusters are sufficiently shielded from solvent, they are weakly luminescent (Green et al. 1994). The principal tools for the study of these sites are XAS (XANES and EXAFS) and structural determinations by x-ray crystallography and NMR. Based on the analysis of a number of Cu(I)-thiolate centers by XAS and crystallographic studies, the Cu(I)s in these sensor proteins are bound in a 3-coordinate manner with trigonal planar geometry (Pickering et al. 1993). Detailed comparisons of the XAS of these proteins with control compounds containing mixed 2- and 3-coordination suggest that the site can have mixed coordination (Pickering et al. 1993). Cu(I)-thiolates can form 2-, 3-, and 4-coordinate complexes (Cotton et al. 1999). EXAFS analyses show that the metals ions in these clusters are close to van der Waals contact; the average Cu-Cu and Cu-S distances were 2.685 ± 0.0085 Å and 2.256 ± 0.0072 Å in CopY (Cobine et al. 2002a).

The clusters are very compact and thermodynamically stable, but isotope exchange studies show that the metals are kinetically labile; the metals can exchange rapidly. A number of computational studies have been applied to these clusters to investigate their properties (Ahte et al. 2009; Sivasankar et al. 2007).

Definition

Copper-zinc superoxide dismutase (SOD1) is an antioxidant metalloenzyme that is present throughout the body. It catalyzes the conversion of two molecules of superoxide into hydrogen peroxide and molecular oxygen in a reaction that involves alternate oxidation and reduction of the active site copper ion. Amyotrophic lateral sclerosis (ALS, Lou Gehrig's disease) is a fatal neurodegenerative disease characterized by progressive loss of motor neurons, leading inevitably to paralysis and death, usually within 3–5 years. Onset of disease is usually after age 50, and there is no cure. Most cases have no known genetic component, but in a small fraction of cases, ALS is caused by point mutations in SOD1. This linkage of SOD1 and ALS, first published in 1993, provided the first experimental route to understanding the cause of the disease.

Amyotrophic Lateral Sclerosis (Lou Gehrig's Disease)

Amyotrophic lateral sclerosis (ALS), commonly referred to as Lou Gehrig's disease because of the

famous New York Yankee's baseball player whose career was ended by the disease, is the most common adult motor neuron disease. Originally described by the French neurobiologist and physician Jean-Martin Charcot in 1869, ALS is characterized by the progressive degeneration of spinal motor neurons leading to atrophy of voluntary muscles and spasticity, resulting in paralysis and relatively rapid death (Cleveland and Rothstein 2001). Some cognitive impairment is found in about 50% of cases, but ocular and sensory neurons are generally unaffected by disease. The average survival time is 3–5 years although much longer disease courses have been reported. ALS affects most patients in middle to late life with an incidence rate of 2 per 100,000 but a lifetime risk of 1 in 1,000.

Research efforts directed toward the understanding of ALS during most of the twentieth century involved epidemiological studies, which, although numerous, were overall inconclusive. The more recent breakthroughs in the genetics of ALS have driven the bulk of the research during the past two decades. However, despite tremendous efforts in research, there is still no cure for ALS, and treatments and clinical trials so far have only provided marginal beneficial effects.

The progressive uncovering of epidemiological and genetic factors has had the greatest impact in the area of ALS research. Some of the better known studies addressed the causes of an ALS epidemic on the island of Guam, where in the 1950s, it was discovered that the ALS frequency was 50 times higher than that of the rest of the world (Lelie et al. 2011). While a genetic factor was first hypothesized, it was later disproven when follow-up studies showed that the incidence rate rapidly decreased coinciding with changing environmental conditions including diet. Potential factors suspected to be involved include environmental toxins such as heavy metals and the neurotoxin beta-N-methylamino-alanine found in local food sources.

In 1991, geneticists identified a linkage to ALS in a gene somewhere on chromosome 21, and 2 years later, this gene was identified as the gene that encodes for SOD1 protein. The majority of ALS research since 1993 has focused on SOD1 in two ways: as a model of the disease in the form of genetically altered mice overexpressing mutant SOD1 and in efforts to determine how mutations in the SOD1 protein alter its properties and ultimately lead to ALS.

Copper-Zinc Superoxide Dismutase (SOD1)

SOD1 was first isolated from red blood cells in 1938 and, due to its characteristic copper binding property and ubiquitous presence in erythrocytes and liver tissue, it was initially termed haemocuprein, hepatocuprein, or erythrocuprein, depending upon its tissue source. In 1969, scientists J.M. McCord and I. Fridovich published their discovery that it catalyzed the disproportionation of superoxide, whereby two molecules of superoxide are converted into to hydrogen peroxide and dioxygen, and they named the enzyme superoxide dismutase. The substrate superoxide is classified as a reactive oxygen species (ROS), a reactive molecule derived from molecular oxygen that can lead to cellular oxidative damage either directly or indirectly. Superoxide is produced in small amounts as a byproduct of mitochondrial respiration and by some other reactions in vivo. Superoxide can exert its toxicity directly by inflicting damage to labile iron sulfur clusters of iron-containing proteins such as aconitase. However, its role as the starting point for the generation of other, more reactive ROS, such as hydroxyl radical or peroxynitrite, is probably more important (Valentine et al. 2005). The toxicity of superoxide is exploited by the immune system, which intentionally produces superoxide in macrophages using NADPH oxidase enzymes to destroy invading pathogens. Superoxide dismutase is included in a group of protective enzymes induced by various pro-oxidant stimuli and toxic compound such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), *para*-methoxyamphetamine (PMA), and ultraviolet radiation. Superoxide dismutase is regarded as a first line of defense against the damaging effects of reactive oxygen species and is present in every cell in the body.

Copper-zinc superoxide dismutase has been well characterized since its first description in 1938. SOD1 is an abundant enzyme, being present at concentrations up to the hundreds of micromolar in human cells, with a well-conserved sequence preserved across all eukaryotes. The human protein monomer is a 153-amino-acid polypeptide, and the protein is predominantly found in the cytosol, nucleus, peroxisomes, and mitochondria intermembrane space. To reach its fully mature homodimeric state, SOD1 undergoes several posttranslational steps besides the usual removal of its initiating methionine residue and N-terminal acetylation, SOD1 also acquires a copper

and a zinc ion, forms an intrasubunit disulfide bond, and its two subunits dimerize.

