Today, human iodine deficiency is next to iron the most common nutritional deficiency in developed European and underdeveloped third world countries, respectively. A current biological indicator of iodine status is urinary iodine that reflects the very recent iodine exposure, whereas some long term indicator of iodine status remains to be identified. We analyzed hair iodine in a prospective, observational, cross-sectional, and exploratory study involving 870 apparently healthy Croatians (270 men and 600 women). Hair iodine was analyzed with the inductively coupled plasma mass spectrometry (ICP MS). Population (H0) hair iodine (Ih) respective median was 0.499 μg·g−1 (0.482 and 0.508 μg·g−1) for men and women, respectively, suggesting no sex related difference. We studied the hair iodine uptake by the logistic sigmoid saturation curve of the median derivatives to assess iodine deficiency, adequacy and excess. We estimated the overt iodine deficiency to occur when hair iodine concentration is below 0.15 μg·g−1. Then there was a saturation range interval of about 0.15–2.0 μg·g−1 (r 2 = 0.994). Eventually, the sigmoid curve became saturated at about 2.0 μg·g−1 and upward, suggesting excessive iodine exposure. Hair appears to be a valuable and robust long term biological indicator tissue for assessing the iodine body status. We propose adequate iodine status to correspond with the hair iodine (Ih) uptake saturation of 0.565–0.739 μg·g−1 (55–65%).

Introduction

Today’s lack of iodine is one of the most common nutritional deficiencies in the world that is present in both the underdeveloped third world countries, as well as in developed European countries like the United Kingdom, Italy, and Germany [1,2]. Thus far various methods have been suggested to assess the human iodine status and to detect the iodine deficiency and/or excess to combat the nutritional iodine deficiency [3]. Today, urinary iodine (UI) excretion is conventionally considered to be tolerable approximation of the very recent dietary iodine intake. However, the determination of UI provides little useful information on the long term iodine status of an individual [4]. Since even mild iodine deficiency should be avoided [5], there is a need for a robust and reliable diagnostic indicator for assessing the iodine body status [6].

The aim of this paper is to explore how much iodine may be found in the human hair of an apparently healthy population, to study the frequency distribution of the observed iodine concentrations relative to the sex, and to estimate the possible risk of iodine deficiency and overexposure [7]. We have previously demonstrated the high reliability of hair for the multi-element profile analysis [8]; the hair is easily accessible growing biological structure of keratin fiber protein [9], easy to store and transport, and it usually has concentrations of iodine well above the detection limits necessary for accurate chemical analysis.
Subjects and methods

This prospective, observational, cross-sectional, and exploratory study was approved by the Ethical Committee of the Institute for the Research and Development of the Sustainable Eco Systems (IRES) and conducted by strict adherence to the Declaration of Helsinki on Human Subject Research [10], and to the complementary Croatian national bylaws and regulations [11]. Every subject gave his/her written consent to participate in the study and filled out a short questionnaire on his/her health status and medical history [12] (data not shown).

Hair iodine (\(I_h\)) was analyzed in a random sample of 870 apparently healthy adults (270 men, 600 women), 42.6 years old on average (SD 15.7, median 46), who were concerned with their health status. They came from a general population from across the country; most of them living in Zagreb, the capital city of Croatia. All the subjects were fed their usual home prepared mixed diet, and reported no adverse medical conditions. In Croatia dietary salt is regularly iodized and today Croatia is categorized as a country having an optimal urinary iodine (UI) excretion of 100–199 μg L\(^{-1}\) [13,14]. Hair analysis was performed by following the International Atomic Energy Agency recommendations [15] and other validated analytical methods and procedures [16]. Approximately 0.5–1.0 g of the hair was cut off from the occipital head region above the protuberantia occipitalis externa, and stored in numbered envelopes and kept refrigerated at 4 °C before they were randomly assigned for analysis. Individual hair samples were cut prior to chemical analysis to be less than 1 cm long, stirred 10 min in an ethyl ether/acetone (3:1, w/w), rinsed three times with the redistilled H\(_2\)O, dried at 85 °C for one hour to constant weight, immersed one hour in 5% EDTA, rinsed again in the redistilled H\(_2\)O, dried at 85 °C for 12 h, wet digested in HNO\(_3\)/H\(_2\)O\(_2\) in a plastic tube, and sonicated. The samples were analyzed for iodine content (\(I_h\)) by the inductively coupled plasma mass spectrometry (ICP MS), (Elan-9000, Perkin-Elmer, USA) at the ANO Center for Biotic Medicine (CBM), Moscow, Russia; an ISO certified high tech analytical laboratory. All chemicals were pro analysis grade (Khimmed Sintez, Moscow, Russia). We used certified GBW0910b Human Hair Reference Material (Shanghai Institute of Nuclear Research, Academia Sinica, Shanghai 201849, China) (CV (SD/mean) 0.48) [17].