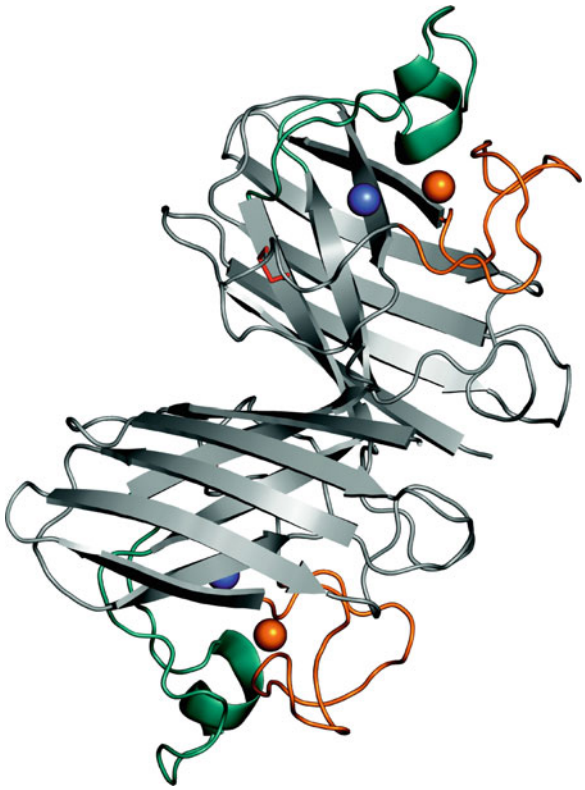
SOD1 and ALS

The discovery of the link between SOD1 and ALS in 1993 was very exciting and has helped propel research on both the protein and the disease. In particular, it led to the first animal model of the disease in the form of transgenic mice and rats that overexpress mutant forms of SOD1 and exhibit ALS-like symptoms. Ten percent of all ALS cases occur by a genetic component, and approximately 20% of these familial cases (fALS) are linked to mutations in the SOD1 protein. Over 100 different mutations occurring along the length of the protein have been identified, mainly from single amino acid substitutions, but also including deletions, insertions, and C-terminal truncations. Interestingly, humans are not the only species to develop a myelopathy from SOD1, mutations in canine SOD1 have also been associated with ALS in dogs. The initial hypothesis for why mutations in SOD1 lead to disease was simply that a loss of dismutase activity resulted in toxicity due to excess ROS. However, soon after the genetic discovery, several studies demonstrated that the disease is not due to a loss-of-function but rather a gain-of-function (Cleveland and Rothstein 2001). First, the mutations are genetically dominant, meaning that the disease occurs even though at least 50% of the normal activity of SOD1 is present. In addition, most of the mutated proteins do not lose activity. Secondly, transgenic mice lacking all SOD1 do not develop the disease, while mouse models overexpressing mutant SOD1 fall ill with disease phenotypes even though they retain their own endogenous wild-type mouse SOD1. Thirdly, mouse models overexpressing both the dismutase-active and dismutase-inactive mutant proteins induce the disease phenotype with similar onsets and survival time.

The creation of these mouse models was invaluable not only because it established the gain-of-function feature of SOD1 mutations but also because it provided the first experimental platform to investigate the causes of ALS, particularly at early stages of the disease, to delineate the features of ALS pathology and to test possible treatments. The mouse models were used to investigate further the nature of the gain-of-function property of SOD1 as well as to elucidate the cellular pathologies that lead to motor neuron degeneration. Several hypotheses have been proposed for the gain-of-function property, including a pro-oxidant mechanism resulting from aberrant copper chemistry; however, other studies showed that a subset of mutants do not even bind copper, making this hypothesis less popular. Currently, the most widely accepted hypothesis centers on the misfolding, aberrant oligomerization, and aggregation of SOD1 mutants, bringing ALS into the larger family of neurodegenerative diseases that are due to aberrant protein aggregation (Valentine and Hart 2003). The central basis for this hypothesis comes from the appearance of large SOD1 inclusions in the ventral horn of both human fALS and transgenic mice spinal cords. To gain insight into how SOD1 aggregates, researchers have narrowed in on its folding, structure, and function, and how mutation affects these steps. This entry reviews the central aspects of SOD1 structure, function, and maturation as they relate to the disease and then highlights the pertinent pathological features learned from studies using animal models.

Structural Insights

SOD1 is an extremely stable dimeric protein that has a conserved eight-stranded Greek key beta-barrel structure, one zinc and one copper ion bound per subunit, and a single intrasubunit disulfide bond (Fig. 1). The zinc ion and disulfide bond are structurally important, and the copper ion is critical for enzymatic activity. The arrangement of the beta strands is shown in Fig. 2a where the beta-barrel structure, normally rolled up to form a closed barrel, is shown flattened out (Chattopadhyay and Valentine 2009). In the case of SOD1, there are eight antiparallel beta strands, which form a hydrophobic core with a flattened beta-barrel-like structure (Fig. 2b). Two main loop elements, the electrostatic and zinc loops (shown in teal and orange, respectively, in Fig. 1 and purple and light blue in Fig. 2), are important in metal binding and enzymatic activity. The zinc loop is held in place by the zinc ion, which is bound through one aspartyl side chain, Asp83, and three histidyl side chains, His80, His71, and His63 (shown in red in Fig. 1). His63 is a shared ligand and forms an imidazolate bridge to the copper ion. Thus, the copper ion remains in close proximity to the zinc but binds to SOD1 via three histidyl side chains located on beta

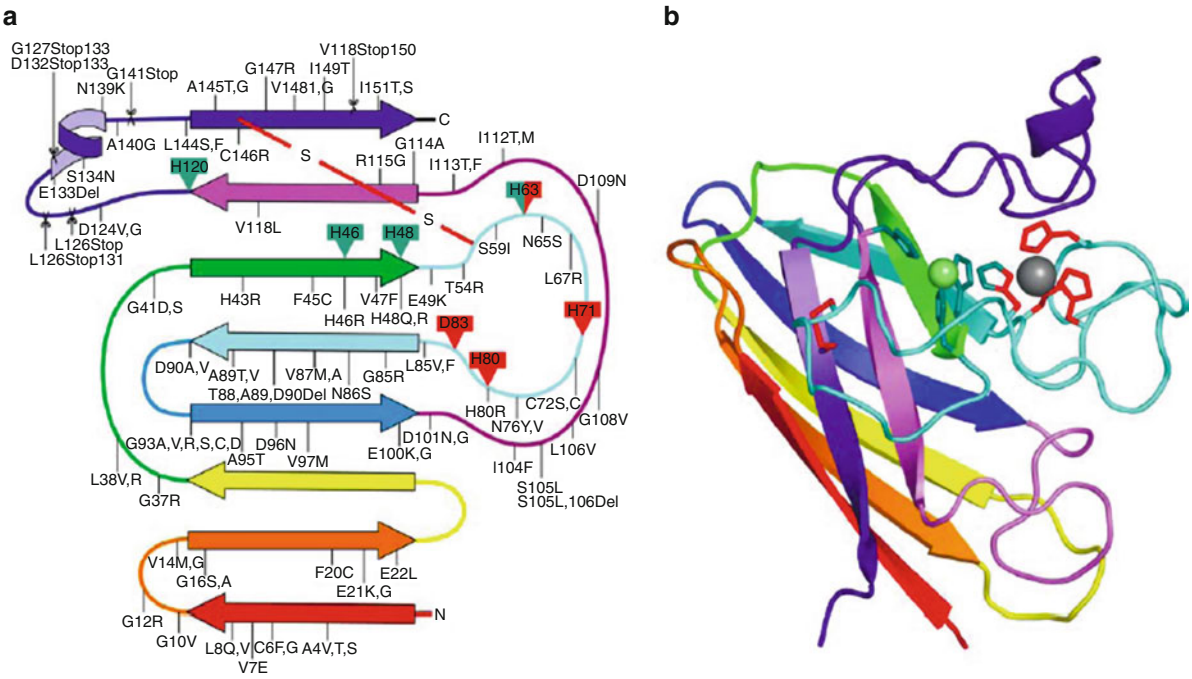


Copper-Zinc Superoxide Dismutase and Lou Gehrig's Disease, Fig. 1 Structure of dimeric metal bound SOD1. Copper is shown as a *blue sphere* and zinc as an *orange sphere*. The electrostatic loop is in *teal* and the zinc loop is in *orange*. The intrasubunit disulfide bond is shown as a *red connecting line*