Current CBM iodine reference values (μg g\(^{-1}\)) for \(I_h\) are 0.65–9.00 and 0.65–8.00 for men and women, respectively. Our detection limit for hair iodine was 0.01 μg g\(^{-1}\), and the coefficient of variation between the assays was 0.408 (SD/mean) [8]. Iodine belongs to the pleiad of 208 elements sharing the same mass number (number of isotopes/elements): 1 Ag, 7 Cd, 12 In, 21 Sn, 27 Sb, 26 Te, 24 I, 25 Xe, 17 Cs, 17 Ba, 12 La, 11 Ce, 6 Pr, and 2 Nd [18].

To scrutinize the hair iodine concentration frequency distribution we used the median derivative model to fit the sigmoid logistic regression analysis function for men and women separately (Appendix) [7,19]:

\[
A_2 + \left[A_1 - A_2\right]/\left[1 + (x/x_0)^p\right]
\]

where \(A_1\) is initial value (lower horizontal asymptote), \(A_2\) is final value (upper horizontal asymptote), \(x_0\) is center (point of inflection, in our case it is the median \(M_o\)), \(p\) is power (the parameter that affects the slope of the area about the inflection point). The Qtiplot Data Analysis and Scientific Visualization program was used for this analysis (www.soft.proindependent.com/qtiplot.html). The same program was used to assess the saturation exponential functions.

Results

Iodine was detected in all the 870 hair samples and its concentration varied over a wide range from 0.01 to 114 μg g\(^{-1}\), with a common median \(M_0\) \((n_{870}) = 0.499 \mu g g^{-1}\) [men \((n_{270}) = 0.482 \mu g g^{-1}\), women \((n_{600}) = 0.508 \mu g g^{-1}\)] (Fig. 1). The mean, SD, and CV were 1.98 ± 6.88 (4.38) and 1.01 ± 1.62 (1.60) for men and women, respectively (Fig. 1, left). The box plot data were log transformed to correct for skewedness and kurtosis and the new distribution became Gaussian (Fig. 1, right). There was no discernable difference between the number of men and women above and below the common median (\(p < 0.5\)) when a Chi square test used. We checked the health data from the interview records and contacted 10 subjects (subjects # 861–870) having the highest hair iodine: in 6 of them the diagnostic X-ray contrast medium was used within the 6 month period preceding sampling, for another 4 subjects no data could be found to help identify the source of high iodine input/intake.

Median derivatives were pinpointed according to the procedure explained in full detail in the Appendix; they are shown in Table 1, and they were used to generate the logistic sigmoid saturation curve shown in Fig. 2. Three distinct regions may be identified by simple visual examination of Fig. 2 – (1) the lower horizontal

Common median \((M_{0})_{870} = 0.499 \, \mu g \, g^{-1}\) iodine.

Fig. 2. The difference between the hair iodine median derivatives of men \((n=270)\) and women \((n=600)\) combined. (D, U) Men downward (D) and upward (U) median derivatives, (d, u) Women downward (d) and upward (u) median derivatives. — Logistic function: \(A_2 + (A_1 - A_2) / [1 + (X/X_0)^p]\), \(95\%\) confidence limit, \(95\%\) prediction limit. Men: \(Y = 0.978 \times (-0.015 - 0.978) / [1 + (X/0.456)^{1.624}]\), Women: \(Y = 0.995 \times (-0.011 - 0.995) / [1 + (X/0.499)^{1.532}]\). Box A. Iodine linear saturation range for \((♂ + ♀)\) (log conc). Box B. Iodine linear saturation range separate for \(♂\) and \(♀\) (log conc). (See Appendix for model and Table 1 for input values.)