strands 4 and 7, His46, His48, and His120 (shown in green in Fig. 1). The electrostatic loop serves two purposes: to provide a charged surface that guides the superoxide anion toward the catalytic copper center and to strengthen and stabilize the metal-binding region by creating a hydrogen bonding network between the metal-coordinating residues and the electrostatic loop residues Asp124, Gly141, and Arg143. The intrachain disulfide bond links residues Cys57 and Cys146, pinning the loop containing Cys 57 to beta-barrel strand 8 and stabilizing residues important for formation of the dimer interface. The same Arg143 that stabilizes the metal-binding site in the electrostatic loop also retains a hydrogen bond with Cys57, hence linking the important structural features of disulfide bonding, metal binding, and dimerization. Folding of the protein, binding of metal ions, formation of the disulfide bond, and dimerization are critical maturation events for the formation of the active enzyme (see below for more information). The structural interrelationships between these features lead to interesting features, many of which contribute to the extreme stability of the protein (Valentine et al. 2005). For example, the apoprotein is able to dimerize only if the disulfide bond is formed or if a metal is bound. Additionally, copper or zinc binding stabilizes the disulfide bond, making it less prone to reduction, which is vital in the reducing environment of the cytosol. Similarly, the disulfide bond contributes to enzymatic activity by strengthening the metal-binding region. The different structural features of SOD1 work in a synergistic manner to produce an extraordinarily stable protein.

Mature human SOD1 is among the most stable enzymes in the body. In its fully metallated, disulfide-oxidized, dimeric form, wild-type SOD1 (WT) has a melting temperature above 90°C and is resistant to 8 M urea, 1% sodium dodecyl sulfate, and proteolytic degradation. It retains enzymatic activity even after 1 h in 4% sodium dodecyl sulfate and is believed to have a very long half-life in vivo (Valentine et al. 2005). A central factor in driving this stability is the aforementioned posttranslational events, as is apparent by the 48°C difference in melting temperature between the disulfide-oxidized holo form and the apo (metal-free) disulfide-reduced form, which melts (unfolds) at 42°C (Shaw and Valentine 2007).

Compromising the intricate structural interrelationships of these posttranslational modifications leads to an overall less stable protein, providing a possible explanation for how mutations might lead to protein misfolding and consequent toxicity. Initially, many findings supported this hypothesis. For instance, many familial ALS mutant proteins, such as A4V, I113T, G93C, G37R, G41D, and G85R, have significantly reduced half-lives relative to the WT protein in cell culture systems. Additionally, many mutants, particularly those that have impaired metal binding, such as S134N, D125H, D124V, and H46R, have much lower melting temperatures, as measured by differential scanning calorimetry (DSC), because they are not properly stabilized by metal ions. Another class of mutants, termed "wild-type-like" (WTL) mutants, have similar metal-binding properties to wild-type SOD1 and are relatively stable when metallated but still exhibit reduced stability in their apo states relative to the wild-type protein. However, certain mutants do not follow these trends, for instance, D101N has



Copper-Zinc Superoxide Dismutase and Lou Gehrig's Disease, Fig. 2 Secondary structure representation and colorcoded structure of one subunit of SOD1. (**a**) The secondary structure diagram shows the beta barrel unrolled. The location of many of the ALS-causing SOD1 mutations is indicated, as are other important residues. The disulfide bond is shown as a red line. Zinc-binding residues are highlighted in red, and copperbinding residues are highlighted in green. (**b**) Backbone structure of one subunit of the dimeric SOD1 protein, color coded to match the flattened Fig. a. Copper and zinc are shown as green and grey spheres, respectively. The metal-binding ligands are fully drawn, and the disulfide bond is indicated in red

a melting temperature that is very similar to the wild type in the various states of metallation and disulfide status. Attempts to classify the mutants in terms of stability, activity, and metal-binding properties have helped define the effects of each mutation but have yet to elicit an obvious common misfolding mechanism. Taken together, it remains unclear if all mutations affect a common critical aspect of SOD1 structural stability that causes them to form aggregates (Valentine et al. 2005). More recent hypotheses for how mutations can lead to misfolded SOD1 include alterations in protein net charge, aberrant oxidative modifications, decreased metal-binding affinities, impaired folding and/or maturation (see below), or a combination of these four factors (Shaw and Valentine 2007).

Functional Insights

SOD1 functions as an important modulator of reactive oxygen species. SOD1 is expressed ubiquitously in human cells, and within these cells, it is found in the cytosol, nucleus, and mitochondrial intermembrane space, where it catalyzes the disproportionation of two superoxide anions into hydrogen peroxide and dioxygen.

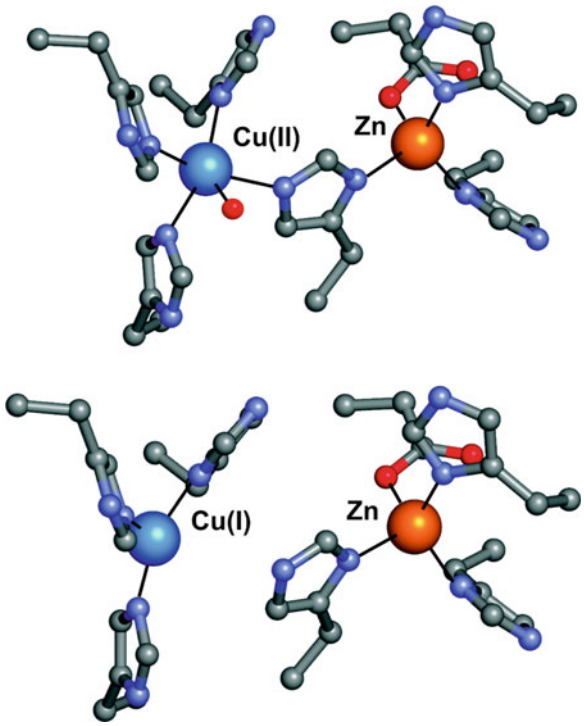
SOD Reaction

$$(1)\quad O_2^- + \mathrm{Cu(II)ZnSOD} \rightarrow O_2 + \mathrm{Cu(I)ZnSOD}$$

$$(2)\quad O_2^- + \mathrm{Cu(I)ZnSOD} + 2H^+ \rightarrow H_2O_2 + \mathrm{Cu(II)ZnSOD}$$

$$(3)\quad \mathrm{Sum}: 2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$$

Copper is at the heart of the enzymatic ping-pong mechanism. In the two-step reaction, first, a superoxide anion reduces the cupric ion to form dioxygen (step (1)). Copper makes a 1.3 Å shift, breaking its bond with the bridging histidine, and the resulting cuprous ion is reorganized from a distorted square planar geometry, coordinated by four ligands, to a nearly trigonal planar three-coordinate configuration (Fig. 3). A second molecule of superoxide reoxidizes the cuprous ion to form hydrogen peroxide



Copper-Zinc Superoxide Dismutase and Lou Gehrig's Disease, Fig. 3 Metal-binding-site geometries. The *top* shows copper in the oxidized state (Cu^{2+}) with an intact imidazolate bridge and a five coordinate square planar geometry to four histidyl side chains and a water. The *bottom* shows that the reduction of copper to Cu^{1+} breaks the bond to the bridging histidine, shifting the copper 1.3 Å *left* to form a nearly trigonal planar geometry

(step (2)) and reestablishes the copper bond to the ε-nitrogen of His63. The reaction is highly efficient, occurring at near diffusion-controlled rates at physiological pH.

Despites the efficiency of SOD1 as a superoxide dismutase, other chemistries have also been associated with the protein. For example, hydrogen peroxide can also aberrantly react with SOD1, resulting in oxidation of the copper histidine ligands and leading to metal ion loss, loss of activity, and decreased protein stability. This mechanism may represent the basis of a possible inactivation and degradation pathway for SOD1 but may also provide an additional route by which the protein might misfold and aggregate (Valentine et al. 2005).

While the biochemical function of SOD1 in reducing intracellular superoxide concentrations has long been known, recent studies have helped shed new light on mechanisms of superoxide toxicity. Using *Saccharomyces cerevisiae* (yeast) as a eukaryotic model system, SOD1 was knocked out to investigate the cellular effects of excess superoxide. The observed characteristic phenotypes for these SOD1Δ yeast include sensitivity to millimolar concentrations of zinc, diminished growth rate compared to wild-type yeast in nonfermentable carbon sources, sensitivity to 100% oxygen, and air-dependent amino acid auxotrophies for lysine and methionine. Interestingly, zinc sensitivity cannot be restored even with the introduction of MnSOD but is restored in the presence of an inactive mutant SOD1 (H46C), suggesting that yeast SOD1 might have an additional nondismutase function in zinc metabolism. Human SOD1 has also been suggested to play a role in zinc metabolism (Lelie et al. 2011).

The Maturation of SOD1

The steps along the maturation pathway for SOD1 have garnered increased interest with regard to understanding the mechanism of SOD1 misfolding and aggregation in ALS. Zinc acquisition by SOD1 is believed to be an early and important event that stabilizes the nascent polypeptide as it comes off the ribosome, but the detailed mechanism is unknown. Copper acquisition by SOD1 is better understood. It is mainly delivered to SOD1 specifically by the copper chaperone for SOD1 (CCS), which also serves to catalyze the formation of the intrasubunit disulfide bond.

The intramolecular disulfide bond in SOD1 serves an important role in stabilizing the quaternary structure by anchoring the loop from Glu49 to Asn53 thereby stabilizing the dimer interface. Interestingly, it has been reported that disulfide bonds in SOD1 mutants are more susceptible to reduction than those in WT, suggesting a possible mechanism whereby mutants are more prone to misfolding than the WT (Valentine et al. 2005).

It is unknown whether SOD1 dimerization occurs before or after the other posttranslational steps since it can occur in both the apo, disulfide-oxidized protein or in the partially metallated disulfide-reduced protein. Thus, there is a possibility that dimerization can occur at more than one point along the maturation pathway but it is probably dependant on the local concentration of SOD1. While the similarity in the overall thermodynamic stability of mutant and WT SOD1 does not reveal an obvious misfolding

mechanism, the multiple steps along the way to mature SOD1 constitute a series of events that could, due to altered kinetics, lead to a greater sampling of off-pathway intermediates and ultimately a route to misfolding.

Misfolded SOD1

The misfolding of SOD1 and its consequent oligomerization and aggregation are now widely believed to underlie the toxic property of mutant SOD1 that causes ALS. Several key findings support this theory: Protein inclusions containing aggregated SOD1 have been identified in familial ALS patients and all mutant SOD1 transgenic mice. Also, formation and accumulation of aggregated protein occurs coincidently with the onset and progression of disease in fALS-model transgenic mice, and detergent-insoluble aggregates containing SOD1 are a unique property of mutant SOD1 but not of WT SOD1 when it is overexpressed in cell culture or in transgenic mice. Proteomic analysis on aggregates isolated from mice indicates that these aggregates contain some ubiquitin and neurofilaments but are dominantly composed of unmetallated full-length SOD1 (Lelie et al. 2011). However, animal studies suggest a role for WT SOD1 in accelerating the disease progression when it is coexpressed with an ALS-mutant SOD1 (Chattopadhyay and Valentine 2009). WT SOD1 may also play a role in sporadic ALS since spinal cord tissue samples from sALS patients consistently contain proteinaceous inclusions that have recently been shown to contain misfolded WT SOD1. Interestingly, immature WT SOD1 has been observed to aggregate and form amyloid fibrils under mild conditions in vitro. Together, these data highlight the relationship between SOD1, aggregation, and ALS.

While it is clear that mutant SOD1 can aggregate, it remains a mystery whether aggregation is truly the cause of toxicity and, if so, what form of aggregate (oligomer, amyloid, etc.) is toxic and how is toxicity exerted. In general, aggregates might be toxic in a number of ways: by interfering with normal cell function, depleting essential chaperones, overwhelming the proteasome, or inhibiting mitochondrial function (Cleveland and Rothstein 2001). A major portion of current research focuses on understanding the aggregation paradigm. This includes elucidating the folding, structural, and functional consequences of mutations in SOD1 that can possibly lead to misfolding in the cell. Extensive biophysical characterization of many SOD1 mutants has not revealed an obvious single converging pathway toward misfolding. Though the misfolding theory has the strongest support, it remains imperative to investigate all possible angles of disease including other pathological features present in tissues, which are not directly related to misfolded SOD1. In this light, the mutant SOD1 transgenic mice models have rendered tremendous insight into pathogenic mechanisms of ALS.

SOD1 and Sporadic ALS

Cases of familial ALS linked to SOD1 constitute only ~2% of all ALS cases, raising two questions: What is (are) the cause(s) in the other 98% of cases? What is the role of SOD1, if any, in these other cases? Recent evidence suggests that WT SOD1 might play a role in sporadic ALS cases. Misfolded forms of WT SOD1 are found in sporadic ALS tissue sections, but not controls, using antibodies that selectively recognize misfolded forms of SOD1. Furthermore, immature forms of WT SOD1 can readily fibrillate under physiological conditions in vitro suggesting that in vivo WT SOD1 could play a role in sporadic ALS. Additionally, oxidatively damaged WT SOD1 can misfold and acquire toxic properties similar to mutant SOD1 suggesting that oxidized SOD1 could be involved in sporadic ALS (Lelie et al. 2011). These findings provide hope that the studies on the SOD1 ALS transgenic mice may someday translate into therapeutics for all ALS patients.

ALS Pathology

The pathological clues gained from studies on ALS rodent models and actual human patient tissues have provided a greater understanding of neurodegenerative mechanisms involved and have helped pave the way for the creation of possible therapeutics (Bruijn et al. 2004). Mutations in SOD1 can trigger the series of deleterious events that lead to this midlife disease. Among the events that have been identified and characterized in one or another of the fALS-SOD1 mouse models are oxidative stress, apoptosis, excitotoxicity,

neurofilament disorganization, mitochondrial dysfunction, proteasome inhibition, impaired axonal transport, reactive astrocytes, and protein aggregation (For a comprehensive review of these pathological features, please refer to Bruijn et al. 2004; Cleveland and Rothstein 2001; Turner and Talbot 2008). However, many questions remain regarding the significance of these events. For instance, it is unclear which event is the main upstream trigger that leads to the demise of motor neurons. Furthermore, the specific role of mutant SOD1 in each of these pathological abnormalities is unclear but has been attributed to its role as an antioxidant, its aggregation potential, and its partial mitochondrial localization. Therapeutics that target each of these pathological conditions have not provided the hoped-for benefit, confounding the issue of what the upstream event(s) may be. Additionally, the variability of disease manifestations in the different mutant mouse strains (expressing different mutant SOD1 proteins and/or at different levels) makes it difficult to ascertain the significance of each event (Turner and Talbot 2008). An updated theory suggests that ALS possesses a complex etiology reliant on a multifactorial convergence of pathways, all of which can be related to developing disease. The misfolding of SOD1 is regarded as the most pertinent of these factors due to its very early appearance in mice models, and understanding how mutations lead to aggregated protein remains a major priority for the SOD1-ALS field.