Based upon the logistic sigmoid curve of hair iodine median derivatives we suggest that iodine concentration below 0.15 \(\mu g \, g^{-1}\) for both men and women entails the overt iodine deficiency (Fig. 2). Evidently, because of such low hair iodine concentrations body asymptote, (2) the linear segment, and (3) the upper horizontal asymptote. By following the principles of bioassay analysis, we consider them to represent the iodine deficiency (1), adequacy (2), and excess (3), respectively.
metabolism is in great need of iodine, so that little may be left for the hair follicle and hair growth, which may be used to explain the poor hair quality of iodine deficient persons; thyroxine advances the onset of anagen in resting hair follicles [20]. Above the lower horizontal asymptote hair iodine concentration of 0.15 μg g−1, there is progressive linear upward trend of iodine accumulation in the hair that is characteristic of a physiological saturation mechanism [18]. This distinct saturation curve begins to plateau somewhat below 2.0 μg g−1, such that the state of hair iodine oversaturation/overexposure has been reached (here the overexposure should not be confused with the toxicity). Thus, the linear part of iodine physiological saturation dose–response curve covers the range of about 0.15–2.0 iodine μg g−1. The hair iodine linear saturation range is shown for both men and women combined (Fig. 2, Box A) and separately for both sexes (Fig. 2, Box B); apparently there was no discernible sex dependent difference in the hair iodine status. That is quite a novel possibility to present data on iodine status in a range format and what may be of great help to provide for the personalized iodine supplementation if and when needed.

Thus, the I1 concentrations of 0.209–0.497 μg g−1 (saturation capacity 20–50%) may be regarded as iodine sparse (not deficient but low adequate), those from 0.565 to 0.739 (saturation 55–65%) true iodine adequate, and concentrations of 0.857–1.222 (saturation capacity 70–80%) may be regarded as iodine ample (high adequate but not excessive).

**Discussion and conclusion**

Our results on hair iodine are in agreement with the other reported values. Iyengar [24] has reported hair iodine range of 0.4–0.8 μg g−1, Caroli et al. [25] reported a range 0.03–4.2 μg g−1, and Wolowiec et al. [26] in their review of the results of control subjects in the six different studies, reported hair iodine means of 0.62, 0.59, 0.64, 0.61, 1.55, 1.50 μg g−1, respectively.

Today, after a lot of refinement, the prevailing consensus is that trace element hair analysis is a valuable method for assessing the nutritional metabolic status and assessing toxicity in a non-invasive way [27,28]. To our surprise the observed hair iodine median was I1(I=0.499 μg g−1 (0.482 and 0.508 μg g−1 for men and women, respectively), and what is below the current ANO CBM concentration standard for hair iodine of 0.65–9.00 and 0.65–8.00 μg g−1 for men and women, respectively. That may suggest either an inadequately high ANO CBM standard, or an inadequate nutritional iodine intake, or both. We think that the observed discrepancy between this IRES study having lower estimates of adequate iodine nutritional status and those of higher ANO CBM standards steams, in part, from ANO CBM’s mechanical implementation of a preconceived percentile grid upon the untransformed (log) iodine analytical data. Instead of mechanically throwing the preconceived percentile grid upon the observed data, we inferred the median derivative grid out from the data set itself (Appendix). Contrary to the recently published data on how Croatian population is well supplied with iodine according to the WHO urinary iodine data criteria [3], apparently more than half of our population has an unsatisfactory low-adequate iodine status according to the data from this study. Indeed, our true/desired adequate iodine status would require a hair iodine saturation of 0.565–0.739 μg g−1 (55–65%) and that ample-adequate iodine would not exceed 2.0 μg g−1. What would be the hair iodine toxic level remains to be elucidated. This finding further emphasizes the importance of methodological challenges in the evaluation of a chosen and nutritionally influenced biomarker like hair and/or urine [29]. In our opinion, current indicator of iodine nutritional adequacy in Croatia (urinary iodine) provided too “optimistic” results in regard to the population iodine status, and a large sparse-adequate level iodine population segment may be lurking beneath the cover of a urinary iodine indicator. Furthermore, there may be a problem in supplying and/or usage of iodized salt to/by the public. We have been under constant pressure to reduce the daily salt intake for decades, and thus reduce available dietary iodine intake. Our method of analyzing trace element median derivatives [7,19] offers for a new way to accurately analyze samples with a large inherent variability and apparently skewed and kurtosis population frequency distribution when presented in a standard linear fashion. This study presented a novel concept to derive iodine status in human population from frequency distribution properties of hair iodine concentration in a large cohort of subjects. Such a concept of deriving the “true adequate status” is completely different from the present concept of deriving recommendations in terms of avoiding iodine deficiency, including a safety margin [30].