Direction of Research

Recent genetic studies have helped expand the ALS field to focus on two new ALS-associated proteins, TDP-43 and FUS. They both play roles in RNA metabolism, although this may be irrelevant to their roles in ALS. Interestingly, TDP-43 is involved in aggregation, and comparing its function and toxicity with that of ALS-SOD1 may help clear up the questions generated by the SOD1 studies regarding (an) underlying pathological mechanism(s).

The link between ALS and SOD1 has provided a tremendous impetus to research in both the disease and the protein. The focus on ALS has stimulated a number of studies leading to much better understanding of the biophysical properties of mutant SOD1. Conversely, the identification of mutations in SOD1 as a cause of fALS led to the first animal models for the disease and a great increase in our knowledge of that disease. While a cure for ALS remains stubbornly elusive, potential treatments are beginning to emerge largely due to the contributions of the ALS-SOD1 mouse studies. A central focus is determining the toxic form of mutant SOD1 and barring any major paradigm shifts, which includes understanding what drives mutant SOD1 to misfold and aggregate. By determining the underlying mechanism involved in SOD1-mediated ALS, researchers will hopefully be able to figure out what causes all forms of this devastating illness.

Synonyms

Heavy metal efflux; Metal homeostasis; Metal-resistant bacteria

Definitions

Tripartite efflux complexes are protein export systems that span both membranes in Gram-negative bacteria and are involved in efflux of compounds from the cell. These systems are composed of three proteins: an inner membrane protein, an outer membrane protein, and a periplasmic adaptor that connects the two membrane proteins.

RND proteins are Resistance-nodulation-and cell division proteins. These are membrane proteins that expel compounds from bacterial cells using the protein gradient as an energy source. In Gram-negative tripartite efflux complexes, RND proteins are the inner membrane component.

MFPs are membrane fusion proteins; they function as the adaptors in the tripartite efflux complexes. They are also called periplasmic adaptor proteins.

Periplasm is the region between the inner and outer membranes in Gram-negative bacteria.

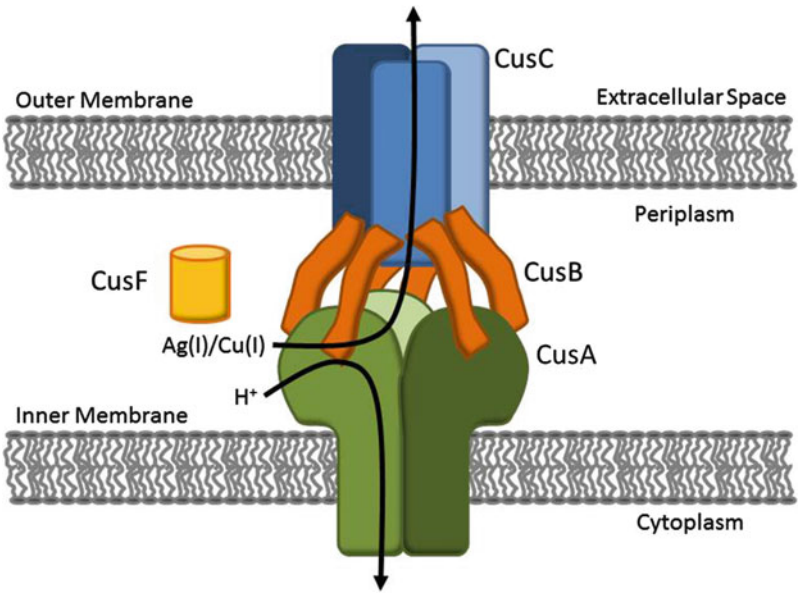
Introduction

Several transition metals are necessary as trace elements to carry out reactions inside of living cells. However, transition metals can be extremely reactive and cause cellular damage or even death when present in high concentrations. This toxicity allows the use of metals as biocides in clinical or industrial settings. In particular, copper and silver are commonly used to control microbial populations in hospital settings such as burn wards. Bacteria have developed elaborate protein systems that allow for the maintenance of homeostasis in response to copper or silver stress. This entry focuses on the CusCFBA system in *Escherichia coli*, which mediates Cu(I) homeostasis and Ag(I) resistance.

Copper ions are used in many cellular processes such as respiration and oxidative damage response. The ability of copper to cycle between the Cu(I) and Cu(II) oxidation states allows it to be used as an electron carrier and redox center inside of proteins. This reactivity, while useful for biology, can cause cellular damage when copper is present in excess of the required amounts (Mealman et al. 2012). Silver is found primarily as Ag(I) and is not biologically utilized. Thus when silver is present in cells it acts as a toxin by inappropriately binding to biomolecules and disrupting their function. Because of chemical similarities between copper and silver, the cellular machinery maintaining copper homeostasis is often used to confer silver resistance.

In *E. coli*, copper homeostasis is mediated by two complementary protein systems, the Cue and the Cus systems (Mealman et al. 2012). This entry focuses on the CusCFBA transport system, which is composed of CusCBA, a tripartite efflux system and CusF, a metallochaperone (Fig. 1). In addition to functioning in copper homeostasis, the Cus system is the main determinant of silver resistance for *E. coli* (Franke et al. 2003).

CusCBA contributes to silver and copper resistance by transporting excess metal out of the cell to the extracellular space. This tripartite system is an active transporter that uses the proton gradient across the inner membrane to provide an energy source to move substrates up their concentration gradient. The tripartite CusCBA system is similar in many ways to multidrug resistance systems, such as AcrAB-TolC. The main difference between metal and multidrug transporting systems is substrate specificity. CusCBA provides resistance to Cu(I) and Ag(I), while multidrug transporters export many different substrates. This difference makes comparing the two systems tricky. Although they assemble similarly and use proton gradients to actively transport substrates out of bacterial cells, the way in which these pumps handle their substrates is different due to the systems' specificity and chemically different nature of the substrates.



CusCFBA Copper/Silver Efflux System, Fig. 1 *The CusCFBA efflux system.* Trimeric CusA resides in the inner membrane and trimeric CusC resides in the outer membrane. Six CusB monomers interact with the inner and outer proteins. CusF is a soluble metal-binding protein that resides in the periplasm. Proton movement across the inner membrane is coupled with substrate export to the extracellular space

The CusCFBA system of *E. coli* has been studied genetically, biochemically, and structurally. Many studies have focused on the isolated proteins in this system, and those findings are reviewed below. More recent work has addressed how these proteins work together to export metal ions. What is known to date is summarized below, and some of the remaining outstanding questions are addressed.

CusA

CusA is the trimeric inner membrane transporter that drives efflux through the CusCBA complex. It is vital for Cu(I) and Ag(I) efflux, as deletion of the gene encoding CusA abolishes all efflux by the CusCBA complex (Franke et al. 2003).

CusA is a member of the RND family of transporters and is related to the multidrug transporters AcrB and MexB. RND proteins form homotrimers in the inner membrane and couple substrate export from the cell to the transport of protons into the cytoplasm. Experiments with AcrB show that RND proteins cycle between three major conformations to transport their substrate (Seeger et al. 2006; Murakami et al. 2006). RND proteins have a periplasmic substrate binding site and a channel that opens to the outer membrane protein, though how substrates move through RND proteins is not known.

In CusA, it was hypothesized that three conserved methionine residues, M573, M623, and M672, form the Cu(I)/Ag(I) binding site (Franke et al. 2003). A crystal structure of CusA was recently solved showing Cu(I) or Ag(I) bound to these methionines, confirming this is the periplasmic substrate binding site (Long et al. 2010).

At this point, there are uncertainties as to the path of metal ions through CusA. The periplasmic binding site has been confirmed, but how do Cu(I) and Ag(I) get to the periplasmic binding site? Does CusA acquire metal from the periplasm directly, or does it possibly interact with other metalloproteins? Recent work has also suggested that CusA can acquire metal from the cytoplasm as well as the periplasm (Long et al. 2012). Additional studies are needed to clarify these issues.

CusB

CusB is the membrane fusion protein (MFP) of the CusCBA complex. CusB is a soluble periplasmic protein that binds both CusA and CusC. As demonstrated in other systems, the membrane fusion protein stabilizes the formation of the tripartite complex (Nehme and Poole 2007). It is a necessary component of the CusCBA system, since deletion of *cusB* abolishes CusCBA efflux activity (Franke et al. 2003).

In addition to its role in stabilizing the CusCBA complex, CusB is also a metalloprotein (Bagai et al. 2007). This is unlike the multidrug efflux MFPs, which generally do not bind their substrates (Mealman et al. 2012). The fate of the metal bound to CusB is still a matter of investigation. It could be that the metal bound to CusB is transferred to CusA for efflux. Alternatively, metal binding to CusB could serve as a switch to activate the CusCBA complex for efflux (Kim et al. 2011). Both of these mechanisms are possible, and no current evidence completely rules out one or the other.

CusB binds Cu(I) and Ag(I) through three conserved methionine residues, M21, M36, and M38 (using the numbering of the mature protein sequence, Bagai et al. 2007). When the CusB crystal structure was solved, the N- and C-termini were missing, so the metal-binding site is not structurally characterized (Su et al. 2009).

From biochemical and structural characterizations, it has been shown that CusB is structurally flexible (Bagai et al. 2008; Long et al. 2012). In the crystal of CusB and a co-crystal with CusA, four separate conformations of CusB were crystallized (Su et al. 2009; 2011), further demonstrating the structural flexibility of this protein. The function of this flexibility is not clear. It could aid in assembling the CusCBA complex or the different conformations could allow CusB to aid in metal efflux, or serve as a regulator of CusCBA activity.

CusC

CusC is the outer membrane protein of the CusCBA complex. Three CusS monomers assemble to form a large aqueous channel that connects the periplasm with the extracellular space. CusC is not essential for CusCBA-mediated metal efflux; deletion of *cusC* decreases silver resistance but does not abolish it (Franke et al. 2003). It may be that one of the multidrug outer membrane proteins can substitute for CusC, but that protein has not been identified.

The crystal structure of CusC shows that it is a hollow channel with an inner diameter of ~25 Å (Kulathila et al. 2011). No metal-binding sites have been identified in CusC, so potentially Cu(I) or Ag(I) are solvated by the extracellular medium once in the CusC channel. Because CusC may be partially substituted by an unidentified outer membrane protein, this lends support to the idea that CusC has no functional metal-binding sites.

CusF

CusF is a novel protein partner to the CusCBA complex. It is a soluble periplasmic protein that binds Cu(I) and Ag(I). Homologs of CusF are not seen in multidrug efflux systems, but are only found in other Cu(I)/Ag(I) tripartite efflux systems. Deletion of *cusF* decreases, but does not eliminate, copper or silver resistance, suggesting that CusF contributes to CusCBA efflux, but is not required (Franke et al. 2003).

The structure of CusF has been solved in both apo and metal-bound states (Mealman et al. 2012). CusF coordinates a metal ion in a two methionine, one histidine binding site with cation-pi interaction from a tryptophan (Xue et al. 2008; Loftin et al. 2007).

CusF is believed to be highly upregulated in response to copper or silver shock (Kershaw et al. 2005), so it is theorized to sequester metals and act as a molecular sponge. As a soluble periplasmic protein, it can bind excess toxic metal ions, thus protecting the cell from the damaging effects of free metal ions.

CusCBA Complex Formation

Since CusCBA forms a complex, the protein-protein interactions between components are crucial to understand function of the pump. CusA and CusC are trimeric membrane-bound proteins (Long et al. 2010; Kulathila et al. 2011). From a co-crystal of CusA and CusB, it is now known that two CusB monomers bind to each CusA monomer, such that the overall stoichiometry of C:B:A is 3:6:3 (Long et al. 2012).

From a CusBA crystal structure, it is shown that CusB interacts with the periplasmic domain of CusA. CusB also extends upward from the top of CusA to form a hexameric channel with an average internal diameter of 37 Å. This channel may form the beginning of the pathway out of the CusBA complex (Long et al. 2012).

To date, the interactions between CusB and CusC are unknown. However, the protein models can be docked onto each other using simulations. CusC has an external diameter smaller than the internal diameter of the CusB channel, and simulations show that CusC could fit inside

the upper channel of CusB. It is not known if CusA and CusC interact directly, but simulations show that it may be possible for CusB to hold CusA and CusC close enough for them to come in contact (Long et al. 2012).

CusF-CusCBA Interactions

CusF is the soluble periplasmic protein in the Cus system. CusF has been shown to transiently interact with CusB and transfer metal ions to CusB (Bagai et al. 2008). Whether CusF interacts with or transfer metal to CusA is still under investigation. The interactions of CusF with the other Cus components are functionally important, and thus CusF has roles that are still being defined beyond that of a metal ion chelator.

CusCFBA Prevalence in Microorganisms

Cus protein homologs are found in bacteria besides *E. coli*. A BLAST-search found CusF and CusB homologs distributed throughout the Proteobacterial phylum (Kim et al. 2010). No CusF or CusB homologs were found in other phyla.

CusF homologs are found in a variety of genomic contexts. In the Enterobacteriales order, *cusF* was found with *CusCBA* efflux genes (Kim et al. 2010). However, in other systems, *cusF* was found as a fusion gene with *cusB*-like genes. Occasionally, *cusF*-like genes were found in close proximity to copper-responsive genes besides the *cusCBA* efflux genes. These genomic data suggest that *cusF* can function in Cu(I) and Ag(I) resistance through two pathways: one dependent on CusCBA, the other CusCBA independent. In CusCFBA in *E. coli*, though CusF has the ability to interact and transfer metal to CusB, it is not known how this contributes to metal resistance. The prevalence of CusF throughout bacteria necessitates its further study to understand its role in Cu(I) and Ag(I) resistance.

Conclusion

The CusCFBA system provides an important function in removal of excess Cu(I)/Ag(I) from cells to enable survival under conditions where these metal ions are in overabundance. From structural, genomic, and biochemical studies, much progress has been made to understand the working of this system. Future studies will reveal more fully the complex interplay between the components of the system and how they function dynamically to remove toxic metal ions from cells.

Binuclear mixed-valent electron transfer copper center

Definitions

CuA is a binuclear, mixed-valent [Cu(1.5+)-Cu(1.5+)], spin S = 1/2 electron transfer center present in respiratory chains of numerous organisms, specifically in cytochrome *c* oxidase (CcO) which reduces O_2 to two molecules of H_2O and nitrous oxide (N_2O) reductase (N2OR) which reduces N_2O to N_2 and H_2O. The core structure of CuA consists of a Cu_2S_2 rhomb with unique spectroscopic features, specifically the seven-line electron paramagnetic resonance spectrum observed at low temperatures.