Based upon the results of this study we suggest hair iodine can be used as a valuable and robust indicator of the long term dietary status.
iodine exposure. Growing at a pace of about 0.3–0.4 mm/day, hair is the memory tissue where the elements are irretrievably accrued; hair is the memory log of the intermediary metabolic events in homeostatic control of all the essential elements. At the same time, blood iodine and/or urinary concentrations are indicative of a short time internal balancing of this element between the various tissue compartments before it is rapidly excreted from the body. This difference in time scale for different biological indicator tissue of hair iodine (weeks) vs. urinary iodine (days) readily explains why they are incommensurable for the meaningful comparison [31]. Hair is itself a dynamic tissue structure – some 90% of hair follicles are active (anagen phase), some 10% are dormant (telogen phase), and some degenerate only to rise anew some other time [20]. Moreover, the rate of cell division in the human hair follicle is second only to the bone marrow cells, and should accurately present the metabolic changes within the body [32]. Indeed, the initial diet is only a part of the gastrointestinal input into the “black box” of intermediary metabolism before its output end point is expressed in some relevant bio-indicator tissue [33,34]; the relationship between the entry point of dietary iodine and its end point of hair concentrations is not of a “copy-paste” variety, since hair is an actively growing tissue of itself.

The primary goal of this paper is to draw attention of clinicians and other public health personnel that body iodine status is only partially assessed by measuring the thyroid gland hormones, instead of measuring iodine directly in some suitable biological matrix tissue like hair [11]. Indeed, when iodine intake is abnormally low, adequate secretion of thyroid hormones may still be achieved by marked modification of thyroid activity. This adaptation to iodine deficiency is triggered and maintained by increased TSH stimulation [35]. We think that the newly implemented Clinical Practice Guidelines for Hypothyroidism in Adults [37] would be supplemented with data on hair iodine. Indeed, evidence based iodine status assessment with hair iodine, would provide a reliable guide for proper iodine prophylaxis in preventing endemic goiter and would help personalized health protection in people under the increased metabolic energy demands [38].

In conclusion, we analyzed hair iodine in 870 apparently healthy subjects (270 men and 600 women) with the ICP MS. Hair appears to be a valuable and robust biological indicator tissue for assessing long term iodine body status. We propose that the true adequate iodine status would correspond with the hair iodine (I) concentration of 0.565–0.739 μg g⁻¹, i.e., 55–65% of hair iodine uptake saturation capacity. The evidence presented qualifies hair iodine as a long-term personal bio-indicator of human iodine status. Therefore, we believe hair iodine analysis may help the WHO&UNICEF efforts to control IDD [39,40]. This is one of the first uses of iodine assessment using a novel source (hair) and in a relatively large cohort, as a potentially more widely-applicable use of population iodine nutrition. The data need to be complemented in the future with data that permit to establish reference ranges indicating adequate iodine intake through the assessment of other parameters such as thyroid volume, thyroglobulin levels, thyroid function tests, and urinary iodine.

\]

We studied the frequency distribution of hair iodine (\(I_{H}\)) median and its derivatives to assess the iodine deficiency, adequacy and excess. First we assess the median (\(M_0\)) hair iodine concentration of our subject population. By definition, one half of the studied population was above the median (upward median branch, \(U_0\)), and the other half was below the median (downward median branch, \(D_0\)). Hence, the population size (\(PS\)) for \(M_0\) is the sum of the respective upward and downward median branches around the central inflection “hinge” \(M_0\), i.e., \(PS = U_0 + D_0 = 0.5 + 0.5 = 1.0\). Both the respective upward and downward median branches can be further divided in the same “median of median” way into a series of sequential median derivatives (\(U_{0,1,2,3,...,n-1}\) and \(D_{0,1,2,3,...,n-1}\)). For every median derivative of the population, the actual hair iodine concentration can be identified. Thus, instead of mechanically throwing the pre-conceived percentile grid upon the observed data, we inferred the median derivative grid out from the data set itself [41].