Structure and Function of CuA

Occurrence

CcO (ferrocytochrome *c*:oxygen oxidoreductase; cytochrome aa_3; complex IV; EC 1.9.3.1) is the key enzyme of cell respiration in all eukaryotes and many prokaryotes. In bacteria, CcO is located in the cell membrane, whereas in eukaryotic cells, the enzyme resides in the inner mitochondrial membrane (Wikström 2010; Yoshikawa et al. 2011). Mammalian and "classical" bacterial CcOs carry three Cu atoms: the binuclear mixed-valent CuA electron transfer center and CuB coupled to heme a_3 forming the dioxygen-reducing site. The enzyme catalyzes the terminal reaction in aerobic respiration, the reduction of dioxygen to water. This energy-conserving process is coupled to the generation of a proton gradient across the membrane (Babcock and Wikström 1992), with CcO acting as a redox-driven proton pump (1):

$$4\text{Cyt}-\text{c}-\text{Fe}^{2+} + 4\text{H}_\text{c}{}^{+} + n\text{H}^{+}{}_\text{i} + \text{O}_2 \rightarrow 4\text{Cyt}-\text{c}-\text{Fe}^{3+} + n\text{H}^{+}{}_\text{o} + 2\text{H}_2\text{O} \quad (1)$$

Hereby, $\text{H}_\text{i}{}^{+}$ and $\text{H}_\text{o}{}^{+}$ refer to protons being translocated from the inner (i) to the outer (o) side of the membrane. This process is also called proton-pumping, usually with a stoichiometry of one proton per electron ($2\text{H}^{+}/\text{O}$). However, a lower stoichiometry, $1\text{H}^{+}/\text{O}$, has been reported for several microorganisms. $\text{H}_\text{c}{}^{+}$ refers to so-called chemical protons which are taken up from the inside for the formation of water.

By comparison, the copper enzyme ▶ N_2O Reductase (N2OR), a head-to-tail homodimer (6Cu/monomer), is a soluble protein located in the periplasm of denitrifying bacteria. It is involved in the transformation of the greenhouse gas N_2O to water and dinitrogen (2) (Zumft and Kroneck 2007):

$$2\text{H}^{+} + 2\text{e}^{-} + \text{N}_2\text{O} \rightarrow \text{N}_2 + \text{H}_2\text{O} \quad (2)$$

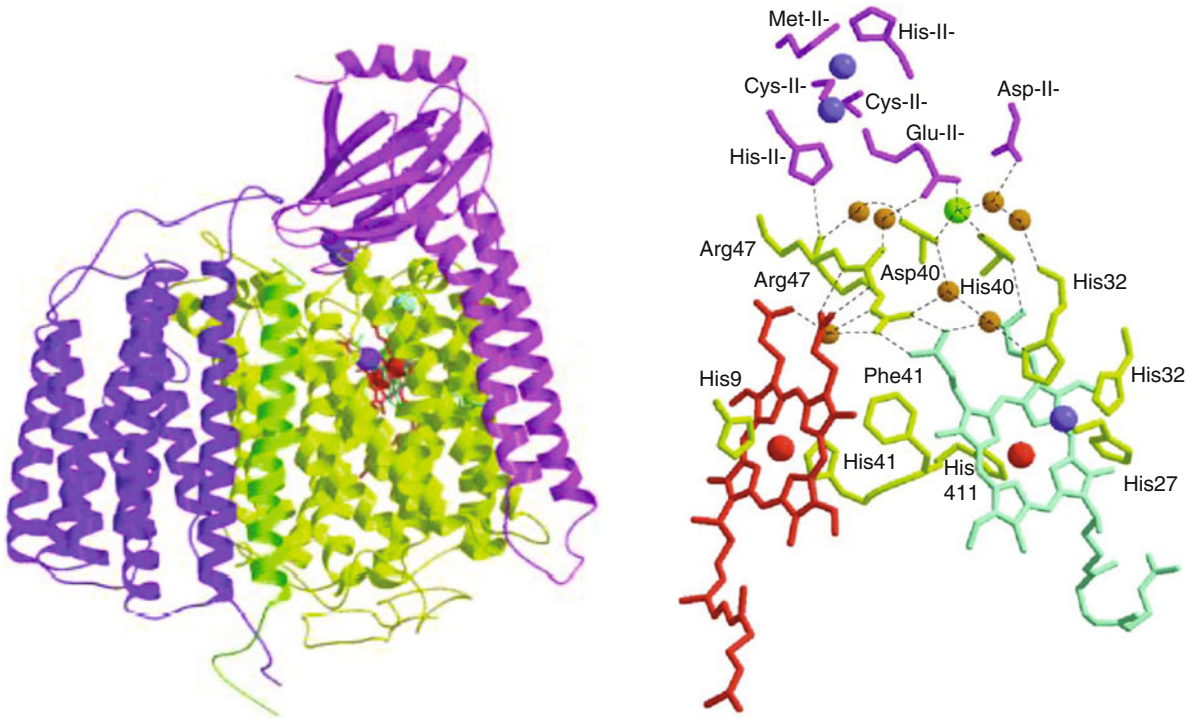
Recently, a nitric oxide reductase (NOR) in *Bacillus azotoformans* was identified as the third CuA-containing enzyme. In addition, artificial CuA sites have been engineered by loop-directed mutagenesis of ▶ Monocopper Blue Proteins (Savelieff and Lu 2010). These small proteins, such as ▶ Plastocyanin, azurin, or amicyanin, host the so-called blue type-1 Cu center. The similarity between the CuA-carrying enzymes N2OR and CcO becomes evident at the level of the amino acid sequence in a short region constituting the CuA-binding domain (Zumft and Kroneck 2007).

The cytochrome *c* oxidases belong to the superfamily of heme-copper oxidases, a group of structurally and functionally related enzymes. Within this superfamily, there exist two major branches: (1) cytochrome *bo* quinol oxidases with ubiquinol as primary electron donor and (2) cytochrome *c* cytochrome oxidases which use cytochrome *c* (Wikström 2010).

Overall Protein Architecture and Cupredoxin Fold

The "classical" CcO isolated from bacteria consists of three to four subunits depending on the organism, as illustrated for the enzyme isolated from the soil bacterium *Paracoccus denitrificans* (Fig. 1). Subunit I is located in the membrane; it constitutes the largest subunit with 12 transmembrane helices, and it contains the heme a_3-CuB dioxygen-reducing active site. Subunit II is attached to the periplasmic side of the membrane, anchored by two N-terminal helices. It has a large globular domain at the periplasmic side with a fold very similar to that of type-1 copper proteins. Subunit II harbors the mixed-valent CuA center which functions as the primary electron acceptor; the role of the other subunits remains unclear. In contrast, CcO isolated from bovine heart has 13 subunits, with subunits I and II carrying the canonical copper and heme iron redox sites (Iwata et al. 1995; Tsukihara et al. 1995). Note that the CuA center is absent in subunit II of the functionally related cytochrome *bo* quinol oxidases.

Comparisons of the overall folds and the copper binding sites have suggested a common evolutionary ancestry (Adman 1995). Notably, the key enzymes ▶ Nitrite (NO_2^-) Reductase, nitric oxide (NO) reductase, and nitrous oxide (N_2O) reductase of the denitrification pathway, which constitutes an important branch within the biogeochemical nitrogen cycle, share common structural elements with CcO (Castresana et al. 1994; Zumft and Kroneck 2007). This observation led to the hypothesis that aerobic respiration preceded photosynthesis during evolution (Wikström 2010). The cupredoxin family includes copper proteins carrying the mononuclear type-1 Cu as well as the binuclear CuA electron transfer centers. This can be clearly illustrated by circular dichroism (CD) spectroscopy of the CuA domain in CcO which



Cytochrome c Oxidase, CuA Center, Fig. 1 Structure of a "classical" cytochrome *c* oxidase. *Left*: Overall structure of CcO isolated from *Paracoccus denitrificans* showing the functionally essential subunits I (*magenta*) and II (*yellow*). *Right*: Redox metal centers (copper in *blue*, heme iron in *red*) (PDB code 1QLE) (Redrawn from Kannt and Michel 2001)

documents the presence of the so-called cupredoxin fold, a Greek key ß-barrel and common structural motif in small type-1 Cu proteins of plants and bacteria (Adman 1995). This structural relationship helped to engineer, through loop-directed mutagenesis, the purple CuA binuclear center into monocopper blue proteins (Fig. 2) (Savelieff and Lu 2010). On the other hand, the CuA center of CcO from *Paracoccus denitrificans* could be transformed into a mononuclear type-1 Cu center by exchange of one bridging cysteine ligand (C216) into serine.

CuA Structure and Spectroscopy

CuA is a S_{Cys}-bridged electron transfer center, [Cu(1.5+)-Cu(1.5+)]. Interest in CuA is directly related to its unique spectroscopic properties. Numerous investigations by electron paramagnetic resonance (EPR), nuclear magnetic resonance (NMR), magnetic circular dichroism (MCD), resonance Raman, and X-ray absorption spectroscopy were key to establish a highly resolved picture of the electronic properties of the CuA site and the interaction of the metal atoms with neighboring amino acids (Zumft and Kroneck 2007). UV/visible, MCD, and EPR spectra of the binuclear CuA center differ significantly from spectra typical of the blue mononuclear type-1 copper site. The intense purple color of CuA is the result of mainly S(Cys) → Cu charge transfer bands at ~480 nm (~21,000 cm^{-1}), 530 nm (~19,000 cm^{-1}), and a class III mixed-valence charge transfer band in the near-IR region around 800 nm (~13,400 cm^{-1}) (Zumft and Kroneck 2007).

CuA is paramagnetic, with one unpaired electron resulting in a total spin S = 1/2. It comprises two Cu ions: one in the Cu(1+) $3d^{10}$, S = 0 configuration and one in the Cu(2+) $3d^9$, S = 1/2 configuration, respectively. However, the unpaired electron is fully delocalized over both Cu atoms within the $Cu_2(SCys)_2$ rhomb as documented by the typical seven-line electron paramagnetic resonance spectrum observed at low temperatures (Fig. 3). Consequently, a mixed-valent [Cu(1.5+)-Cu(1.5+)] S = 1/2 configuration has been assigned to CuA (Zumft and Kroneck 2007). The distance between the two copper atoms in CuA is in the range of 2.5 Å, similar to the Cu–Cu distance observed in metallic copper. As a consequence, the existence of

a Cu–Cu metal bond has been proposed. Two cysteine sulfur atoms function as bridging ligands between the metal ions, and two histidines are terminal ligands of each of the two copper ions. The overall structure of the Cu_2S_2 rhomb is rather symmetrical, in agreement with the spectroscopic data, properties of variants obtained by site-directed mutagenesis, and theoretical calculations of the CuA binding site (Zumft and Kroneck 2007; Savelieff and Lu 2010). The purple [Cu(1.5+)-Cu(1.5+)] center will accept one electron upon reduction leading to the colorless reduced [Cu(1+)-Cu(1+)] state, with a virtually identical arrangement of the two coppers. The fully oxidized [Cu(2+)-Cu(2+)] state has not been detected so far.

By recombinant DNA technology, it was possible to express only the water-soluble fragment of CcO subunit II which contained the CuA center. As both hemes *a* and the bimetallic heme a_3-CuB catalytic site are located in the membrane part of CcO (Fig. 1), important spectroscopic information, without the spectral contributions of these metal sites, could be obtained to elucidate the electronic properties of CuA. Clearly, the unraveling of the binuclear and mixed-valent character of the CuA center in N2OR by spectroscopic techniques, most importantly by electron paramagnetic resonance spectroscopy (Fig. 3), was crucial for identifying the same structure in CcO (Beinert 1997). Later, high-resolution crystal structures of both bacterial and mammalian CcOs confirmed the binuclear nature of CuA (Iwata et al. 1995; Tsukihara et al. 1995).

Another distinct physical property of the mixed-valent CuA site is its unusually fast electron relaxation, which allowed extensive investigations of soluble CuA-containing protein fragments by ^{1}H-NMR spectroscopy and assignment of the individual ligands of the two Cu atoms.

Electron and Proton Transfer

The reduction of molecular oxygen catalyzed by CcO (Eq. 1) is highly exergonic, with a change in free energy $\Delta G = \approx -192$ kJ mol^{-1}. A major portion of this energy is conserved as an electrochemical proton gradient across the membrane (Wikström 2010). In "classical" CcO, CuA accepts electrons from cytochrome *c* which are then transferred *via* heme *a* to the coupled heme a_3-CuB dioxygen-reducing site (Fig. 1). As mentioned above, despite its binuclear composition, CuA will only transfer one electron at a time; it shuttles between the two biologically relevant redox states [Cu(1.5+)-Cu(1.5+)] (CuA_{ox}) and [Cu(1+)-Cu(1+)] (CuA_{red}). The water-soluble cytochrome *c* is located on the outer surface of the membrane; it docks to a specific site of CcO subunit II. Similar to the blue type-1 Cu ($\lambda_{max} \approx 600$ nm), the purple CuA ($\lambda_{max} \approx 530$ nm) is a very efficient electron transfer center. The reasons for utilizing a binuclear electron transfer center in CcO and N2OR are suggested to be its unidirectional electron transfer through the site or the lower energy of reorganization. In studies on intramolecular electron transfer in a purple azurin variant carrying an engineered CuA center, the rate constant of the intramolecular process, k_{ET}, was almost threefold faster than for the same process measured for the wild-type azurin carrying the mononuclear type-1 Cu (Zumft and Kroneck 2007).

The production of two molecules H_2O from one molecule O_2 requires the transfer of four electrons and four protons (so-called chemical protons) to the O_2 molecule which are coming from opposite sides of the membrane. This corresponds to the translocation of four electrical charge equivalents across the membrane per molecule of O_2 (Wikström 2010; Yoshikawa et al. 2011). Furthermore, in addition to the translocation of chemical protons, CcO translocates up to four protons across the membrane per O_2 reduced (Eq. 1). Thus, CcO is a redox-driven proton pump, with CuA acting as the primary electron acceptor. Uptake of protons into CcO, either to be used in $O_2 \rightarrow H_2O$ reduction or translocation across the membrane, occurs via defined pathways. Mutagenesis experiments in combination with X-ray crystallography helped to identify these pathways including their entrance and exit gates. In summary, CcO represents a remarkably efficient energy-transducing machine involved in the production of adenosine triphosphate (ATP) in aerobic life (Wikström 2010).
